POWER AND THE ENGINEER

INDEX FOR VOLUME XXX, 1909,

JANUARY 1 TO JUNE 30.

Explanatory Note.

Illustrated articles are marked with an asterisk (*). Book notices are marked with a dagger (†). Cross references to a particular initial word may refer to any cognate work beginning in the same way. Thus, a reference from "Oil" to "Lubricant" would apply equally to "Lubricating," "Lubrication" or "Lubricator." The cross references condense the matter and assist the reader, but are not to be regarded as conclusive. So, if there were a reference from "Boiler" to "Furnace" and if the searcher failed to find the required article under the latter entry, he should not regard it as useless to turn back and look through all the "Boiler" entries, or others that the topic may suggest, as he would have done had there been no cross reference. Not all articles relating to a given topic necessarily appear under the same entries. Users of the index should bear in mind further that frequently more regard is paid to the actual contents of an article than to the precise title under which it appeared.

G

An Extensive Power System in the South

The Development of the Southern Power Company in the Carolinas
Four Hundred Miles of Lines Operated at 44,000 to 100,000 Volts

BY CECIL P. POOLE

The Development Stage

Until within the last two or three years the hydroelectrical developments in the South were mostly local in scope, furnishing power to a few cotton mills in the immediate neighborhood of the power plant, or at the end of a comparatively short transmission line. This was due in part to the attitude of the mill men who, although the reliability, convenience and economy of the electric drive had been demonstrated in several instances, still looked upon it with distrust, and in part to the mistaken idea that power could be produced with a local steam plant cheaper than purchased from a hydroelectric company. But their feelings in this respect have recently undergone a change, a fact which capitalists were not slow to note, and the indications at present are that the next ten years will produce networks of systems extending over hundreds of square miles, and rivaling in amount of power transmitted any of the great Northern or Western systems.

It may be asked here where is the market for so much power, to which the reply is that in cotton mills alone nearly 13,000,000 spindles, using approximately 400,000 horsepower, are in operation in the South today. Less than one-third of this is furnished by water power, while something like 2,000,000 horsepower is still undeveloped in the very heart of the cotton field.

One of the pioneer companies to organize for this work was the Catawba Power Company. The first plant was built on India Hook Shoals on the Catawba river, 18 miles from Charlotte, N. C. This plant commenced operation in March, 1904, and the quick sale of the entire output (10,000 horsepower) led Dr. W. Gill Wylie, president of the company, to consider the advisability of developing other plants in different parts of the country. The result was the formation of the Southern Power Company, with a capital of $10,000,000, to acquire and develop a sufficient number of water powers to furnish power to a section of the country 130 miles in length and 100 miles in breadth in the heart of what is known as the Piedmont region, the richest and most fertile section of the Carolinas. This section is dotted with cotton mills throughout its length and breadth and 150,000 horsepower is used, generated mostly by steam.

Eight undeveloped water powers on the Catawba river, besides that at the Catawba station, were taken over and one on the Broad river, the water rights covering a distance of 110 miles on the Catawba river, giving an aggregate head of 500 feet, and an average capacity of about 150,000 horsepower. At the outset it was clear that the most practical plan of development involved beginning at Great Falls, and three generating plants hydraulically "in series" were planned. These are designated the Great Falls, Rocky Creek and Fishing Creek stations. The original plan was slightly modified, however, by distribution conditions, which made it advisable to establish a generating station farther up toward the center of the area covered by the system before putting in the Fishing Creek station. Consequently, as soon as the Rocky Creek plant was about completed, work was begun on a 10,000-horsepower generating station at the Ninety Nine Islands (see Fig. 11).

FIG. 1. VIEW OF GREAT FALLS STATION AND DAM FROM THE TAIL STREAM

Problems Involved

The engineering problems involved were somewhat different from those found in any other system of comparable size. It was not definitely known how much power could be marketed in any one town or district, which left unsettled the capacity of the lines and amount of territory to be covered. This complicated the question of voltage regulation, as did also the fact that power would first be taken off at two or three points toward one end of the system, and finally at ten and probably a great many more points over the whole area covered. It was also necessary to make provision in the scheme for line regulation in order that the most economical method of passing water from the upper stations to those lower down in dry seasons could be practiced. The generators and step-up transformers were purchased under specifications covering a 15 per cent. rise in voltage and will operate under full load continuously under these conditions. Taps were also put on transformers in case this increase of voltage was not sufficient.

it would help matters materially to be able to throw a large amount of power on the system at one point in order to give other stations on the system sufficient time to cut in before the load would become too large to be carried. The three projected stations in the neighborhood of Great Falls would together be capable of carrying a load of 90,000 horsepower, so it was decided that this point be made the principal one of the system.

In order to carry out this idea and to make the system pliable, it was further decided that the equipment of these three stations should be subdivided into four units, consisting of two generators and three transformers, at each station; that the high-tension leads from each bank of the insulation; that choke coils and series transformers should withstand a shop breakdown test of 120,000 volts for one minute, and that the complete high-tension equipment should withstand a breakdown test of 100,000 volts to ground after installation.

Great Falls, on the Catawba river, 50 miles below Charlotte, N. C., and 24 miles from Camden, S. C., was selected for the first development. Surveying was begun in June, 1905, and the water was turned on early in March, 1907. This station is now working in parallel with the Catawba station, the auxiliary steam plant having been shut down a year ago, and a sister station has been built at Rocky Creek, 1¾ miles from the Great Falls station, and

FIG. 2. VIEW IN THE GREAT FALLS GENERATOR ROOM

It was estimated that at least one hundred substations would be necessary to dispose of 150,000 horsepower and in the neighborhood of 800 miles of transmission line, no point of which would be more than 60 miles from the nearest power house. The large number of small substations and the comparatively short transmitting distance made it feasible to adopt 44,000 volts for the potential at receiving stations.

From the foregoing it is evident that the design of the switching arrangements necessary to facilitate the location of a fault in a line or substation, and for synchronizing after the fault had been repaired or the line cut out, was a serious problem. Much study was given this subject and the conclusion was reached that transformers should pass through one switch and connect with a switching station common to all three stations; that the busbars in the switching station should be divided into as many sections as there would be outgoing lines and arranged so that in case of necessity one or more units in any one station could feed into one or more lines; that provision for synchronizing should be made at first only on the switch between the transformers and the low-tension busbars, and that provision for synchronizing at the old Catawba station should be made on the low-tension side of transformers.

It was also deemed advisable to use as few switches as possible and to have a large factor of safety in all, with regard to both the current-carrying capacity and put into operation. These three stations are supplying current to 385 miles of transmission—or more accurately, high-tension distribution—lines, other stations are being laid out, and the construction of 240 miles of 100,000-volt transmission line is in progress. The potential of the existing lines is 50,000 volts at the Great Falls end and 44,000 volts at the substations.

Great Falls and Rocky Creek

These two stations are mates, the buildings and equipment being practically the same in both. The only important difference is in the exciter equipment, which will be described in detail farther on in this article. Fig. 2 is an imperfect view of the interior of the Great Falls generat-

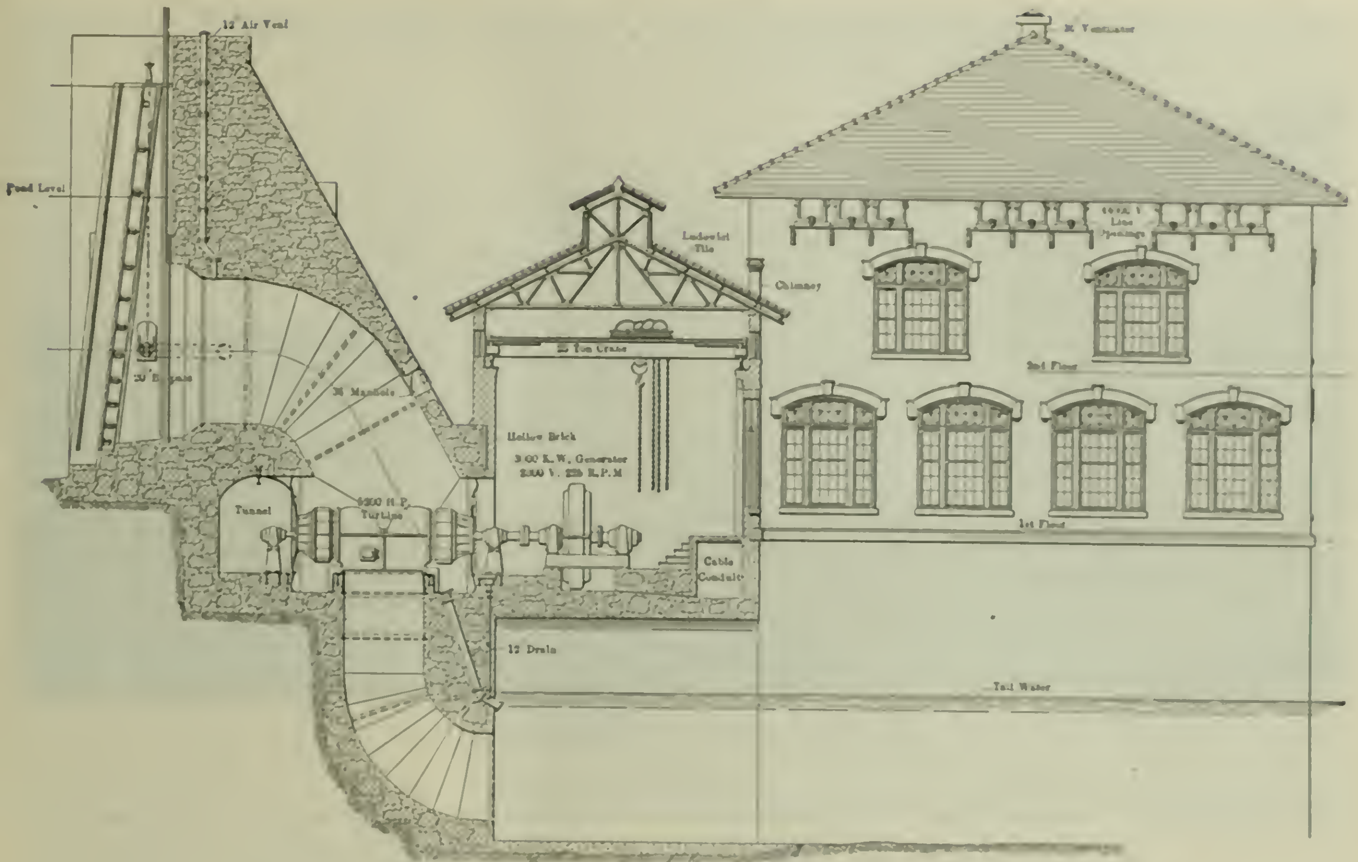

FIG. 3. SECTIONAL ELEVATION OF ROCKY CREEK GENERATING HOUSE, INTAKE AND HEAD GATES

ing room, which is 250 feet long by 37 feet wide and is 30 feet pitch. The transformer and switch house is 85 feet long by 71 feet wide, and is three stories high. The basement, which is on a level with the cable conduit and contains the cables and pipe work, is 8 feet pitch The next story, which is on a level with the switchboard gallery and contains transformers and low-tension switching apparatus, is 22.8 feet pitch, and the third story, in which at present are the high-tension switches, busbars, choke coils and lightning arresters, is 22 feet pitch Both buildings are of fireproof construction throughout, red pressed brick outside and light gray inside. The roof is built of large tile made of reinforced concrete with a waterproofing burned into it. The vertical cross-section, Fig. 3, and the plan view, Fig. 4, show the construction of the buildings, intake flumes and tail flumes, and the general arrangement of the generating equipment. Fig. 5 shows the dam at Rocky Creek during construction; the cross section of the unfinished portion on the right is clearly shown

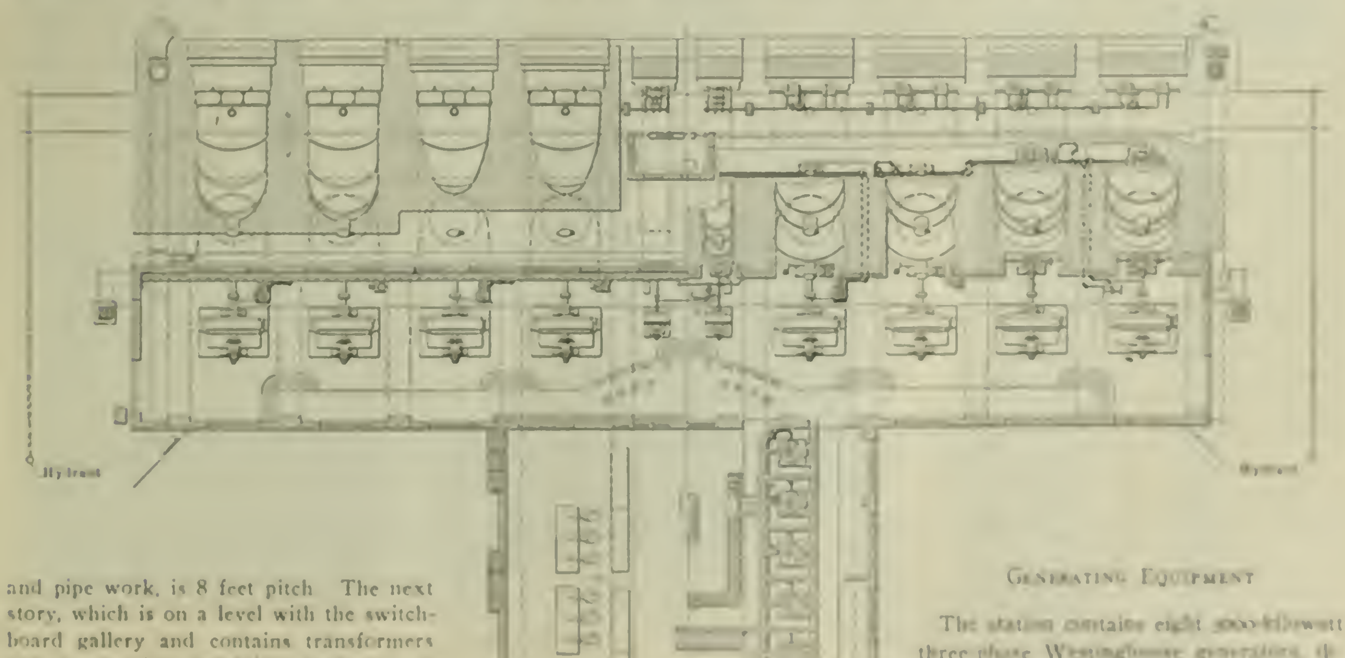

FIG. 4. PLAN OF GREAT FALLS STATION

Generating Equipment

The station contains eight 3000-kilowatt three-phase Westinghouse generators, direct-connected to six horizontal-shaft turbines of the Escher-Wyss pattern, built by the Allis-Chalmers Company, and two Hercules turbines of 5300 horsepower capacity each, built by the Holyoke Ma-

FIG. 5. THE ROCKY CREEK DAM DURING CONSTRUCTION

chine Company, with two 400-kilowatt, 250-volt exciters, each capable of carrying the total exciter load. The main generators were designed for an efficiency of 96 per cent. and to operate at full load at any voltage between 2200 and 2530, with 80 per cent. power factor, with a rise in temperature not to exceed 35 degrees Centigrade at any part. Tests have shown that the machines more than meet the specifications. They are driven at 225 revolutions per minute and deliver current at 60 cycles. Each two generators are connected in parallel through power-operated switches to a bank of three 2000-kilowatt step-up transformers connected in delta. This arrangement gives four complete 6000-kilowatt units capable

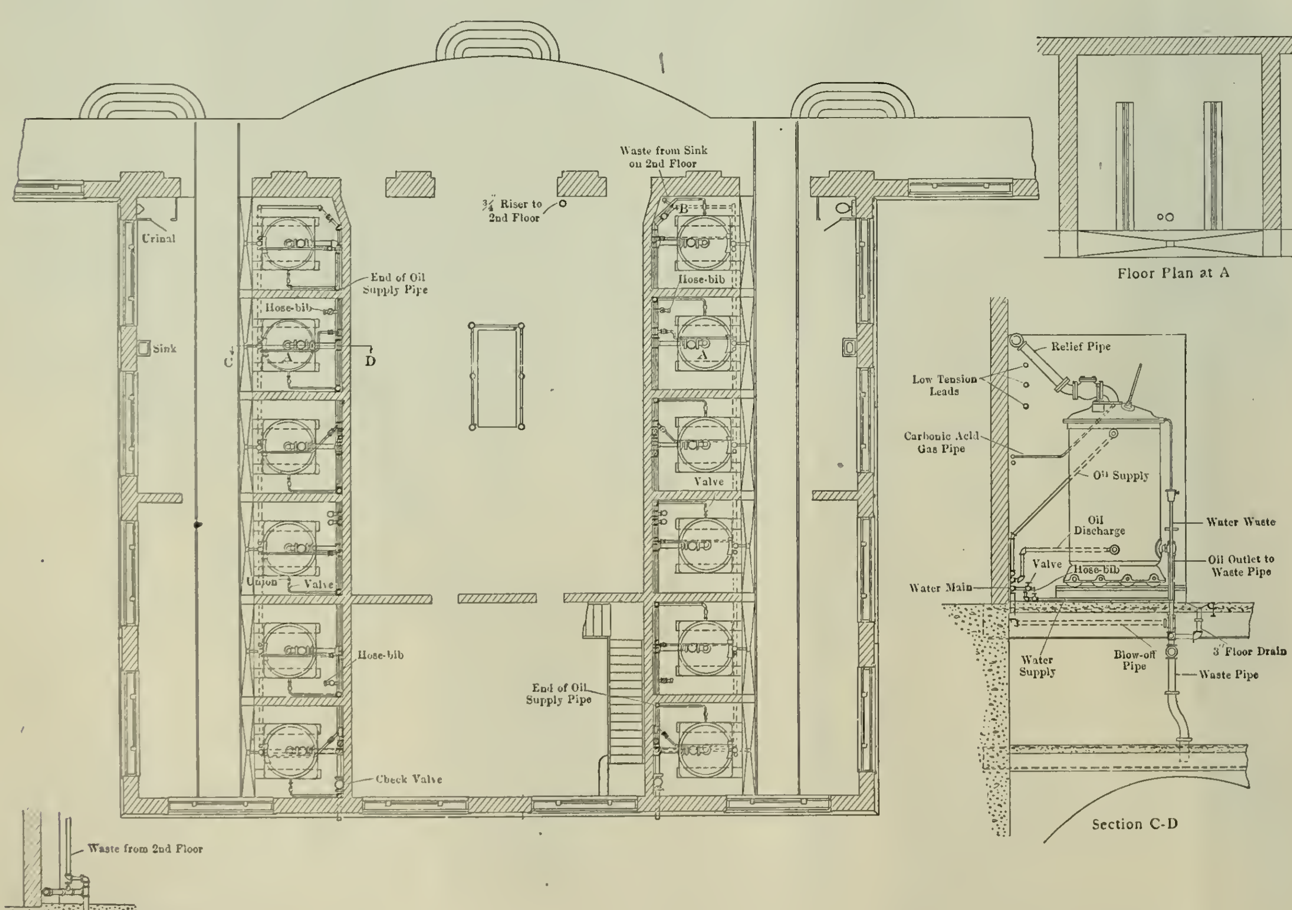

FIG. 6. PLAN OF TRANSFORMER ROOM AND ELEVATION OF TRANSFORMER-PIPE CONNECTIONS

of being run independently or in parallel, as may be found necessary.

The generators are controlled from pedestals standing in front of instrument posts, arranged in an arc of a circle to enable the operator to see all instruments without moving from one point. The advantage of the instrument posts and control pedestals in comparison with panel boards is that the operator can look over the pedestals and under the instruments at any machine which he is putting in service. On each of the eight instrument posts are mounted a 3000-volt voltmeter, a 1500-ampere ammeter, a 4500-kilowatt indicating wattmeter and a 400-ampere ammeter in the field circuit of the generator. On posts Nos. 1, 3, 6 and 8 are also mounted busbar voltmeters. To avoid confusion these are in a different type of case from the generator voltmeters. On posts Nos. 2 and 7 frequency meters are mounted and on posts Nos. 4 and 5 synchroscopes are mounted.

On the control pedestals are mounted the controllers for operating the oil switches, the hand wheels for operating the field rheostats, and the field switches; jacks used in calibrating instruments are also mounted on these pedestals.

Transformers, Switches, etc.

All transformers are oil-insulated and water cooled; they are located in separate fireproof compartments, as shown in Fig. 6, and mounted on trucks to facilitate handling. The tanks are made of heavy boiler plate which will stand 150 pounds pressure per square inch, and the tops are provided with check valves opening into a 6-inch pipe which leads to the tail water, to provide for any explosion which might take place due to the ignition of oil gas. The transformers are controlled from a standard blue Vermont marble board set in an archway between the control pedestals in the generating room and the low-tension switch room. For each bank of transformers the board carries an ammeter, a power-factor meter and an integrating watt-hour meter. In this archway are

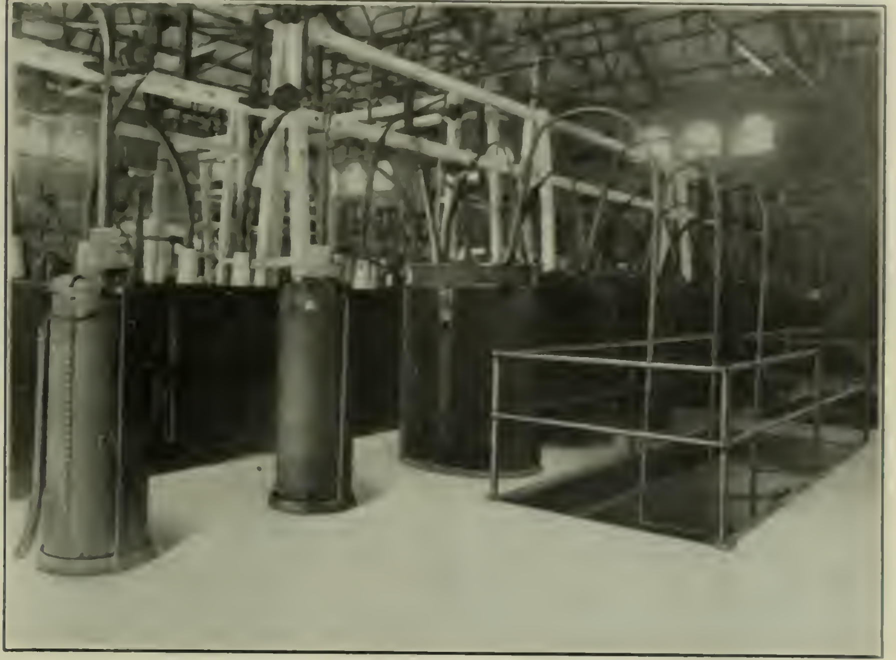

FIG. 8. VIEW IN HIGH-TENSION SWITCH ROOM

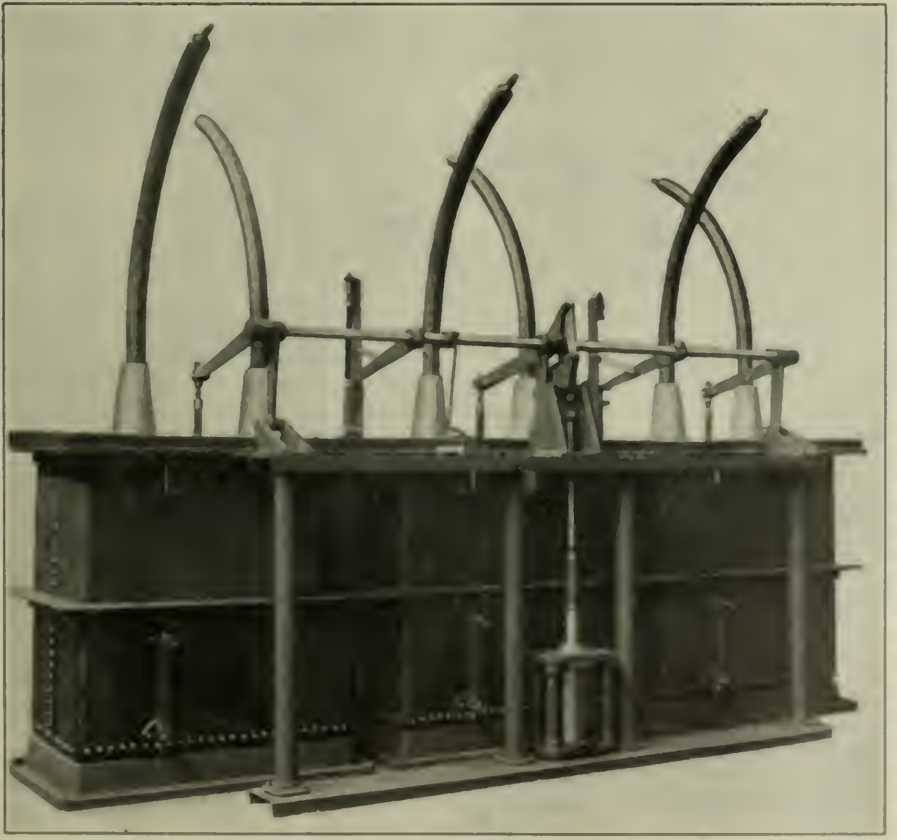

FIG. 7. SOLENOID-OPERATED OIL SWITCH

also set the panels for controlling the switches in the high-tension switch room. Ammeters only are used on the outgoing feeders.

The low tension switches and busbars are mounted in a concrete structure forming three sides of a rectangle in a separate room. The oil switches and circuit-breakers are each capable of breaking the entire output of the plant on short circuit; they are of the solenoid type, shown by Fig. 7, and operated with current from the exciter busbars.

The switchboard is located on a gallery raised above the power-house floor, but on a level with the transformer room and low-tension switch room. In the space below are the field rheostats, exciter busbars and control wires. This gallery is narrowed and extends in either direction to form a conduit for the cables between the generators and the transformers. These cables are laid on concrete shelves provided for the purpose, and are brought through floors and walls in vitrified conduit.

All the 44,000-volt apparatus is in an entirely separate room, occupying the third story of the transformer house. The high-tension switches are capable of breaking the entire output of the station on short circuit. The three poles of these switches are mounted in individual boiler-plate tanks sufficiently strong to resist any explosion that might be caused by opening the circuit during short-circuits on the high-tension line. The line and transformer switches are controlled from the panel board in an archway between the generator room and the low-tension switch room. All high-tension conductors in the buildings are made of insulated copper pipe.

Fig. 8 is a view in the high-tension switch room, and Fig. 9 is a schematic diagram of the main wiring and switching arrangements in the Great Falls and Rocky Creek stations, and this will be used also in the Ninety Nine Islands station when it is built. This illustrates clearly the banking of the transformers and generators into four equivalent units or "batteries."

The equipment at Rocky Creek is exactly the same as that at Great Falls, except as to the arrangement of the exciters. At Great Falls the two exciters are driven by individual water wheels. At Rocky Creek the two exciters and a 600-horsepower induction motor are set in line with the shaft of a single water wheel, and clutches are provided by means of which either the water wheel or the motor can be used to drive the exciters. Fig. 10 is a diagrammatic plan of the arrangement.

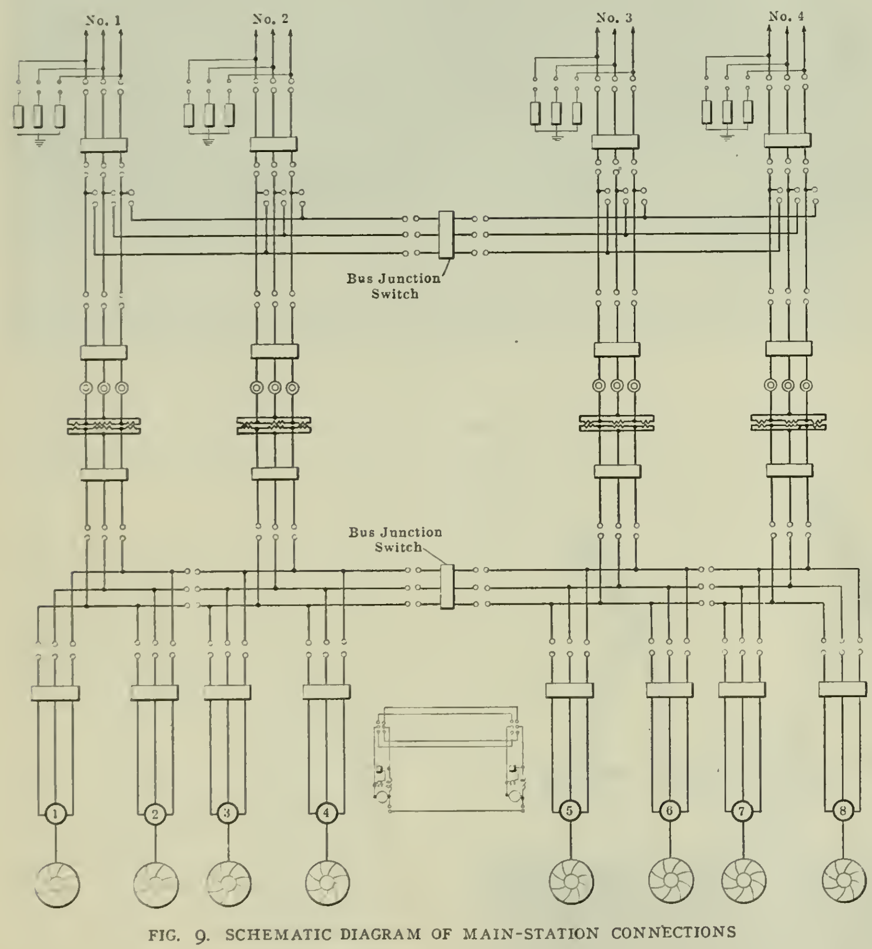

FIG. 9. SCHEMATIC DIAGRAM OF MAIN-STATION CONNECTIONS

The Catawba Station

The original station at Catawba contains four 750-kilowatt and four 900-kilowatt General Electric generators driven by Holyoke turbines and delivering three-phase currents at 13,000 volts to step-up transformers on the main 50,000-volt system. This station also supplies a separate system extending to Rock Hill, Pineville and other nearby towns, working at 10,000 volts at the receiving substations. This system takes current directly from the generator busbars. The Catawba power house serves also as a switching station for the 50,000-volt lines radiating northward from it, and is provided with facilities for connecting the short line to Rock Hill and other towns to the main system through step-down transformers. That is, the station contains three 2000-kilowatt delta-connected transformers with switches whereby they can be used to step up current from the generators and deliver to the main system, or to step down from the main system to the short line.

Transmission Lines and Connections

Fig. 11 is a map of the system, including lines under construction and those which it has been definitely decided to build. The double lines between the Great Falls district and the town of Concord, passing through the Catawba station, give some indication of the growth of the system, but even more significant than these are the double 100,000-volt lines now being built from Great Falls northward to Greensboro and westward to Greensville, S. C. These are transmission lines in the strict sense, while the 44,000-50,000-volt lines are really primary distribution feeders with respect to the general system. This is more clearly shown by Fig. 12, which is a diagram of the connections at all of the important stations and substations and also gives the distribution of power amongst the principal secondary stations.

At the generator end of each 100,000-volt line a 12,000-kilowatt group of two-to-one transformers connect these lines with the 50,000-volt busbars; at Salisbury, the two sets of lines will be tied together through a 9000-kilowatt group and at Spartanburg through a 6000-kilowatt group of two-to-one transformers. From Fig. 11 it is evident that each of the important points receives current from two or more directions; consequently, the supply cannot be cut off by trouble on any one feeder.

The main trunk line from Great Falls to Catawba station is 33 miles in length. It is carried on steel towers and consists of two three-phase circuits. Fig. 13 is a view of this line. Three sizes of tower are used, standing 35, 43 and 50 feet, respectively, from the lowest wire to the ground, as the nature of the country demands; 500-foot spans are used in general. The conductors are each built up of six strands of No. 6 copper, with a hemp center, equivalent to No. 000 Brown & Sharpe gage. Tests of this conductor gave a breaking strength of about 62,000 pounds per square inch for the individual strands, and about 58,000 pounds per square inch for the complete cable. The elastic limit was taken at 40,000 pounds, two-thirds of which gives 3330 pounds per conductor as the maximum working strain. To be on the safe side this was taken at 3000 pounds and the corresponding sag adopted, assuming a maximum change in temperature of 125 degrees Fahrenheit. After the lines were strung and before current was turned on they were subjected to a severe sleet storm and no breaks occurred.

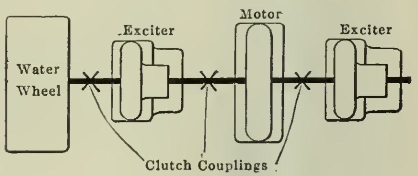

FIG. 10. ARRANGEMENT OF ROCKY CREEK EXCITERS

The trunk lines are sectionalized at points of transposition in order that in case of trouble on one line one section of the other may still be used and the remaining parts of both lines paralleled. The ordinary line towers are built of galvanized-steel angles with rod braces, and will withstand a total pull of 8000 pounds at the top. The sectionalizing and transposition towers are similar to the ones

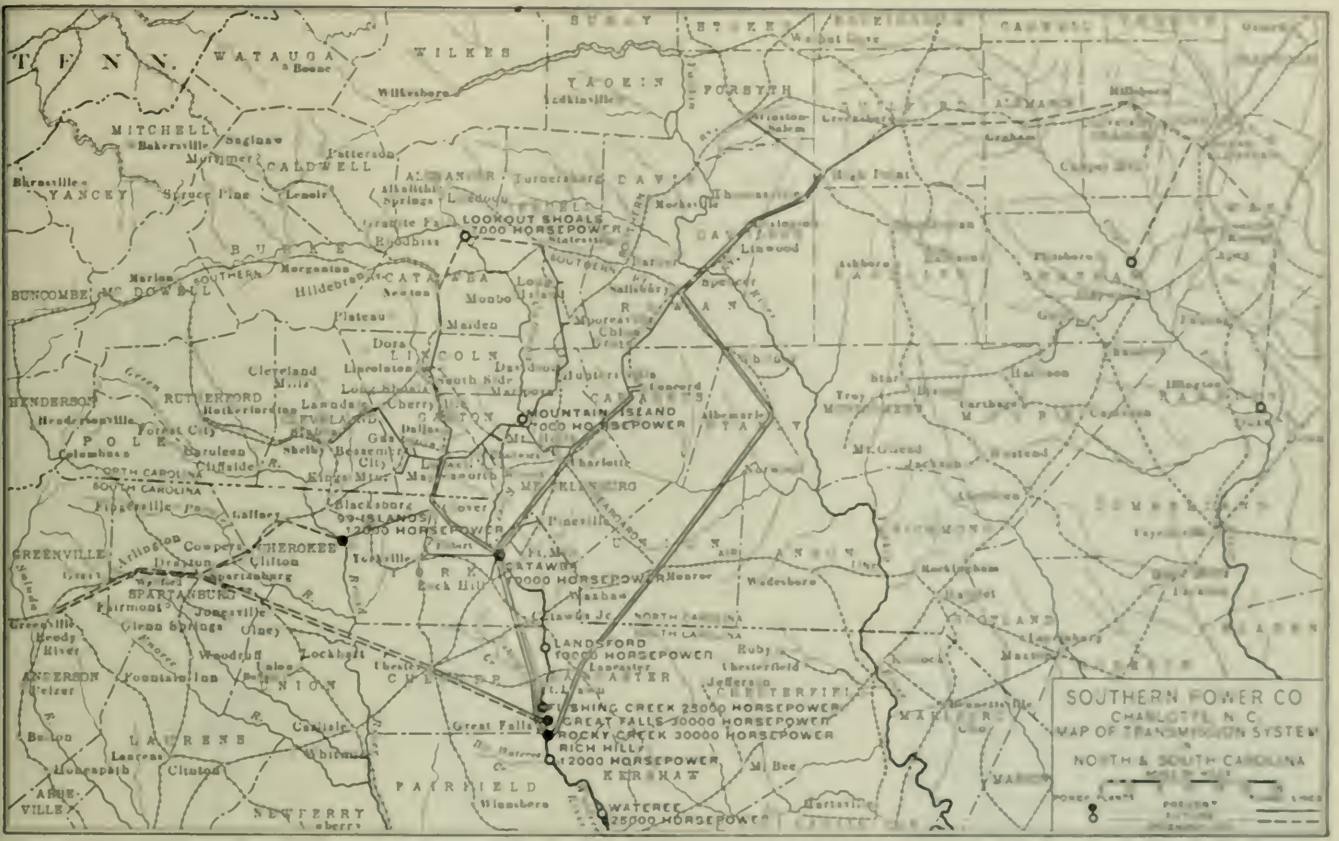

FIG. 11. MAP OF THE SOUTHERN POWER COMPANY'S TRANSMISSION SYSTEM

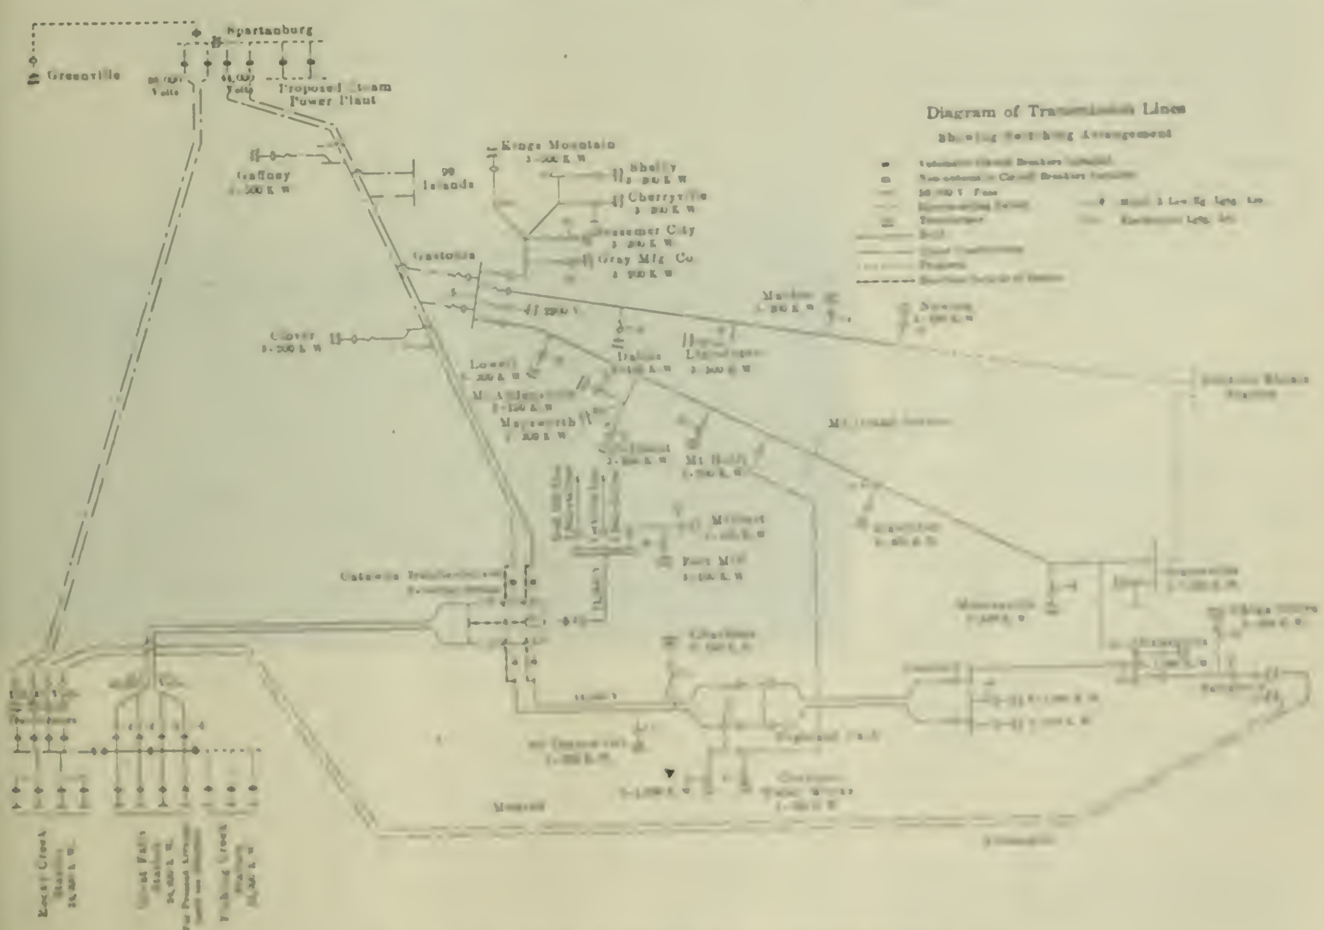

FIG. 12. DIAGRAM OF TRANSMISSION AND FEEDER CIRCUITS

used at angles greater than 30 degrees or for terminal or tap-off towers, except for the arrangement to which lines are connected. They were tested to 6000 pounds per conductor. The line between Catawba station and Gastonia, a distance of 25 miles, is carried on the same type of tower, though it consists of only one circuit of No. 00 Brown & Sharpe stranded copper at present.

The remaining 44,000-volt lines now completed or under construction are carried on 35-foot wood poles, 8 inches in diameter at the top, and spaced 150 feet apart. The cross-arms are 4¾ inches by 5¾ inches by 7 feet hard pine treated with hot carbolineum. The pins are iron and a special iron cap was designed to accommodate the top pin and to support a galvanized pipe, which in turn supports a grounded wire. An iron pin was also designed which has proved very satisfactory, not only with regard to convenience and strength, but also with regard to cost. The shank is cast and the pin head may either be cast or forged, according to strength required. These pins with cast heads were used on terminal towers and three of them proved amply strong. The bolt can be made any length and makes a very convenient method of fastening an insulator to a wall or wood beam. The heads are cemented in the insulators either at the factory or before insulators are taken out of the shipping crates.

On account of using towers that would not withstand the strain of a broken wire, a tie-clamp had to be designed that would allow the wire to slip through in case of emergency. The clamp is made of cold-pressed steel, galvanized, and will allow the conductor to slip at about 350 pounds pull. In other words, the strain will be distributed amongst ten towers, leaving an ample margin for wind pressure. This clamp costs less than an ordinary tie-wire.

The line insulators were specially designed to meet the views of the company's engineers and were mostly made by the R. Thomas and Sons Company. Those on the 44,000-50,000-volt lines are of the construction shown by Fig. 14. They will arc over at approximately 88,000 volts under a precipitation test of ¼ inch of water per minute at a pressure of 50 pounds per square inch from a sprinkler nozzle played on the insulator at an angle of 30 degrees above the horizontal. They were all subjected to a dry test of 120,000 volts for ten minutes. The insulators used on the 88,000-100,000-volt lines are of the suspension double-petticoated type 14 inches in diameter.

Substation Equipment

The substation transformers were all purchased under one specification in order that they could be changed from one point to another in case of a burnout, or in case the output became too large for the size of the transformer. They are capable of carrying full load continuously at 5 per cent. above and 10 per cent. below the rated voltage, taps being provided for these voltages on the high-tension side.

In the small transformer substations the cost of automatic high-tension switches such as are used at the generating stations would be excessive and a comparatively cheap oil switch, with the poles mounted separately in brick cells, and equipped with expulsion fuses (of type similar to what is known as the "T. D." fuse made by the General Electric Company) is used. Before the adoption of these fuses they were tested on short-circuit on lines of large capacity and proved very satisfactory. It is hoped that these fuses will prove more satisfactory than the automatic switch in that the series transformers necessary for the circuit-breaker, which has been such a source of trouble in lightning storms, are now not necessary.

Lightning Protection

An equal number of General Electric multiple-unit and Westinghouse low-equivalent lightning arresters, together with horn arresters, have been used in the main and substations, and an electrolytic lightning arrester is now being installed for comparison with the arresters of the older type. In addition to the lightning arresters, grounded wires are strung over all transmission lines. On the twin steel line towers two grounded wires are used, and on the pole line one 9/32 galvanized S. M. strand. Each pole is grounded by attaching to the side thereof a galvanized plate 12 inches

FIG. 13. TRUNK LINES BETWEEN GREAT FALLS AND CATAWBA

square of No. 20 metal. This plate is connected with the overhead wire by means of a No. 8 iron wire. The effectiveness of this grounded wire has been questioned, but the company's experience on the old lines has shown that it is well worth the money spent on it.

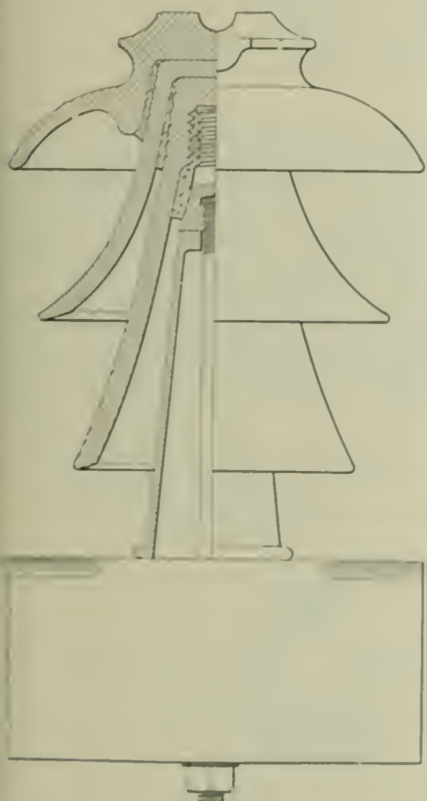

FIG. 14 INSULATOR USED ON 50,000-VOLT LINES

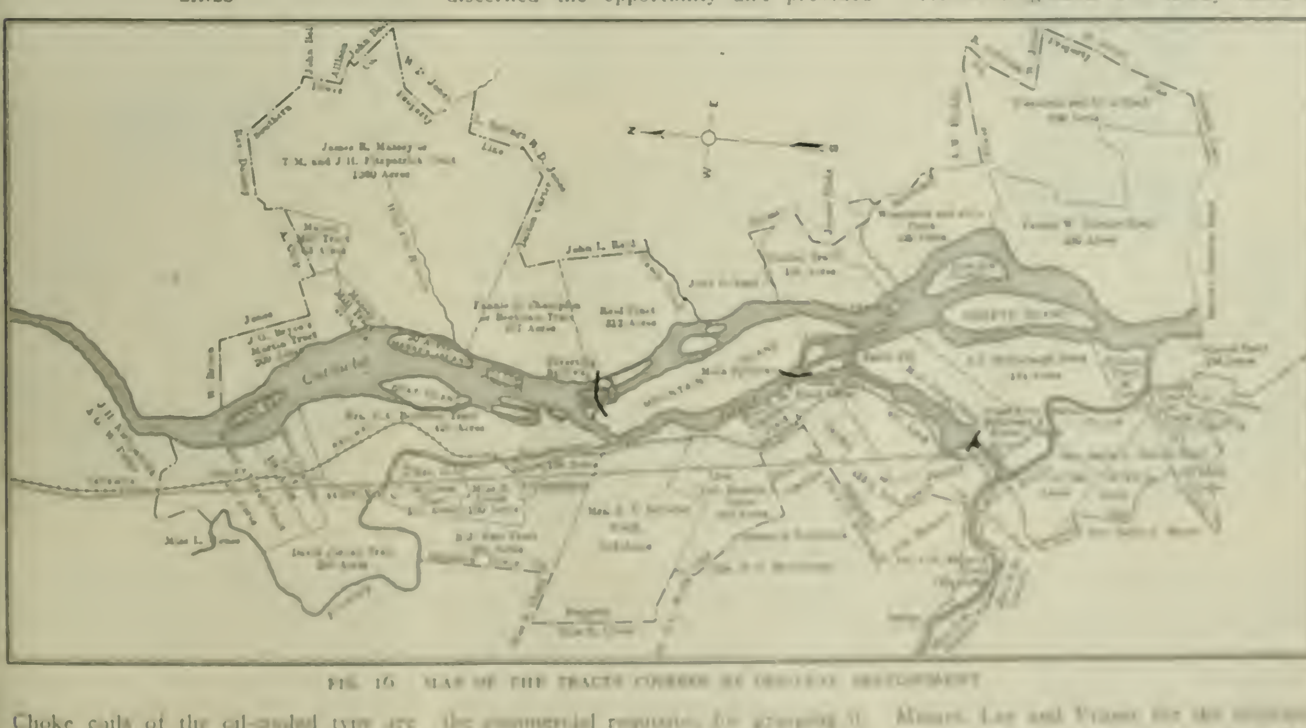

FIG. 16 MAP OF THE TRACTS COVERED BY [illegible] DEVELOPMENT

Choke coils of the oil-cooled type are used at the generating stations. The impendance drop in these is about 1 per cent. of the line voltage and the resistance loss about 1800 watts when the transformer bank is carrying normal full load current. Smaller choke coils of air-cooled type are used in substations.

In General

As the load on the system is constantly increasing and changing in distribution characteristics, any specific statement concerning it would be out of date by the time this article actually appears in print. It is of interest to note, however, that on November 1, more than one hundred cotton mills were operated by current from the system; all of the street lighting in Charlotte, Salisbury, Concord, Statesville, Lincolnton and some twenty smaller towns was being done by it, and countless small factories and industrial plants depend on it for their motive power. In the cities and towns where general lighting and power service is supplied, the current is stepped down to 2300 volts for distribution by the local primary network. In most of these places the Southern Power Company merely sells power "in bulk," so to speak, to local companies who formerly operated central-station plants; the prime movers in most of these plants have been discarded, and the station equipment restricted to transformers and series-circuit regulators, reducing the problem of attendance to a state of beautiful simplicity. In many of the towns, however, the power company maintains its own substations and deals directly with the consumers.

The success and rapid progress of the company was primarily due to two men—Dr. W. Gill Wylie, the president, whose foresight, energy, and financial ability discerned the opportunity and provided the commercial resources for carrying it and W. S. Lee, Jr., chief engineer, whose sound engineering judgment and executive ability are responsible for the working out of the details and the technical application of Dr. Wylie's industrial scheme. During the past four years Mr. Lee has had an invaluable assistant in J. W. Fraser, who has practically the entire responsibility for the mechanical and electrical portions of the work. Since Mr. Fraser's advent, in the spring of 1904, Mr. Lee has confined his attention to the

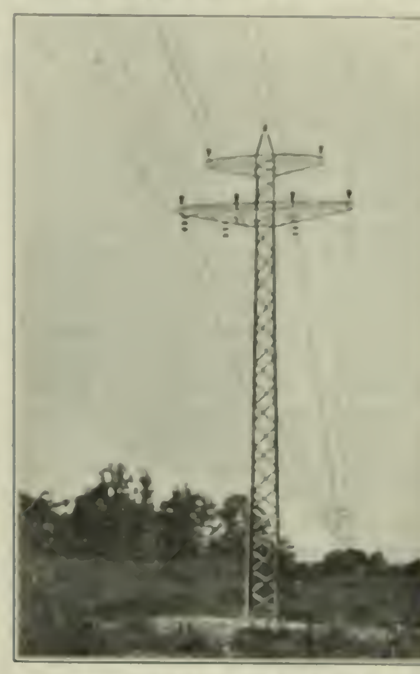

FIG. 15 TOWER USED FOR LINES IN CITIES

practical construction work—the executive side of the engineering department. During this period the load carried has increased from 300 horsepower to 50,000 horsepower for ten hours.

Acknowledgments are hereby made to Messrs. Lee and Fraser for the information presented in this article and to Mr. Fraser for his cheerful cooperation in the preparation of it, as well as for several drawings and photographs made especially to illustrate the description here.

The Use and Abuse of Globe Valves

Plain Descriptions of the Principal Features of the Different Types, with Practical Suggestions for the Guidance of Engineers

BY W. H. WAKEMAN

The ordinary globe valve is a mechanical monstrosity, illogical and crude when viewed as a machine, but owing to its convenience of operation and low cost of repairs it has gained well deserved popularity among engineers and steam users. A few suggestions concerning its proper use, and in disapproval of the abuse to which it is often subjected, ought to prove profitable to all concerned.

Fig. 1 illustrates the first thing that I do to one of these valves when it is to be used in my plant. A stout bench, well braced from the ceiling to hold it down firmly, is shown at *A*, on which there is a pipe vise *B*. A short piece of pipe of a size suited to the valve is clamped in this vise, and the valve is screwed on it. A large monkey wrench is fitted to the bonnet, and a quick, strong pull on the handle loosens the screw and removes the bonnet without further trouble under ordinary conditions. The reason for using a large wrench for this job is because a small one is much more liable to spring and round off the corners without loosening the bonnet.

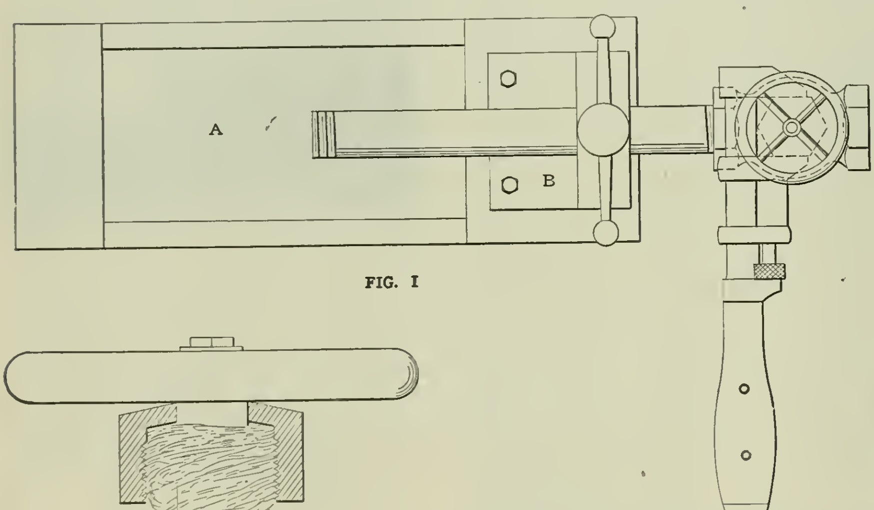

FIG. I

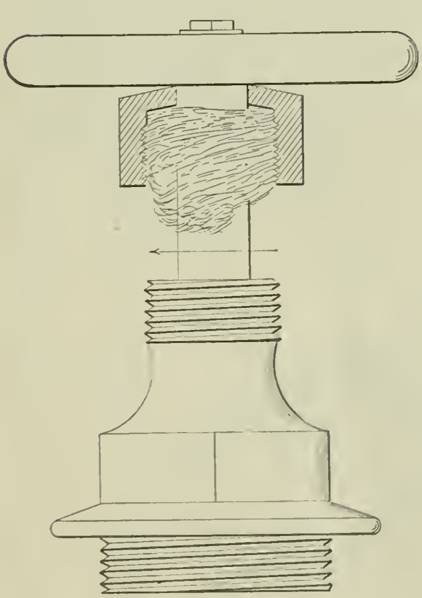

FIG. 2

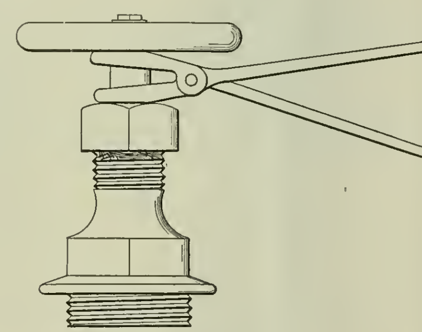

FIG. 3

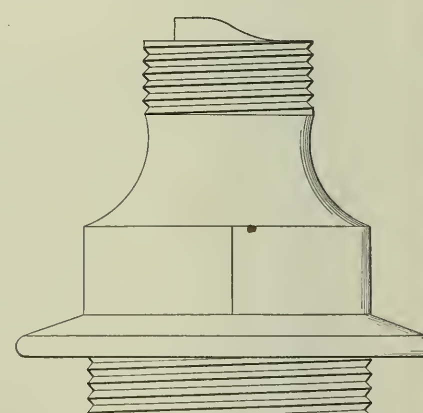

FIG. 4

The reason for removing the bonnet at this time is owing to the assumption that it was screwed on very tightly when first assembled; therefore, if not loosened before it is subjected to the action of steam, it will be almost impossible to take it off when it must be repaired in order to stop a leak at this point. If it is replaced and brought to its proper seat by reasonable pressure on the wrench handle, it will be steam- and water-tight, and later it can be removed without serious injury. The use of lead or anything else on these threads is not recommended, for whatever is applied will prove detrimental when the bonnet is again removed after long service. When considering this point it is well to remember that the joint is not made in the threads (like a pipe joint), but where the two flat surfaces come together and are held in close contact by the threads.

The next move is to unscrew the packing nut, remove whatever packing may be there, and fill the nut as nearly full as possible with asbestos wicking, either oiled or coated with graphite, according to the conditions under which the valve is to be used. It is surprising to note the indifferent way in which engineers sometimes pack these valves. A short piece of packing is put in and the nut is screwed down as far as it will go, which means that nearly all of the threads on the bonnet are covered. If this prevents the escape of steam it is considered sufficient. When it does begin to leak, a wrench is applied and a hard pull brings it around perhaps one-quarter of a turn, but it will go no farther, and steam still blows out; consequently, pressure is removed from the pipe line, the nut is taken off, more packing is added (without removing the old material) and the nut is screwed on. The result is the same as before, but the process is repeated indefinitely, as the unsatisfactory results obtained do not suggest an improved method.

A better plan is to press the packing tightly into the nut with a packing hook, or other suitable tool, and wind it around the stem until it appears as shown in Fig. 2. The end of this packing is left so as to show the direction in which it should be wound, because the nut is turned as indicated by the arrow, in consequence of which action the packing will be smoothly prêssed into plâce, whereas if it were wound in the opposite direction, turning the nut would unwind the packing and prevent smooth action. It ought to be wound around the stem in the opposite direction from that in which the nut is turned when screwing it on the bonnet.

FIG. 5

Having thus filled the nut, it is pressed down until a pair of packing pliers can be inserted between the nut and the wheel, as illustrated in Fig. 3. These pliers are designed to open when pressure is applied to the handles (instead of closing in the usual way); consequently, the nut is forced down until it begins to screw on the bonnet, when a wrench is applied to it. Usually it can be turned until the packing is compressed into about one-half of the nut, then it ought to be unscrewed and another ring or two of packing put in.

This calls attention to the form adopted for the top of the bonnet on which the packing rests. Originally it was a plain, flat surface, and this is better than any other kind for the following reason: When the packing nut (or waste nut, as it is technically called) is unscrewed as described, the packing remains in it; therefore, more can easily be added until the desired amount is secured. If anything prevents free movement of the packing, it is pulled out of the nut and it must be replaced, but it is then loose and requires force to make it compact, as when it was first put in.

Fig. 4 illustrates a device that appeared on a certain kind of globe valve a few years ago, but it is not used much at present. The tapering side of it is presented to the packing when the nut is screwed on, but any movement in the opposite direction is opposed by the square edge which effectually pulls out the packing. About the first thing that I did with a valve of this kind was to take a flat file with a safe edge and file off these objectionable projections, leaving the top flat and smooth.

Another Device for Holding Packing

Fig. 5 represents another device for holding packing, consisting of a depression in the top of the bonnet next to the valve stem. This is of hexagon form, and when packing is forced into it by screwing down the nut, it cannot turn easily. To overcome what is an objectionable feature from my point of view, I put one ring into this depression and make it independent of the remainder of the packing used; therefore, after it has been forced downward into place, the top of the bonnet is smooth and practically flat. Valves of this kind that I have recently purchased contain a ring of fibrous packing nicely fitted to and forced into this cavity, thus leaving the top perfectly free from obstruction. This is an excellent idea, because it gives the engineer a chance to

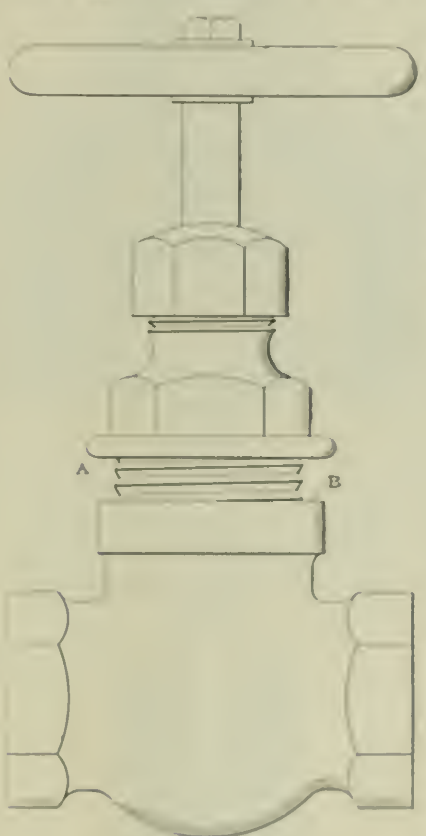

FIG. 6

choose which he will use. If this ring is not taken out he has a plain top on the bonnet, but if removed it leaves the hexagon cavity to prevent the packing from turning.

The object of the features shown in Figs. 4 and 5 is to prevent the nut from unscrewing when the valve is opened, but this very seldom happens in my plant, and there is no good reason why it should in others. If the packing is lubricated and the nut screwed down as it ought to be, no other precautions need be taken to hold the packing from turning. This refers to ordinary globe valves. There should always be enough in the stuffing box or nut to allow for screwing it down another revolution or turn, if it leaks after being in use for several weeks.

When the bonnet of a valve that has been used more or less is removed for any purpose, the surfaces at *A* and *B*, Fig. 6, ought to be thoroughly cleaned, then they will come together, metal to metal, when the bonnet is replaced. If there is a slight leak at this point when full pressure is on the valve, the only safe plan is to remove all pressure, take off the bonnet, clean the surfaces as described, and screw the bonnet on again, using force enough to secure perfect contact at all points. It is dangerous to force it down farther with full pressure on, as the leak may be due to a defect which careless usage will develop into a rupture, allowing steam or hot water to escape. Many accidents have resulted from poor management along this line.

Fig. 7 is a valve that is not always satisfactory, at least in my experience; therefore, it is never used in an important place. It is all brass, with a beveled seat and a disk that adjusts itself to the seat. This disk can easily be taken from the stem and, by fitting a wooden handle onto it, there is what may be termed "a fighting chance" for regrinding it and thus repairing a leak; but as there is no provision made for grinding the disk, the operation

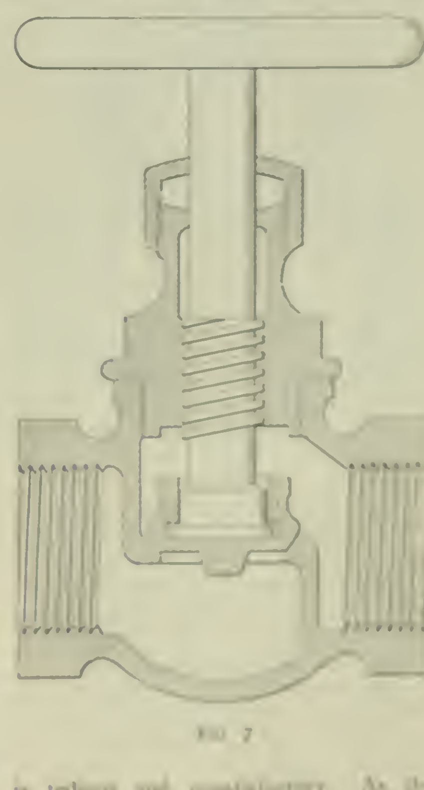

FIG. 7

is tedious and unsatisfactory. As the manufacturers of these valves are not willing to put their names or trademarks on them, it is assumed that they are not guaranteed.

The disk shown in Fig. 8 is loose on the stem in ordinary use, but provision is made for fastening it when it leaks enough to make regrinding necessary. The guide near the lower end of this stem is held in the position shown by a screw, but when a screwdriver is inserted in the slot and it is given a turn backward, the lug on the lower side of this guide drops into the slot in the disk, where it is fastened by tightening the screw. Of course, it was necessary to remove the bonnet before the screw could be loosened, and by bringing it to the position illustrated the stem and disk can be freely turned for the purpose of regrinding the worn surfaces. As the body of this valve is fitted with an external thread and the bonnet is threaded internally, these threads are not subjected to the direct action of steam, because the joint is made by the surfaces *A* and *B* joining perfectly when the bonnet is screwed into place.

Fig. 9 is another all-metal valve which can be reground at pleasure. The bonnet is removed in the ordinary way, and the disk is then taken off from the stem. A temporary holder is inserted in the disk, then by means of a carpenter's brace the disk can be turned until the regrinding process is complete.

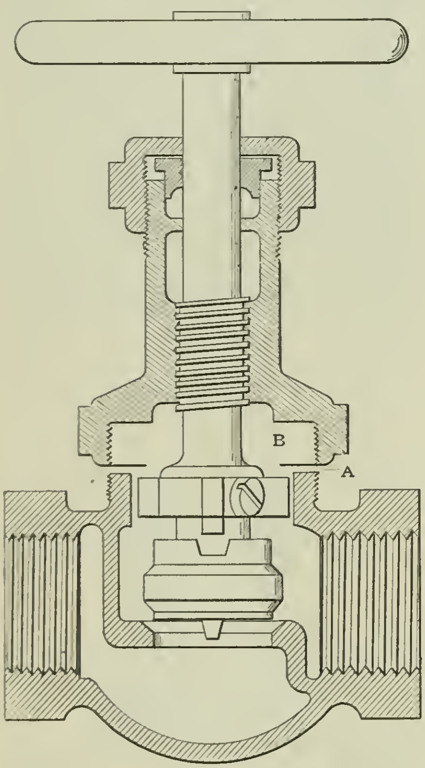

FIG. 8

Special attention is called to the guide forming part of the disk, as it insures true surfaces when efforts are made to eliminate leaks.

Some Peculiar Features

Fig. 10 has peculiar features which are worthy of attention. The bonnet is secured to the body by an internally threaded ring *A*, which resembles a union connection. By unscrewing this ring the trimmings, or, in other words, the entire upper part of the valve can be removed, leaving the body only in place. The disk is now loose on the stem, but by inserting a small wire nail in the hole shown in the former and passing it through a corresponding hole in the latter, as shown in the illustration, the disk is caused to turn with the stem; consequently, the bonnet can be replaced temporarily without screwing the ring down tight, thus forming a guide for the stem, which is turned by the wheel until a perfect joint is secured. It is better to give this wheel not more than one-half revolution and then reverse the motion than always to turn it in one direction, as the grinding material seems to do better work under these conditions. Care must be taken to remove the wire nail and thoroughly clean the internal parts before the trimmings are permanently replaced. When the seat of this valve is badly worn, it can be taken out and a new one inserted.

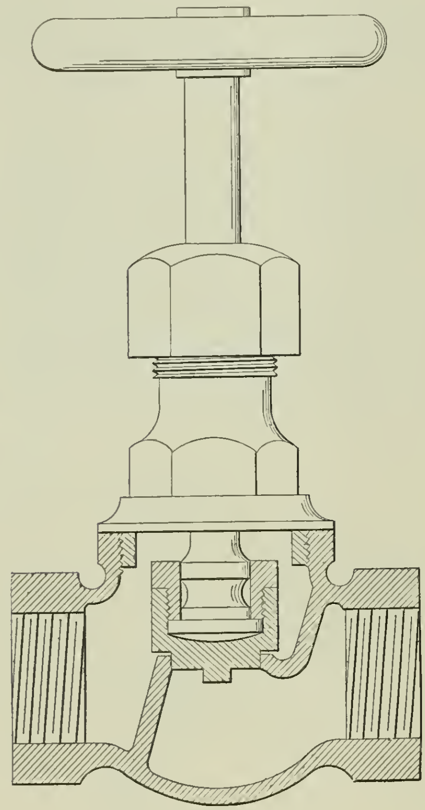

FIG. 9

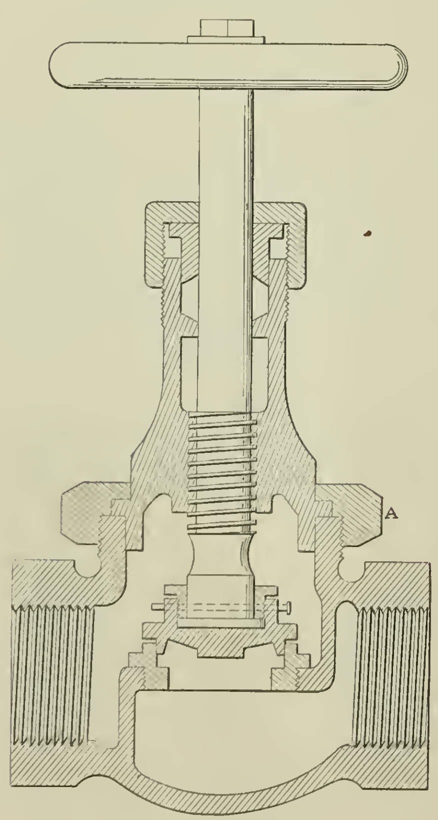

FIG. 10

As this valve is quite different from those previously shown, an external view of it is presented in Fig. 11.

Fig. 12 is fitted with a removable disk holder which cannot come off the stem while in use, but when it is worn out the bonnet is taken off in the usual way, and the stem screwed down as far as it will go, bringing the disk holder clear of the bonnet, thus allowing it to be removed without the use of tools of any kind. A new holder containing a hard-rubber disk is substituted, the stem drawn up and the trimmings put back on the body. Another kind of valve is designed to embody the same principle, but the disk is packed with asbestos which is forced into place under great pressure. Because asbestos is not affected by heat, acids, or oils, these disks should prove durable.

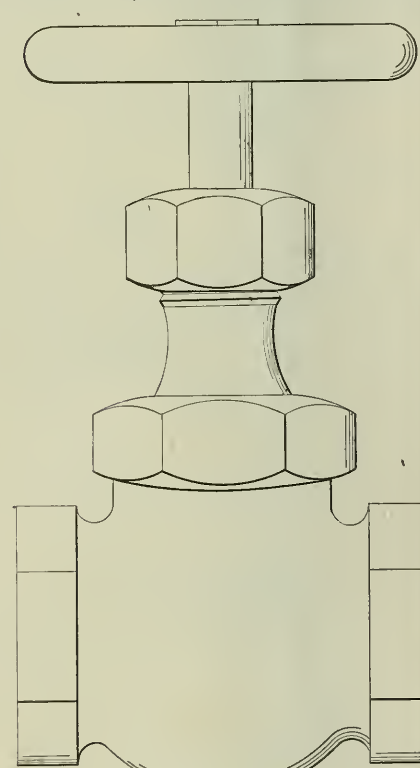

FIG. 11

Fig. 13 is an all-brass valve, except the disk, which is made of copper. The holder is retained on the stem by a slender nut and the disk is kept in the holder by another nut. When this valve is closed, only the round edge of this disk is in contact with the seat; therefore, it forms a tight joint with comparatively light pressure of the stem. This disk will prove durable when used on lines that carry high-pressure superheated steam. It is possible for this nut to become loosened and finally be turned off by the action of steam passing it swiftly, especially when water is mixed with the steam, which is a condition frequently found in practice during the first few seconds after the valve is opened, and it may exist at other times. To prevent this, put two prick-punch marks in the thread after the nut is screwed firmly into place. These will hold the nut while in service, but will not prevent it from being turned off with a

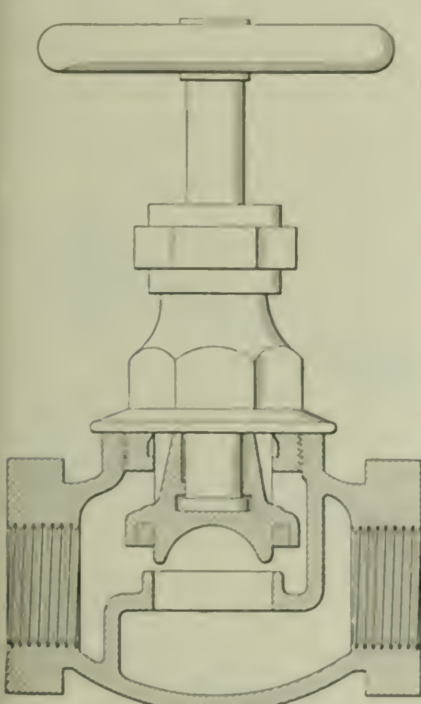

FIG. 12

wrench when a new disk is to be put on.

Fig. 14 shows a brass globe valve fitted with a hard-rubber disk that can be removed at pleasure, as it is held in place by a nut. If the disk does not come out easily with the nut off, hold it in the flame of a gas jet for about one minute. The heat will soften the composition and may be pried out with a small chisel, or a packing hook.

Under common conditions this disk will make a tight joint with no trouble, and will last for a long time. When worn out it can be removed at small expense and with slight trouble. If it lasts only a few days on a steam-pipe line, the pressure is probably too high for that particular kind of disk. Order one that was made to withstand high pressure, and if that fails get one made of babbitt metal. If that does not prove satisfactory, secure a brass disk and grind it to a perfect fit on the seat, as if it were designed for regrinding.

While these valves are used extensively, there are many engineers who do not understand their design and operation.

Shape of Disk Important

Another point to be considered is the shape of the disk, for although the ex-

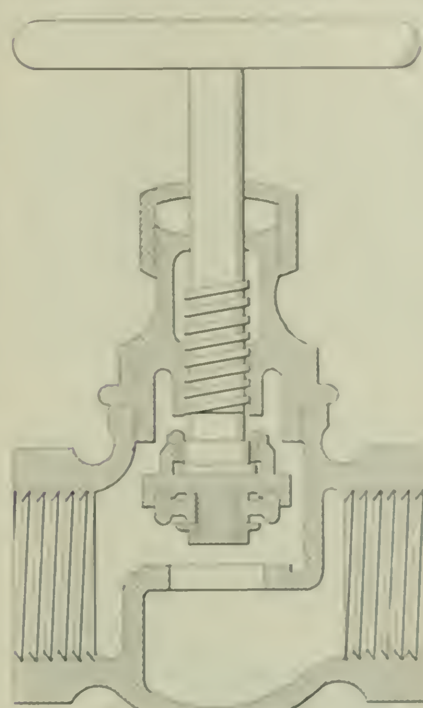

FIG. 13

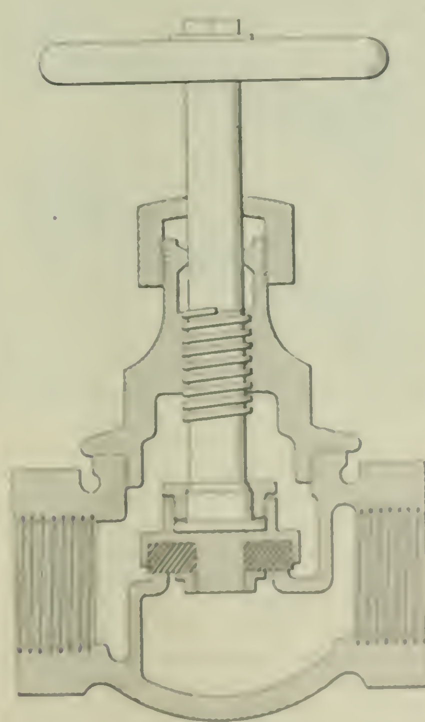

FIG. 14

ternal form is round, it does not necessarily follow that it is the same internally. Fig. 15 illustrates a very common design, the object of which is as follows: The nut projects into the disk and corresponds to it, hence one cannot be turned without moving the other. This is a good feature, because the disk becomes fastened to its seat by the action of steam and holds the nut and prevents it from turning off while in use. When the disk is worn out, and a wrench is applied to the nut, the disk must turn also, so no further trouble is found in removing the old disk, provided the wrench can be made to hold on the nut.

As a general rule the corners are spoiled by the operation. The wrench slips off, and both nut and disk stay where they were until a Stillson wrench is applied; as the teeth sink into the metal, it cannot slip, but the nut is disfigured or perhaps spoiled by the operation. On this account it is better to file out the flat spots and leave the internal surface a true circle. Thus there is a much better chance of unscrewing the nut without injury, and there is really but little danger of losing it in service if it is fastened according to the

FIG. 15

suggestions made in connection with Fig. 13. The advantage of having these disks made as shown in Fig. 15 is that the engineer may use them in this condition or not according to the results of his experience and observation in the matter, but if they were made round internally it would be impracticable to add the flat spots afterward.

Fig. 16 is a globe-valve stem with disk holder and fixtures complete. It has nine full threads which are sufficient to hold any pressure that other parts can withstand, but when the valve to which this stem belongs is closed, only a part of them will be meshed into the threads in the bonnet, while the remainder are not in a position to hold anything. A valve that I have just examined has ten threads, but only four are in service when the valve is closed, and in others there may not be more than two. Assuming that it is connected so that pressure acts on the under side of the disk when closed, the maximum stress is on the threads at this time; therefore, one-half of them ought to be where they can assist in holding the disk to its seat.

A globe valve was located with its stem in a horizontal position. After being used for several years the disk holder was quite loose on the stem, and although the seat and disk were in good order, the valve leaked continually. When lost motion at this point was reduced to a very small amount (leaving only enough for correct operation of the valve), by filing the back of the holder until the nut which screws

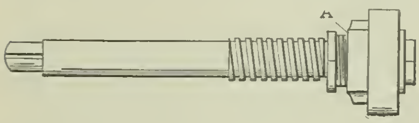

FIG. 16

into it at this point could be turned in almost far enough to grip the stem (see *A*, Fig. 16), the valve was tight when closed. The philosophy of this action is as follows: Lost motion allowed the top of the disk to strike the seat first, and further action of the screw was not sufficient to make it bear evenly; consequently it leaked. When this unnecessary lost motion was taken up, the disk rested against the seat squarely and made a tight joint.

The manufacturers of many of the globe valves now in the market claim that when they are opened wide it is possible to pack them at pleasure. This is undoubtedly correct when applied to the valves actually guaranteed, but it is not wise to apply it to all valves found in a steam plant without knowing their design. To test a valve for this feature, open it wide, apply the packing pliers illustrated in Fig. 3 and cautiously unscrew the packing nut. If steam escapes it shows that this valve cannot be packed under pressure, but the nut can be forced down into its proper place by the pliers, and the application of a wrench will soon stop the leak of steam. Let the matter rest until pressure can be removed from the line, then pack the valve in a workmanlike manner.

The Oppressiveness of Erudition

"The trouble with me is that I know too darn much," drawled the puzzle editor as the chief passed his desk.

"How so?"

"Didn't you ever notice that the less a man knows about a thing the quicker he can give you an answer about it? For instance, here is a fellow who wants to know what is the difference between the gage pressure and the absolute pressure. I was on the point of telling him 15 pounds. If your gage pressure is 75 pounds, the absolute pressure is $75 + 15 = 90$ pounds. That is good enough for most cases, and more exact than men ordinarily read gages or than gages usually are, but I happened to think that that fellow may use Kent's table, where the gage pressures are all given with an 0.3 after them and the gage pressure corresponding with 90 absolute is 75.3. So I start in to tell him to add 14.7 to the gage pressure to get the absolute, and then it struck me that this is only right if the pressure of the atmosphere is 14.7 pounds, and if it happens to be so it is an accident. I can tell him to add the pressure of the atmosphere to his gage pressure, but how is he going to get the pressure of the atmosphere? If he takes it by the barometer, it will be right for that place and time, but may not be right for another place or another time or for the case that he is working on. And then he gets it in inches of mercury and he has to use it in pounds per square inch. No two authorities agree as to the weight of a cubic inch of mercury and it is dollars to doughnuts that he wouldn't have pure mercury in his barometer, and the weight per cubic inch varies with the temperature, which he would not know, and then again a cubic inch of pure mercury at the same temperature weighs less at the equator than it does at the poles on account of the centrifugal force, so that the latitude comes in. Gee, I could write a book about it. If I only knew half as much my work would be twice as easy."

Steam Boiler Water Gages

By H. A. Jahnke

The writer has noticed quite often that the water gage and try cocks on a boiler do not receive the attention they should get. A great many firemen, and some engineers who do their own firing, blow the dirty water out of the water column and gage glass perhaps once or twice a week, which is bad practice.

The water column and gage glass should be blown out three or four times a day, or as often as is necessary to keep the water-column and gage-glass connections free from mud and scale. If there are valves in the water-column connections the steam valve should be closed and the valve in the water connection and drain valves on the bottom of the water column opened for a short time, in order to blow out of the lower connection all obstruction which may have lodged there. Then the valve in the lower connection should be closed and the valve in the top connection opened for awhile, after which the drain valve should be closed and the valves in both connections opened wide.

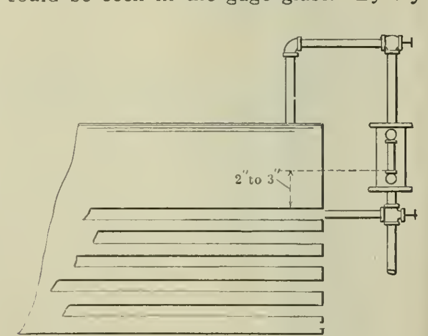
Water columns and gage glasses are often connected up in such a way that as soon as there is no water shown in the gage glass the top row of tubes in a horizontal return-tubular boiler are dry. The proper way to arrange the water column and gage glass is to locate the gage glass fairly high, then as long as water shows in the glass there will be at least 2 to 3 inches over the top row of tubes, as shown in the accompanying sketch.

It is a good plan, when an engineer takes charge of a new plant, for him to find out at the first opportunity how the water column and gage glass are set, in order to determine at what point it is safe to carry the water and to fix the low and high points. He should also find out what condition the water-column connections are in and know if they are clear of obstructions.

Some Causes of Gage Glasses Breaking

Gage glasses often break because the water-gage valves are not in line with each other and when the packing nuts are screwed up tight they bind the glass, causing it to break. The hole in the packing nut may be too small for the diameter of the glass and prevent the glass from expanding. When it gets hot, the hole should be enlarged a little with a file. Air striking the glass in cold weather when a door or window is opened will cause unequal expansion of the glass, which will break it. Where the cold air cannot be prevented I have found that the "Gilbert" gage-glass ring is a good thing to use for the packing nuts of the gage glass.

If the packing rings of a gage glass are in use for a long time they get too hard and there is no cushion to prevent the strain on the glass and it will break. This trouble can be avoided by renewing the packing rings frequently. In steam plants which are in operation only during the daytime it is good practice to close the gage-glass valves at night after shutting down, as the glass is liable to break during the night, and if there is no watchman in the plant there will be trouble in the morning. Some years ago, when I entered the boiler room one morning the room was full of steam. Looking for the cause, I found that one of the gage glasses had broken during the night, and that it must have happened in the early part of the night because most of the steam had been blown out of the boiler and no water could be seen in the gage glass. By try-



SHOWING PROPER HIGHT OF GAGE GLASS

ing the drain cock at the water gage it was found there was water up to this point and there still was water over the top row of tubes. Cold water had to be run into the boiler in order to bring water into the glass again. All the pipe covering in the boiler room on the steam pipes was dripping wet. Had the gage-glass valves been closed the night before all this trouble would have been avoided.

Classification and Uses of Wrenches

A Treatise on the Proper Names, Uses and Abuses of Wrenches in Everyday Practice; Notes on the Screwdriver and a Few General Kinks

BY HUBERT E. COLLINS

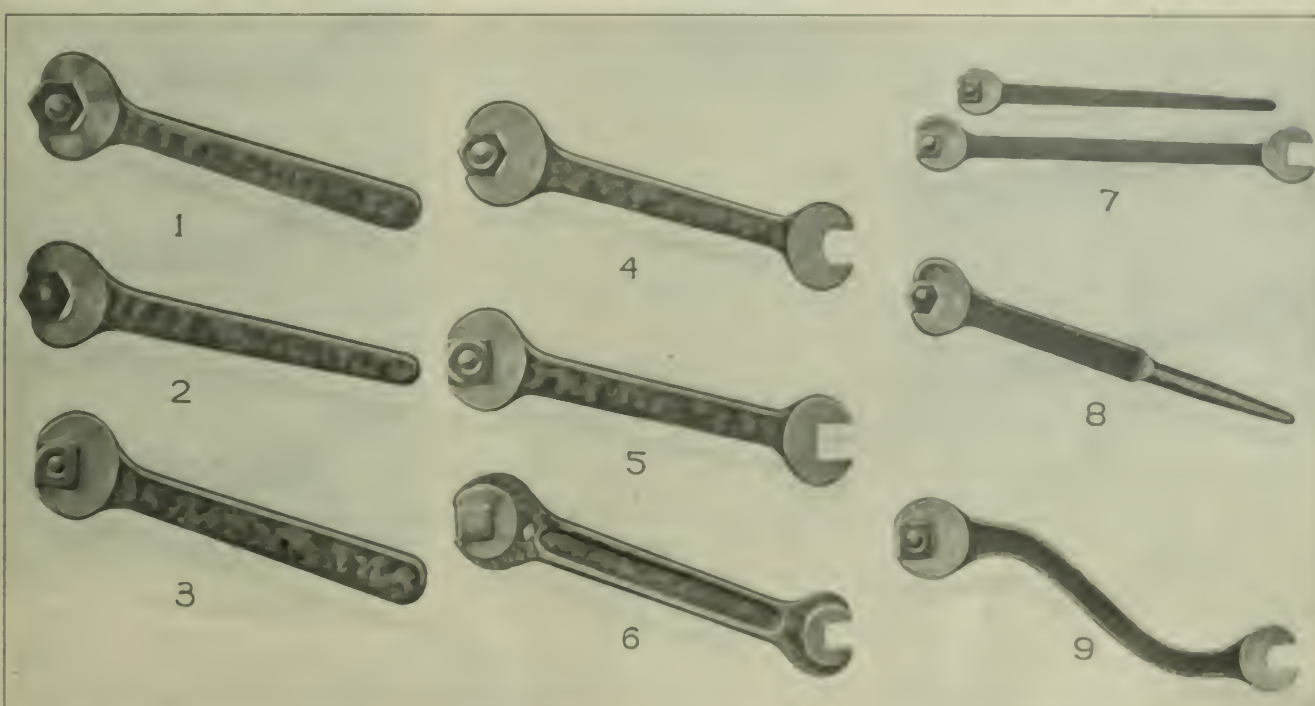
Good machinists understand the proper use of wrenches of every kind and description, and it is only natural that they should, as it is a part of their training. Among engineers with no mechanical training, over 50 per cent. do not know how to properly handle wrenches, and the percentage among steamfitters, firemen, oilers, dynamo attendants and the help generally is nearer 100 than 50. Not only are they ignorant of the proper uses of wrenches, but very few can call them by their proper names. These statements are made after a period of 17 years' observation, and it is believed that they cannot be successfully contradicted.

It is of great importance in the saving of time around a plant to have the men all trained in the use of wrenches, although to many it may seem a trivial matter. In many plants it will be found that there are no wrenches to fit certain nuts or bolt heads. Upon investigation it will be found that when the engine, dynamo, pump, or whatever piece of machinery it is, was installed, a wrench was supplied for the place now requiring its use, but it is either lost or more frequently, through ignorance, it is spoiled so that it cannot be used. For these reasons, it is believed that a talk on this subject should be of value in the engine room, and more especially if proper consideration is given to it. When the reader considers the various types of wrenches here illustrated and the proper uses here explained, it is believed that if he has not the wrench wanted, he can find some way to use what he has or get an idea of how to make the proper wrench for his service.

Classification

Many times in calling for a wrench, the one asked for is not brought, because the man sent for it does not know the names of wrenches and cannot associate in his mind a wrench to fit the name given it, or *vice versa*. This is due to a lack of familiarity with the different types of wrenches and their names. For the purpose of classifying and properly naming, the accompanying illustrations of wrenches are given. Figs. 1 to 9 inclusive, are types of wrenches commonly called solid, open-ended wrenches. They are drop-forged and case-hardened, and are in general use. Fig. 10 is a cut of a special solid, open-ended wrench, as is also the one shown in Fig. 11. Figs. 12 and 13 are types of standard make box wrenches. Figs. 14, 15 and 16 are types of socket wrenches, and Fig. 17 is two views of a socket wrench made for heavy work. Fig. 18 is a box wrench for heavy work. Figs. 19, 20 and 21 are types of spanner wrenches, Fig. 19 being a pin spanner, Fig. 20 a hook spanner, and Fig. 21 a face spanner.

Figs. 22, 23, 24, 25, 26 and 27 are types of strap wrenches, Fig. 28 is the common monkey wrench and Figs. 29, 30 and 31 are types of pipe or Stillson wrenches. Figs. 32 and 33 are types of alligator pipe wrenches, and Fig. 34 is a pair of pipe tongs. Figs. 35 and 36 are two views of a chain pipe wrench or chain wrench, and Fig. 37 is a type of key wrench.



SOLID OPEN-ENDED WRENCHES

The open-end and box wrenches here illustrated are either straight or angle wrenches. Fig. 7 shows two types of straight wrenches, and Figs. 1, 2, 3, 4, 5, 6, 8, 9, 12 and 13 are angle wrenches. These open-end, box and socket wrenches are also single or double headed as shown.

The Various Uses of Wrenches

All types of angle wrenches are for use where a straight or monkey wrench will not reach, the tool held on a nut or bolt

head after starting to set up on or slack the nut. This type of wrench is needed in every plant in places such as the nuts of a cylinder head, flange bolts, engine frames, etc. The angle is the amount the wrench head is offset from the center line of the wrench handle, as shown in Fig. 38, where A is the head of an angle wrench and B the head of a straight wrench. The line CD is the common center line of the two wrench handles. It will be seen that the line EF through the head of A is offset 30 degrees from CD. Many degrees of angle for this offset have been used by manufacturers, but the angles are mostly 15, 30 and 60 degrees for hexagon nuts, and 45 degrees for square nuts.

As angle wrenches are to be used in tight places or close corners, the object is to turn the nut or bolt head just far enough so that the next flats can be caught by the wrench. A hexagon nut must be turned 60 degrees in order that a wrench may catch the next flats, while the wrench remains or is brought back to the first position to start again in the operation of setting up or slacking off. A square nut needs to turn 90 degrees to present a new set of flats to the jaws of a wrench. If there is room enough to turn a hexagon nut 60 degrees or a square nut 90 degrees, a straight open-ended or monkey wrench may serve the purpose as well as an angle wrench, but where closer quarters do not allow of this much play of the wrench, the latter must be offset just enough for it to take hold twice on the same side of the nut in one turning. Then the required pitch or angle of the wrench will be one-fourth of the amount required to turn the other around. For a hexagon nut this would be one-fourth of 60 or 15 degrees, and for a square nut one-fourth of 90 or an offset of 22½ degrees.

Referring to Fig. 38, it will be seen that with the wrench starting at A and moved to B, the nut will be turned 30 degrees, and by turning the wrench over and bringing it back to A, it will engage the nut, and when moved over to B for the second time, the nut will have been turned 60 degrees. By again turning the wrench and bringing it to A, the operation may be repeated and so continued until the work is finished. The same thing applies to the turning of a square nut with a wrench offset 22½ degrees. For this reason, when buying angle

wrenches made to order, do not allow them to be offset more than these amounts.

Box wrenches, shown in Figs. 12, 13 and 18, whether angle or straight, have

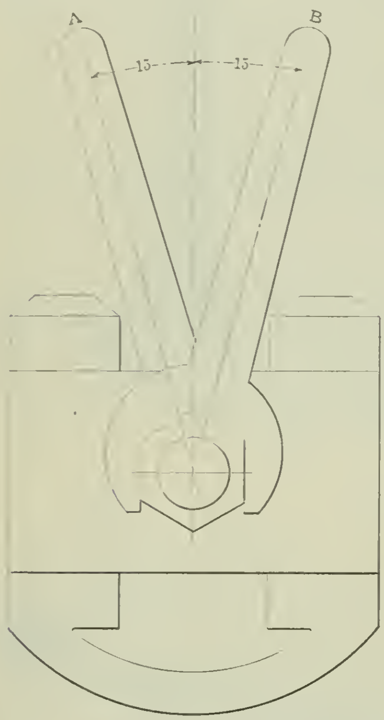

FIG. 39. WRENCH WITH 15-DEGREE OFFSET

many advantages over the open-ended wrench whenever it is possible to use them. The head, fitting all sides of the nut, brings less strain on it, and fitting closer allows it to hold the nut with but little possibility of slipping.

Open-ended wrenches with long leverage, such as those in Figs. 7, 8 and 9, are used on iron work, pipe flanges and other construction work. A good style of wrench for pipe flanges is that shown in Fig. 8. The handle of this wrench can first be used as a drift to bring the bolt holes in line. The wrench shown in Fig. 9 is called an S-wrench because of its shape.

Socket wrenches, such as are shown in Figs. 14, 15 and 16, are used mostly where the bolt heads or nuts are in a recess, as in the case of piston-follower bolts or the screw heads on a universal chuck for a lathe. When socket wrenches are made as in Fig. 17, they are used on the larger sizes of bolt heads or nuts.

Spanner wrenches, like those in Figs. 19 and 20, are used largely on stuffing-box nuts for pumps and small engines. The face spanner, Fig. 21, is a special wrench. One use for it is shown in Fig. 40, where an eccentric, which needs turning around the shaft, is situated between the bearing and flywheel of an engine so close that no other method of grasping it will do. This is only one illustration of its use.

The various types of strap wrenches here shown are to be made for specific purposes, and Figs. 22 to 27, inclusive, offer many suggestions as to type of wrench and places for their use. In Fig. 28 we recognize the familiar monkey wrench, whose uses are many and varied. Owing to the fact that it is easily adjustable to any size of bolt head or nut within its range, it is used more than any other wrench, except for pipe work and in close places. Fig. 37 shows a type of key wrench which also has a wide use. One jaw is slotted to slip over the handle and hold a key *A*. By slacking on the key, the jaws can be adjusted to any size and the key set up so as to hold the jaw rigid.

Figs. 29, 30 and 31 are Stillson or pipe wrenches to be used on pipe and pipe fittings and in some instances on studs. The alligator wrenches in Figs. 32 and 33 are for use on pipe and fittings also, but not for as heavy work as stillsons. The pipe tongs, shown in Fig. 34, are for use on pipe, and more especially on work where there is not much space to operate in. For illustration, in making up pipe coils with manifold headers, the space is so small between the pipes while they are being screwed into place, that a Stillson wrench cannot be used, as the head is too thick. In such an event, the pipe tongs must be called into service. Figs. 35 and 36 show two views of a chain wrench illustrating its application to a difficult job. This style of wrench can be had in small sizes to do the work of a stillson wrench, and with success, but they are used mostly on large pipes and fittings.

Proportions of Wrenches

Manufactured wrenches, whether finished or unfinished in reputable factories, are so proportioned that they will stand all strain brought to bear on them, or that should be put upon the stud or bolt they are used on. The manufacturers have adopted a standard table of proportions in most cases, and where sizes vary from these here given, the variations are in proportion. For example, in the tables given, a wrench is proportioned with a certain thickness of head for a given length of handle or lever. Where tables show a thinner head, the length of handle is shorter. The size of opening in the jaws for the nut or bolt head is the same in all makes of wrenches for nuts and cap-bolt heads. The wrenches for standard finished nuts are larger in the openings than for cap bolts.

For comparison of sizes refer to Tables 1, 2 and 3. Table 1 gives the sizes for engineers' wrenches, single head, as illus-

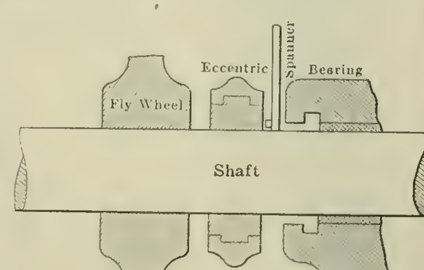

FIG. 40. FACE SPANNER TURNING ECCENTRIC ON SHAFT

trated in Fig. 2; Table 2 the sizes for engineers' wrenches, double head, as illustrated in Fig. 7, and Table 3 the sizes for cap-bolt wrenches, single head, the appearance of which is the same as Fig. 2. Table 4 gives the principal dimensions of socket wrenches, such as are shown in Fig. 16, and is also of use when recesses for bolt heads are to be provided for in castings.

Where wrenches are not easily obtainable and a blacksmith can be found to make some, these tables are of value for the proper proportioning of a wrench for strength and for a fit to standard sized nuts and bolts. For additional information regarding other dimensions of wrenches, refer to Table 5, in which it will be noted that the heads are thinner and the levers shorter than in Tables 1 and 2, but are of the same proportion.

Size of Wrench with Reference to Size of Nut

When the size of a solid wrench is spoken of, the reference is made to the wrench which will fit a nut or head for the given size of bolt. For example, if a ¼ inch engineer's wrench is called for to use on a finished nut, it means a wrench for that size of nut, or on referring to Table 1 to an ¼ inch bolt, it will be noted that the opening in the head for that size is ½ inch between the jaws. If an ¼ inch cap-bolt wrench is called for, the opening will be 7/16 inch, as shown in Table 3. This point is brought out for the reason that many times a helper is sent for a certain size of wrench, and is found measuring all the wrenches for one with the opening the size called for, instead of one to accommodate the nut size.

For the purpose of becoming familiar with the sizes of nuts for a given tap size, and for use in finding the sizes of drills to be used in drilling for a given size of tap, also to show the strain a bolt of given size will stand, Table 6 is compiled. The sizes for unfinished nuts are not given, but it is well to know that an unfinished nut is 1/16 inch thicker and wider from side to side than a finished nut. A finished nut is 1/16 inch thinner than the bolt sizes.

Proper and Improper Uses of Wrenches

Monkey wrenches of all makes have the general appearance shown in Fig. 18, and it must be said that there is no wrench in existence more misused than this type. They are designed for use by hand on the nuts that they will take, and will stand all work put on them with the hands only, giving good service if they are always applied in the proper manner. Invariably on calling for a monkey wrench, one is brought out looking very much like Fig. 21, with the jaws at an angle with each other when closed, instead of being parallel, as they should be. This condition is caused by abuse in the use of the wrench, principally through ignorance.

When the monkey wrench is applied as shown in Fig. 20, there will be no difficulty about it doing its work. When the nut is to be turned in the direction shown by the arrow, the wrench must always be applied as shown. Not only must the wrench be applied in the right direction, but it must come down full on the nut as far as it will go, the reason being that the force which tends to break the wrench or bend the jaws into the shape of Fig. 41 is along the line *A*, Fig. 42, and with the wrench clear down the leverage is reduced to a minimum.

In Fig. 43 it will be seen that the line *A* is increased by not letting the wrench down on the nut, although the jaws are closed up tight on the nut. Fig. 44 shows line *A* not greatly increased, but through the loose adjustment of the jaws the corners of the nut get a greater purchase on the wrench and tend to push the jaws apart more forcibly. In Fig. 45 the two forces which tend to ruin the wrench have the best opportunity on account of the poor adjustment of the width between the jaws and the wrench resting high up on the nut.

These are common faults in the use of monkey wrenches, but the abuse most common is illustrated in Fig. 46, which shows the wrench upside down. As soon as the force is applied in the direction of the arrow, the outside jaw takes hold of the nut at *B* and line *A* is increased at once. This is positively a case where there is only one way that is right, and any other is wrong. Not only can wrenches be saved by applying them as in Fig. 42, but many skinned knuckles and mashed fingers might have been prevented, and of more importance, considerable time saved. When a monkey wrench cannot be applied to its work properly, some other type of wrench should be used.

Another infallible rule for the right use of a monkey wrench, is to never use a piece of pipe over the handle to increase the leverage. Nor is it right to strike on one of these wrenches with a hammer. Most of the ruined handles on monkey wrenches come from these two sources.

All types of wrenches should be used with care and precision, and should always be placed squarely on the nut and made to fit it snugly. With socket wrenches it is often impossible to use them unless they are held squarely and snugly to the work. Pipefitters often handle Stillson wrenches in a manner destined to ruin the pipe. In screwing up or slacking off on a pipe, always catch the wrench as close up to the thread as possible. Many cases of split pipe have been attributed to the wrench being held at the middle of its length, allowing the pipe to twist under the heavy strain and split the seam.

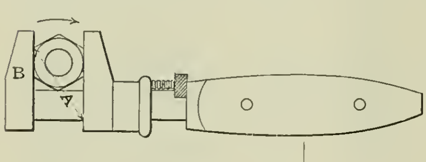

FIG. 46

METHODS OF APPLYING MONKEY WRENCH

Another source of trouble with Stillson wrenches originates from constantly taking hold of the pipe in the same place. When many hard pulls are necessary to set up, the result is a pipe cut through in places. The proper thing to do in taking holds is to move the wrench along the length a little and back again, so that the teeth of the wrench will not grip twice in the same place. A Stillson wrench should also be set down on its work, so that the jaws will take hold with the work well up in them. There is one thing which limits this, however, and that is the amount of pull which the hold must stand. The stronger the pull, the farther up on the work the jaws must be in order for the teeth to take hold. For this reason also, when making a hard pull, it is not advisable to use a very large wrench on small pipe, as the larger teeth may cut through the pipe or crush it.

A Stillson wrench is not so liable to crush pipe as a pipe tongs, and for this reason the former is the best to use. It is best to use a chain wrench on the larger sizes of pipe, discarding the Stillson for sizes over 3 inches. Never use a Stillson on a bolt head, nut, stud or finished work, as there is always a way in which these may be handled with standard or special wrenches.

Kinks

Oftentimes it is necessary to loosen up nuts on bolts which have rusted on. If time is allowed to do so, it will help much to pour kerosene oil over the nut and

allow it to loosen up the rust. If the kerosene will not loosen up the rust enough, then take a hammer and strike the nut sharply on all sides. To do this properly, hold another hammer squarely against the nut on the opposite side. This will loosen up badly rusted nuts, but if it does not do the work, then more kerosene will be needed.

FIG. 47. TIN COVERED TAP TO ENLARGE NUT

When Necessary, Split the Nut

Sometimes a loosened nut will start off and again stick before entirely off. This is caused by the thread of the nut or bolt stripping, and if continued, will ruin one or the other. More often it is the bolt or stud which suffers, and the only way to save them is to split the nut apart. To do this, take a flat chisel and cut into one side, opening the nut up from top to bottom through the center of one flat. Hold a heavy hammer or piece of iron against the nut on the side opposite while doing the cutting.

On pipe flanges it is often cheaper to split all the nuts that are rusted in than to work to get them off with a wrench, providing plenty of spare nuts are available. If this is done, the bolts should be given a bath in kerosene before being used again.

When Nut and Bolt Do not Fit

In some cases nuts will not go on bolts or studs because the nut is tapped a little small or the thread on the bolt is too large. More often it is the latter, and the thread on the bolt should be made smaller to fit the nut, so as to keep the nuts of uniform size. When time, circumstances or material will not allow of the thread being turned down on the bolt, and a tap of the right size is to be had, the nut may be tapped larger as follows:

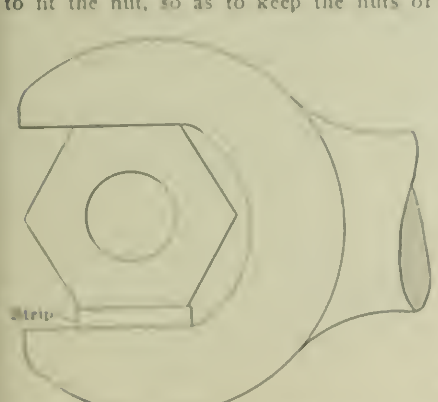

FIG. 48. WRENCH TOO LARGE FOR NUT

Cut into a strip of tin of the right width and length and bend it into the shape shown at *A*, Fig. 47, and just wide enough to cover one set of threads on the tap and long enough to reach over the ends of the threads, as shown. Enter the tap into the nut with this tin over the threads, and the threads in the nut will be enlarged. Some difficulty may be experienced in starting the tap through the nut, but after starting it, it will follow through all right. Use the first tap of a set for this, or as it is called, the taper tap.

Fitting Wrench to Bolt Head

When a wrench does not fit a nut or bolt head (the wrench being too large) and no other is to be had, it is permissible to use a strip of iron, steel or any other metal substance handy to fill up the space between the jaws, as illustrated in Fig. 48. For convenience of handling, the strip can be longer than shown.

Turning a Stud

A great many do not know how to readily remove a stud from its place, when necessary, with the tools at hand. Fig. 49 illustrates how two nuts may be locked together on a stud to withdraw it. If the length of the thread will permit, run two full nuts down on the stud, with the two flat sides of the nuts coming together. Take the two wrenches, as shown in the plan, and pull them together. Note the angle at which the top and bottom wrenches are held in this figure, for if the respective wrenches were held at the same angle and changed, No. 2 to the bottom and No. 1 to the top, the pull together in the direction of the arrows would have the effect of loosening the nuts. The rule of operation is, that while facing the nuts, take wrench No. 2 in the right hand and place it on the top nut and wrench No. 1 in the left hand and place it on the bottom nut at the angles shown or anywhere under the line *A B* down to *C D*. To lock the nuts, pull the wrenches together, and to loosen them, change the top wrench to the bottom, and *vice versa*, and pull them together. There are several other ways of using the wrenches to attain these ends, and in some instances other ways must be found, but this manner of doing it allows the operator to get the strongest pull either while tightening up or slacking off.

To get the greatest purchase on the nuts, place the wrenches at an acute angle from each other, say along the lines *F* and *G*, respectively, while still standing in the same position. After the nuts are locked, if it is intended to take the stud out, take one wrench and use it on the bottom nut to back out a right-hand thread, and if the stud is to be driven in, use the one wrench on the top nut.

Where a great many studs are to be driven home to stay, a stud driver, such as is shown in Fig. 50, can be used. It can be made from a special nut drilled and tapped half-way through its length, and is run down on the thread until the stud bottoms in the nut. When the stud is driven as far as it will go, remove the stud driver by giving it a quick, strong twist with the wrench, in the opposite direction to that followed while driving the stud.

FIG. 50. STUD DRIVER

Increasing the Leverage of a Wrench

It is often desirable to increase the leverage of an ordinary engineer's wrench, and the practice of permissible under certain conditions. Never use a hammer on the handle, as it ruins it. If a sharp blow is required, use some form of a soft hammer, or use a block of hard wood for a ram. It is still better to make a handle of pipe sufficiently long to give the desired leverage. Flatten one end of

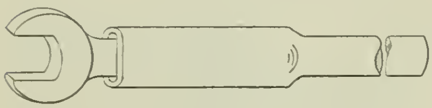

FIG. 51. INCREASING THE LEVERAGE

the pipe to fit over the wrench handle, running the flat back far enough to allow the handle to be run in up to the head, as shown in Fig. 51. It must be remembered that there is a limit to the size of bolt or stud on which it is advisable to use a longer leverage on the handle of the wrench than the makers have allowed for. Bolts up to and including ⅞ inch in diameter can be twisted off with an ordinary wrench and a muscular operator, so that pipe handles are not to be tolerated on any size smaller than that.

Pulling up Joints

All joints should be pulled up square and even all around from start to finish, especially where a metal joint is used. Dirt being left on joint surfaces often causes leaks, because the two cannot be brought evenly together, and just as often the leak is caused by the uneven strain on the bolts. Take, for example, the cylinder head shown in Fig. 52, which has a shoulder all around the inside of the flange. It will be seen that by pulling on one nut first, the head could be tipped out of true, and only one edge of the shoul-

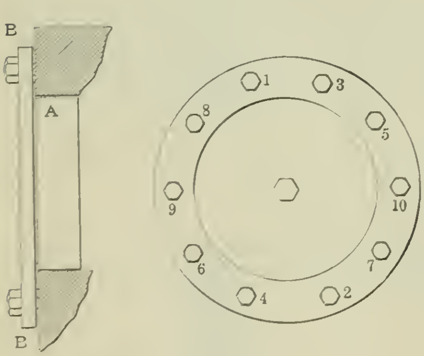

FIG. 52. TIGHTENING UP A CYLINDER HEAD

der joint would touch. When first starting to set up on the nuts, a good method to follow is to set up on No. 1 nut lightly until the surfaces of the joint meet, then take up the same on No. 2 nut opposite to No. 1, then Nos. 3 and 4 in succession, after which the nuts can be taken up the same amount in the order given. Then go over them all again in the same order until the joint is tight. The space *B* will be equal all around if the pulling up has been properly done. This rule applies equally well on all joints, taking any nut for No. 1 and making No. 2 come opposite. Some bolt circles are divided as in Fig. 53, where one nut will be on the center line *A B* and opposite to it the nuts will straddle, perhaps not just as shown in the illustration, but similar. In this event, take up on the nuts in rotation, as indicated by the figures.

Screwdrivers

A screwdriver with a wedge-shaped head which fits the slot of the screw, as at *A*, Fig. 54, is a type which never should be used, and yet is universally sold by manufacturers and used in that form. It is plain that this form of screwdriver never fits the slot in the screw head and takes as much force to hold the driver in place as it does to drive the screw. Another fault is that it puts a strain on the screw head where the power which tends to break it apart is greatest. When the head of the screwdriver is ground so that it takes hold of the screw head in the bottom of the slot, as at *B*, Fig. 54, the strain on the screw head is at a minimum, and the power of the operator is all spent in driving the screw alone. All screwdriver heads should be made as shown at *B*, Fig. 54.

In some cases it is impossible to use ordinary screwdrivers, owing to the cramped space, and the driving force must be applied at right angles to the driving line. Fig. 55, *A* and *B*, show views of two screwdrivers which are useful in such cases. It can be seen that with *A* the screw head can be moved one-fourth of a turn and be picked up with *B* and turned another quarter, when *A* can be used again and so alternately until the work is done.

Things in General

On very large nuts or bolt heads it is necessary to use more than a straight pull. A sharp blow with a hammer often starts an obstinate hold, where a straight pull would not. It is not advisable only in extreme cases to use the hammer on the wrench, but a hardwood block will do as well. In extreme cases a steady pull aided with blows of a ram will do the work. Very extreme cases call for the use of a block and fall on the end of a large wrench and a ram in addition. An aid to the wrench on large sizes of nut, when it is desired to have the nuts extra tight, is to heat the bolts before they are put in place. To do this properly, heat the bolts midway of their length to a dull red, and then place them in position and set up on the nut quickly. The contraction of the bolt will make the nut hold more tightly than a wrench can set it, if the job is done quickly and in a proper manner.

The use of a hammer and chisel on nuts and bolts in place of a wrench is not to be condoned in general practice, for it puts the nuts forever beyond the possibility of using a wrench on them. There are times and places where a wrench cannot be had, and a hammer and chisel must be used. When this is necessary, use a calking chisel or drift so as to spare the nut as much as possible. Then have a suitable wrench made. The illustrations will offer suggestions to fit any case.

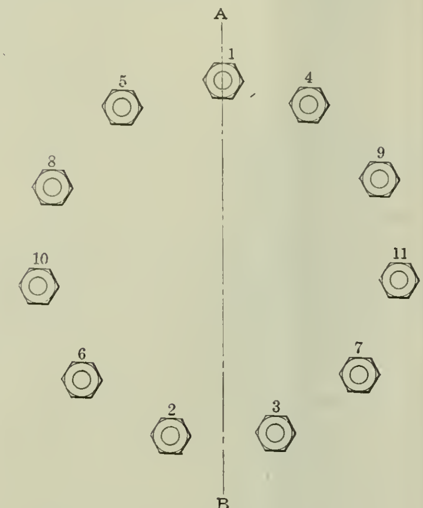

FIG. 53. TIGHTEN NUTS IN ROTATION

Several years ago in one of our Western Indian agencies there was employed an old man called Uncle Bill by the rest of the Government employees. He was a good mechanic of the old school and was often called on to loan his monkey wrench to others. He would do so once, and the borrower could have it again if he showed that he could follow Bill's instructions as to its proper use. If not, and they failed to apply the wrench rightly to its work, they need never ask again for the loan of it. He was right, for he had no wrenches

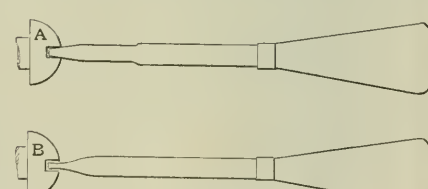

FIG. 54

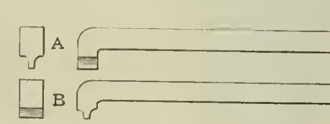

FIG. 55

FORMS OF SCREWDRIVER

to spare, and this article may serve to enlighten the reader as to the reasons why.

Niagara river develops 8,500,000 continuous horsepower. If two pounds of coal were burned per horsepower per hour, the hourly amount necessary to equal the work of Niagara river would be 8500 tons. Continuous work for a year would require over 74,000,000 tons of coal.

An Early American Engineer—Robert Erskine

Sketch of the Life and Activities of One of the Men Who, in Colonial Times, Did Much to Advance Engineering in Many Departments

BY EDWARD P. BUFFET

Among the men of note in our colonial days were few who could be called "engineers" in any sense of the word. Robert Erskine deserves that appellation in many senses. He made his mark as a civil, an hydraulic, a mining and a military engineer, a mathematician, a metallurgist and a first-class works manager. There is a strong hint that he was also something of a steam engineer.

The same old Scottish city—Dunfermline—which furnished our most successful industrial leader of the nineteenth century supplied one who is entitled to almost an equal rank for the eighteenth. As a Scottish ironmaster on American soil, Robert Erskine might be called the Carnegie of the colonies. He differed from Carnegie in being more of an engineer and less of a financier.

His active career was divided between the old and new countries. In the former he established his reputation as inventor of pumps, machine designer and consulting engineer, while in the latter he closed his career as an industrial executive, intrusted with interests of great responsibility.

In the library of the New Jersey Historical Society have been on file for nearly half a century the venerable documentary records of his work—portfolios of family and other letters relating to his early life; numerous manuscripts describing his inventions and their exploitation, with sketches and wash drawings, a dissertation on the tides, account books of the American works, and a volume in which his own epistles concerning their administration are laboriously copied out. There are also many pages written in cryptic characters which may be either shorthand or cipher. The mass of material, if edited with discriminating selection, would form an interesting volume. It is curious that among his sketches, although a century and a half have told upon the tint of the ink lines, the pencil marks remain perennially fresh. Very few of these documents have yet been published, though a few extracts were given by Rev. Dr. Tuttle, a famous local historian by whom the papers were secured for the society.

Robert Erskine was born September 7, 1735, his father being the Rev. Ralph Erskine, minister at Dunfermline, a man of sufficient note to find a place in encyclopedias down to the present day. Ralph's title to fame was acquired by founding, with his brother, Ebenezer, a free branch of the Scottish kirk and in being the author of several books, including a volume of "Gospel Sonnets." A copy of the latter was long ago exhumed by the writer of this memoir in a nook of an old house on Long Island. It was a ninth edition, Glasgow imprint of 1760, and contained, apart from the body of the book, a poem of uncertain authorship, entitled, "Smoking Spiritualized." The verses inculcate a number of edifying lessons that may be drawn from the pipe, its contents and its use.

Robert Erskine's father died in 1752, when the lad was 17. The youth evidently received a collegiate education, or its equivalent, for we find him in London in the sixties, well grounded in scientific knowledge and casting about after opportunities to make it useful. The following letter from his mother indicates that he had his eye on a place in the faculty of Glasgow University:

Dear Robbie—I received yours the [illegible] day. I write to you this day eight days with a shipmasters receipt for a box to you with some linnings which you have got by this time. I shall be very glad that I am in a mistake about your being obliged to be present as a candidat for ye vacancy at Glasgow it was the opinion of your Brother and many others that you should be present but if it is needless it may be they may cause you yet for to be sure the professerie is not pleased with that Buchannan but is like as ye *D* of Argyl is hear he will oblige them to take him fit or unfit if he serves his turn I think you have got a sufficiant swack of his Grace as I hope you will expect no favours from him it would be a great mercy if you could think of doing something hear for I am afrayd you will get some offers to go to Jemeky Gebrallter or some of the colonies abroad which would be very disagreeable to me.

GRAVES OF ERSKINE (ON THE RIGHT) AND [illegible]

It appears that a professorship of mathematics, or some such branch, was suggested to him as a natural opportunity, but although he possessed the theoretical mastery of a university specialist, he had also the instincts of a practical engineer. His ultimate triumphs must have been reached through struggle and vicissitude, and there is ample evidence of the financial embarrassments to which he was at one time subjected.

Among the inventions that Erskine developed as practical machines, was a "centrifugal engine," or rather pump, very simple in principle. If, as he shows, we have a pipe not too long for suction and shaped as an inverted L, the lower end being immersed in water, and if after having started a stream flowing, we continue to revolve the pipe with sufficient speed about its vertical axis, the centrifugal force of the water in the arm will produce a continuous flow. The top part may, if desired, be made in hollow disk form, with

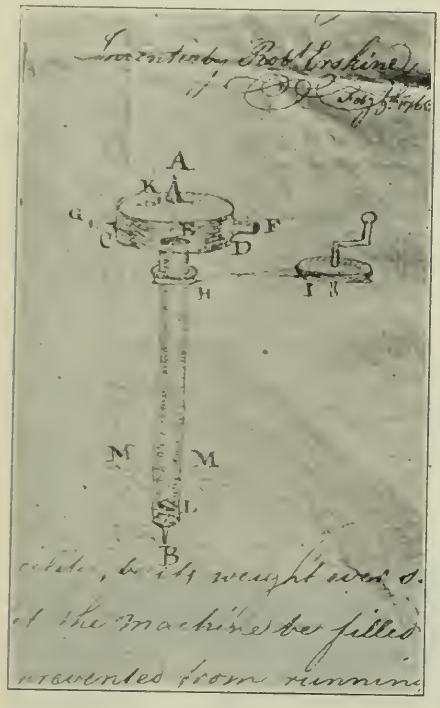

FIG. 1. PRINCIPLE OF THE "CENTRIFUGAL ENGINE" PUMP

several orifices, but their total cross-section should be less than that of the inlet pipe. The mechanical development of this conception was easy. Obviously the device possessed advantages as a pump through minimizing the number of moving parts and reducing frictional losses. The Erskine papers contain several sketches of this pump whether in its most elementary form or put into more marketable shape. Fig. 1 is a drawing that appears on a sheet bearing date February 9, 1763, the time of the writing or of the invention.

This centrifugal pump was offered as a competitor of the chain pump for bailing out ships, which led to a pumping of the ink bottle by their respective protagonists. Disputes over the features of a machine were waged in print 140 years ago quite after the modern fashion, but since specialized engineering papers like POWER did not then exist, the general press served as a forum for the discussion.

A correspondent of the *Gazetteer*, signing himself "W. B.," had atacked the centrifugal pump in favor of the chain pump, for we find among the Erskine manuscripts drafts of a letter to the printer of that newspaper in rejoinder, taking to task "W. B." for having "endeavored to impose on the *ignorant*." One such document is signed with Erskine's name, and another somewhat differently worded, with the disinterested *nom de plume* "Mechanicus." It does not appear which he employed in the letter as finally sent off.

He opened his defense with a remark that the invention had been suggested by a problem which one of the *Gazetteer's* own correspondents had proposed, viz., "contrive a method to make the siphon run out of the shorter end by means of an air pump." Erskine stated that one of the machines might be seen at Mr. Coles', near St. Thomas' Coffeehouse, on the Strand, and proceeded to describe it. With such a pump six men could raise 2 tons of water a minute at least 20 feet. The delivery increased faster than in proportion to the power applied. The radius of the ejecting tubes of the present engine, designed for a 60-gun ship, was 4 feet. He went on to compare the velocities of motion of the centrifugal and chain pumps under practical conditions of operation and to demonstrate that "W. B." had assumed for the operation of the chain pump feats of sustained human activity quite unreasonable to expect. Further, he pointed out that his own machine possessed advantages in its simplicity, high mechanical efficiency and freedom from liability to injury by anything less than a cannon ball.

Fumbling further among the old documents we come across a copy of a certificate by a committee to a comparative test of these two types of pump on board H. M. S., "Princess Mary," at Woolwich, 1766. The chain pump was in exceedingly good order. Ten stout men were allowed to each. Erskine's raised, in ten minutes, 14¾ tons of water, and the chain pump 11½ tons.

The Mr. Coles, to whom reference has been made was the builder of Erskine's pumps. The documents contain proof of extensive dealings between them, some of which were not altogether harmonious. One of the papers is an award of arbitration in a dispute with the result that Mr. Coles was not to make any of certain machines for 12 years. Another of Erskine's memoranda is a permit to certain men to build a machine for their own use in consideration of making one for him within a definite time.

Another of Mr. Erskine's inventions was a "continuous stream pump," which was an ordinary double-acting one in principle, though having an external contour that suggests the pulsometer. (Does Erskine pose as originator of the duplex pump?) Fig. 2 is a sketch of it, while Fig. 3, is an illustrated circular or data sheet relating to a form of it as constructed for domestic uses.

The drawing, Fig. 2, appears in a letter by Erskine to Mr. Watthews, or Matthews, watchmaker, on Fleet street, February 11, 1766, which concludes by describing methods of raising water where there is a fall. He writes:

> If the situation of the place is such that the hight from the surface water to the back level is *greater* than from the back level to the bottom from whence the water is raised, if this is the case there is a method of raising the water from the bottom to the back level [bv] the force of the surface water (if the back level is but a few feet lower than the middle of the pit) without any machinery at all and the same quantity of water that runs down from the surface can be made to flow up from the bottom, it will only require the attendance of a boy to turn the cocks and I suppose will last some centuries. It is called Hero's fountain. I have seen it described with four cocks and some valves, but could improve it to want only two cocks and by a little study and some few experiments I believe I could make it work without any attendance at all . . . . P. S. I.

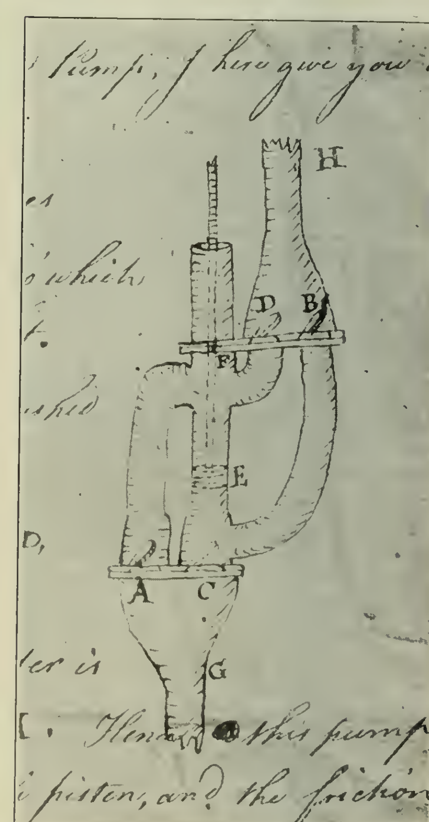

FIG. 2. "CONTINUOUS-STREAM" PUMP

> never undertake to design and give a drawing of any machine for less than five guineas.

The foregoing device was manifestly intended to perform some such task as is now done by the hydraulic ram. Some of Erskine's papers are filled with his study over a device which he terms a "quadruple Hero's fountain," by means of which he sought, "with a fall of 6 feet to raise 1/6 of the whole stream." The stream was divided among five troughs, each of which communicated with five vessels, all except one or both at the ends being air tight. Below them were five other cells piped from near their bottoms to the bottoms of the ones directly above and also piped from their tops to the upper parts of the ones above next adjacent on the left. (The reader may from this description draw his own diagram.) By this means the pressures could be accumulated from right to left so that in the upper vessel farthest to the left the water would rise 24 feet, 20 feet of which was lift. The

Prussia. Lists of installations seem to show that his machines had considerable vogue.

Robert Erskine's hydraulic proficiency must have been a valuable asset for him when, as we shall shortly learn, he came to America, for the development of water powers in northern New Jersey and southern New York was carried on extensively during colonial days. The damming of streams and collection of water in large reservoirs was then resorted to for power purposes on a scale second only to modern undertakings in the same region to supply cities with water. Furthermore, it was

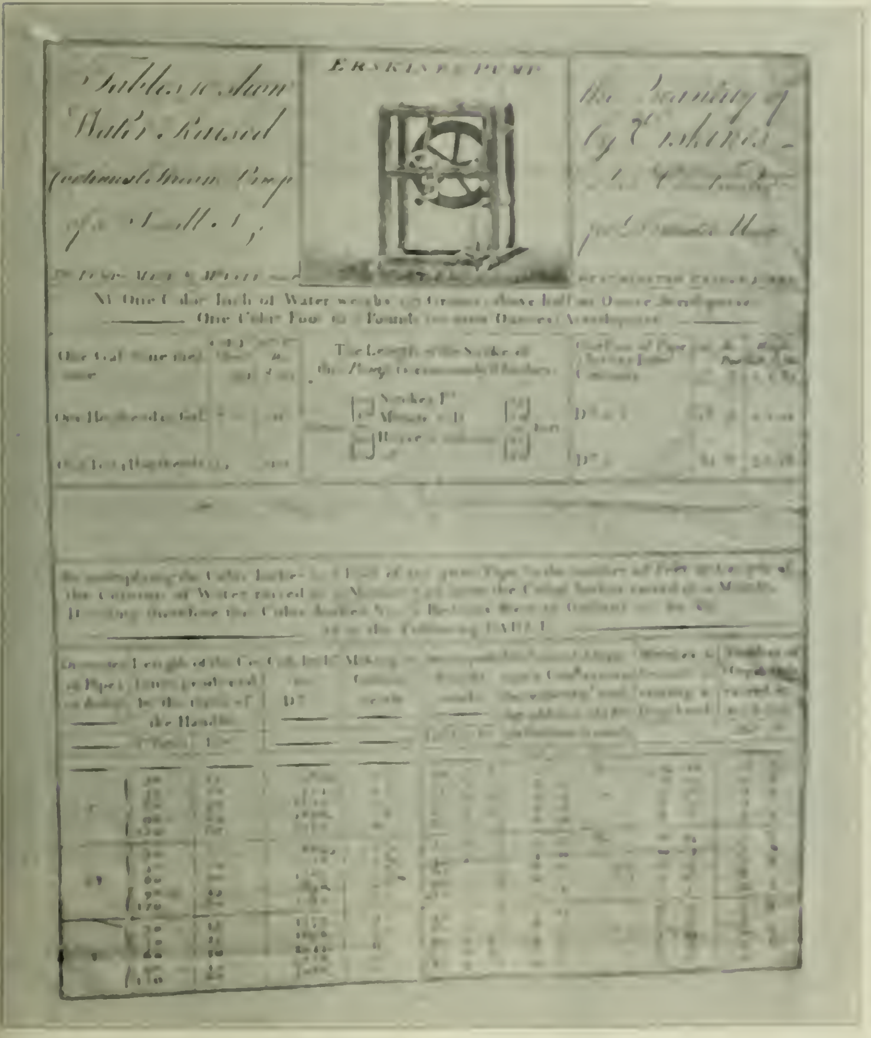

FIG. 3. DATA SHEET OF "CONTINUOUS-STREAM" PUMP

biographer assumes no responsibility for a complete explanation of the details of the machine, nor for its performance according to contract.

Altogether, Mr. Erskine's pumps displayed considerable variety in type and purpose, and in motive power, which might be hand, horse or hydraulic. Characteristic of his engineering activity was the design of plants to meet particular conditions of raising water on gentlemen's estates. Draining mines was another utility. Among orders received by 1765 was one for a large centrifugal engine (pump) to be used in salt works of the king of

a priori requisite of a mine operator that he should know how to handle pumps.

But Erskine's ingenuity was not confined to hydraulics. He invented a horizontal windmill and a conduit [illegible]. The [illegible] drawings [illegible] designs of [illegible] or mathematical instruments [illegible]. His [illegible] is suggested by a letter to the London Chronicle on [illegible]. His [illegible] is shown by the fact that he was made a fellow of the Royal Society. Whatever may have been, or failed to be, the financial [illegible] of his technical skill, he won a high reputation for integrity and ability, as is proved by

the enterprise for a position of great responsibility on the continent. He was engaged, about 1770, to go to America and retrieve the failing fortunes of an iron trust. His salary was to be £250 a year, with sundry additional allowances.

The New York and New Jersey Iron Works, American Company, or London Company, as variously called, was a British concern possessing industrial interests to the value of nearly a quarter of a million dollars at Ringwood, Long pond (now Greenwood lake), and Charlottenburg, N. J., and Cortlandt Furnace, N. Y. The plant that figures most prominently was that of Ringwood, within the limits of the present Passaic county, N. J., close to the New York line. The nucleus of the industrial estate had been established by the Ogdens, a famous New Jersey ironmaster family, who had purchased the land in 1740 and sold out in 1764 to the London company, organized by an alert German, Baron Peter Hasenclever, one of the most distinguished colonial ironmakers. He [illegible] a [illegible] of stock [illegible], to which both gentlemen and ladies of high station in England subscribed, and brought over 535 persons from Germany as a laboring population. There were some 75 square miles or more of territory comprised in the undertaking. Energetically he set about enlarging the plants. By the end of a couple of years they were equipped with four [illegible] furnaces, a [illegible] and pearl-ash manufactory (on the Mohawk river), 235 workshops, stores and dwelling houses, dams for 15 mill-ponds and 15 bridges, with many miles of roads. One of his dams was [illegible] feet long and 12 feet high. But the same story, as with American manufactures, [illegible] works failed to pay, and about 1769 he went into bankruptcy, partly at least, through the misconduct of a partner. He [illegible] was lasting some years. Hasenclever received [illegible] or less vindication of his conduct. Though adventurous, he was a sincere and [illegible] man and, according to the best information, he afterward became a successful linen manufacturer in Silesia. In the management of the American business he was succeeded by John Jacob Faesch, a German, whom he had brought over, and under whom the works remained unprofitable. Hasenclever's bankruptcy does not seem to have destroyed the company, since the document that employed Erskine [illegible], at this time, in controversy with Hasenclever. Erskine used his correspondence with much [illegible] against both Hasenclever and Faesch, and he did [illegible] to [illegible] Faesch as [illegible]. Though [illegible] on this [illegible], he is open to [illegible] of [illegible]. Faesch remained in the [illegible] as [illegible] with [illegible], and he died with a character highly esteemed.

After Erskine had held the management for a few months, he was asked to report on the advisability of selling the works at a sacrifice. His advice, though given with caution, was adverse to such a project. "I am but a taming the Forgemen," he wrote, "though there are several ways in which your expenses may be lessened and your profits increased." He alluded moreover to his intention of trying the sulphury ore in the furnace and to his belief that another body of ore might be found near Charlotteburg. Manifestly, his counsel to hold the works prevailed.

After taking charge, Mr. Erskine adopted the plan of writing long letters to the company or interested individuals at home describing the state in which he found things and the methods of his management. Some letters he regarded as of so confidential a nature that he felt it necessary to write and copy them with his own hand, which he esteemed quite a burden. Today a correspondence equal in magnitude and importance would be dictated to a stenographer or a phonograph between puffs of a cigar.

These reports make an interesting picture of so multifarious an industry as a large ironworks of colonial times. It was a little self-sufficient world, utilizing the products of the soil in many different ways, with a systematic division of labor. In his control of ore and fuel supplies, transportation facilities, etc., Erskine was a primitive Carnegie. He was not, however, like Carnegie, at liberty to work up his pig and bar iron into finished products. If his company had announced the erection of a steel furnace or of a rolling mill beside Long pond, such as, upon a memorable occasion, Carnegie proposed to build at Conneaut, by Lake Erie, the concern would not have been bought out by its competitors with 5 per cent. first mortgage bonds, but would have fallen into the clutches of the law. For the policy of the British government was to reserve the manufacture of finished iron materials as a home monopoly against the colonists, by a principle much like that which the United States follows in some of its dealings with the Philippine islands. A parliamentary act of 1750 had forbidden the erection in America of any new steel furnace or rolling or slitting mill, etc. After that, none could be put up unless to operate by the moonshine method, like the slitting mill of Samuel Ogden, at Old Boonton, which, it is said, ran under the innocent guise of a grist mill.

"The concerns of the company for which I am engaged," wrote Erskine to one of his correspondents, "are very great. The amount of their inventories at New Year in iron, goods, cattle and movables alone was upward of £30,000 currency; the annual circulation of cash and supplies is between £20,000 and £30,000. . . . . I have eight clerks, about as many overseers, forgemen, founders, colliers, wood cutters, carters and laborers to the amount of five or six hundred."

"I design to follow," he remarked, in beginning a report to the proprietors, "the natural order of things as they arise. Wood, Charcoal and Ore are the First in Course the furnace, its Construction and appurtenances, the Roasting, mixing and smelting of ore into pig metal come next, together with a variety of other articles which may occur during (the time when the furnaces) are in Blast, then come the forges with all their connections, which will include the processes of the Manufactory of Bar Iron faults improvements. etc. Provisions and necessaries, Farms, Horses, Cattle, Carriages, Roads, Mills, Dams, Houses, etc., must follow."

Among other subjects requiring discussion were his system of bookkeeping and his relations with labor. He outlines the various time- and piece-work methods by which are paid the different sorts of workman—carters, blacksmiths, coalstockers, furnace fillers, founders, miners, forgemen, managers, clerks, overseers. The lower grade he has found hopelessly in debt to the company store, and describes how he has won the gratitude of some carters by raising their wages £5 a year to a total of £60. The company, he suggests, would better have contented employees than a deceptive balance in its favor, and from other quarters than pinching the hard-earned wages of the laborer he is sure the proprietors would wish their profits to arise. Yet he favorably contrasts the lot of even the poorest with that of their equals in Scotland and Ireland. The necessities of the cheaper workmen keep them bound to the company stores, but the more highly paid, such as the forgemen, do better by purchasing provisions from neighboring farmers. The company itself obtains supplies from these farmers and Erskine denounces their extortion in demanding New York prices for their produce.

"Faesch gave me all the trouble he could," wrote Erskine somewhat later. "The founder at Charlotteburg almost overset [?] the furnace (to appearance on purpose) for which I put him in jail till he found security to answer an action of £200 damages I brought against him. He [Faesch?] decoyed away some of our Forgemen too, to work in some forges adjacent to his furnace which they hired and most of the poor Creatures have been kept without work at the top of all the money they earned at your work, and are now come and earning again very thankful to be employed and will make the better hands than ever."

"The last time I was in Charlotteburg," remarked Erskine in one of his letters, "a bar of iron was tried on purpose to see how many strokes it would take to break it, when it bore above fifty blows of a sledge hammer upon an anvil before it gave way." Again, he is gratified to note that his iron has acquired among the country blacksmiths a reputation for being "plaguy tough." Iron from Charlotteburg, after trial, was marked cold with a star of five rays, from Ringwood with one of six and from Long pond with one of seven.

Fame has fastened upon the steam engine erected at the Schuyler copper mine, near the Passaic river, New Jersey, by Josiah Hornblower, 1753-55, as the first one installed in America. It would appear that Erskine imported engines only a few years later, since in a letter which he must have penned early in 1772 he states: "I hope the Fire Engines are finished and on the way which I mentioned last autumn." "Fire engines," as we should be aware, meant, in that day, steam engines. It is not to be inferred that Erskine ceased to depend chiefly on water power to drive his blowers and other machinery. Doubtless his engines were intended for pumping mines at a distance from any stream.

The term "fire engine," however, was also applied in the modern sense, to pumps for extinguishing fire. In that day they were, of course, driven by hand power. As long ago as 1719, the city of Philadelphia paid "for ye ffire engine." It is entirely possible that the machines imported by Erskine were intended to check the spread of conflagrations in the numerous buildings of his works. Whether they were of this sort or were truly steam engines, may be left as one of the great unanswered riddles of history.

It is significant to peruse Mr. Erskine's letters to his employers as noises of the awakening insurrection of the colonies began to be heard and until correspondence was broken off by the progress of the revolt. Candidly he interpreted to them the sounds of disturbance and gave them due warnings of what was coming. In June, 1774, he said: "I have no doubt that a total suspension of commerce to and from Great Britain will certainly take place. Such I know are the sentiments of those who even wished a chastisement to Boston."

He writes under date, August 2, 1775, that the British man-of-war "Asia," is turning back boats with produce and iron from the Jerseys, in consequence of the restraining act. He will forward as much iron as possible before the tenth of September, when exportation ceases. On October 31 he advises of the probability that the seat of war will be transferred to New York and the business of the works be interrupted. February 10, 1776, he writes, inclosing his cash account for January.

As it proved, the works were kept in operation during the war, since they were within the lines of the insurgents, for whom they became a prolific source of munitions, including some of the iron work of the Hudson river obstructions. Preponderant sentiment in New Jersey and New York hardly sustained the wisdom of the rebellion, yet Erskine eventually threw in his fortunes with it. He organized the employees of the works into a company of militia which he equipped at his own expense. The rebels, moreover, made him geographer and surveyor general to their "Continental army." There is said to be in existence somewhere a letter received by Erskine from Mr. Washington, the leader of the insurgent bands, asking him if he considered himself the proper sort of man for the above-mentioned job. In entering upon this office he again reminds us of Mr. Carnegie, who undertook public service as Eastern superintendent of military railways and telegraphs in the war between the States.

That Erskine was an honest man is evidenced by the books of accounts which he continued to keep with the proprietors of the iron works, whom we may assume still to be the English ones, and to whom, although cut off by the war, he acknowledged a persisting business obligation. The salary with which he credited himself jumped from £370 in 1777 to £1125 in 1778 and £1110 in 1779, which would look like an attempt to make hay while the sun shone did not the inflation of the currency suffice to explain the apparent raise.

Robert Erskine did not live to see the rebellion successful. He died October 2, 1780, the day that Major Andre was hanged and was buried at Ringwood. Mr. Washington came from the gallows at Tappan to attend his funeral. It may be presumed that after the end of the war, if not before, the iron works were sold by the State of New Jersey under confiscation proceedings. These were one of the methods of persecution by which the victorious party took revenge against the loyalist fellow countrymen. Non-resident Britishers, such as the London Company, would not be likely to fare better. The estate may have been split up at this time. It was manifestly divided in ownership a few years later when it was visited by a French author known as the Marquis of Crevecoeur. He found the Ringwood and Charlotteburg plants in the hands of separate managers to whom he refers as proprietors. The master of Ringwood was a Mr. Erskine, who was doubtless a son or nephew of the great engineer. A few extracts from Crevecoeur's narrative are pertinent to quote:

"The proprietor of these [Ringwood] works, Mr. Erskine, had, as we knew, spent three years in Europe visiting the principal forges of Scotland, Sweden and Germany. His operations, although less extensive, seemed to us no less interesting. The construction of the different machines intended to simplify the work was even more perfect than what we had seen at Sterling. A large *movement* for flattening and slitting the iron into rods appeared to Mr. Herman a *chef d'oeuvre* of simplicity, but what rendered it yet more curious was the flour mill by which it was surmounted, and which could be lowered when it was wanted for use and raised when the grinding was finished. . . . [Regarding the forests in this part of the country, one of visitors remarked to Mr. Erskine]:

"'If your posterity preserves these beautiful woods it will for many centuries enjoy the precious advantages of having the charcoal necessary for making iron, facilities for repairing buildings and dams, and all the power required.'

"'You are right,' said Mr. Erskine, 'it is probable that this will come to pass, since the entire chain has long been the property of a few individuals extremely interested in the preservation of the forests.'

"Next day we came across a very mountainous country to Charlotteburg. The works here had been erected before the Revolution by an English company, which the war had ruined. The . . . proprietor was absent. . . . The water reservoir was immense."

The preservation of natural resources was a consideration even in the eighteenth century. It is true now, as it was then, that the Ramapo mountain country is largely held in single ownerships amounting to many thousands of acres each. The hills are remarkably wild for a region only thirty or fifty miles from New York city hall, though I do not venture to say how much of the wood is primeval forest or merchantable timber. At villages not far from Paterson the wildcats are so tame that they come and eat out of the ash barrel. Charcoal burning has ceased to be a necessary industry, but the water powers of the region ought to be valuable. It is probable, however, that the available water will all be needed for municipal supply. A few years ago there was a project to pipe it to New York, but so many political possessions were raised in that the water would have poisoned anyone who had drunk it. One of the accompanying illustrations shows a wash-out by the bursting of a pond or reservoir at Sterlington, not far from Ringwood, in a freshet five years ago. I am told that practically all of the gulley visible was cut by the flood and that the water reached the eves of houses on the plain below.

WORK OF HYDRAULIC POWER, NEAR RINGWOOD

A little journey to Robert Erskine's grave at Ringwood was made in the course of preparing this sketch of his career. The place has long been occupied by the Cooper-Hewitt interests, who still conduct mining operations there, and the country for miles around is kept up as a magnificent residential estate. It was the home of the late Mayor A. S. Hewitt, of New York. C. S. Stoney is the courteous superintendent of the industries. A considerable stream filled with ripples that suggest hundreds of unused horsepower flows down from the north and forms a lake near which the Erskine grave is situated. As shown in the photograph, the slab at the right is Erskine's, while at the left is buried his clerk, Robert Monteith, also of Scotland, who preceded him in death by several years. Near the former tomb is an old stump which does not look very beautiful, and the skilled photographer conveniently kept it out of the field of the picture. Information has since been acquired that the tree was planted there by Mr. Washington (no doubt as a penance for cutting down the cherry tree), but the reader may be regarded too callous to see it by a reiterated assurance that it is quite an ordinary stump and not a bit more worth looking at than those which are planted by the hand of nature.

A vainglorious tree insisted upon posing for her picture.

Testing and Adjusting Watt-Hour Meters

Practical Methods of Handling Westinghouse Instruments, with Wiring Diagrams Showing Proper Connections for Best Results

BY O. F. DUBRUIEL

Every well-equipped power station, in order to get satisfactory performance by its watt-hour meters, should have its own meter department, provided with the best appliances possible for overhauling, testing and checking the meters. The premises containing this department should be absolutely free from vibration and equipped with solid, substantial testing racks. These racks should be suitably provided with lampboards, switchboards and resistances so arranged that the loads through the meters can be easily changed and each load can be maintained at a constant value while readings are being taken.

In testing, a constant voltage is essential and this voltage should be that which is applied to the meter terminals when the meter is installed. To obtain the various voltages for the testing racks a potential regulator is a most convenient piece of apparatus. A transformer with a number of loops brought out from the secondary winding to binding posts will, however, accomplish the same results, but the former is always to be preferred.

It is essential for accurate work that the best standard instruments should be obtained, for good results cannot be secured with inferior instruments. These standard instruments may consist of voltmeters, standard integrating watt-hour meters, standard indicating wattmeters and stopwatches.

There are two methods of checking a watt-hour meter calibration. The first method is by comparing the meter to be checked with a standard indicating wattmeter. When using this method the instruments should be connected to the circuit and a constant load applied; by timing the disk a composition load can be obtained. The second method is by comparing with a standard integrating watthour meter; by this method it is only necessary to notice which of the two instruments was in synchronism to determine whether the wattmeter in question is in correct calibration. A well-equipped station should have the necessary instruments to check by either method.

To Test a Westinghouse Type A Two-wire Single-phase Meter

Connect the wattmeter in circuit with a standard indicating wattmeter as indicated in Fig. 1, being careful to make the connections exactly as shown. Load the circuit until the desired reading is obtained on the indicating wattmeter and keep it at a constant value while the integrating watt-hour meter is being read. Time the number of revolutions of the disk with a stopwatch, commencing to count when the spot on the disk has made one revolution (after the watch has been started), and count the revolutions for at least one minute to arrive at the number of watt-hours registered by the meter. Use the following formula:

$$\frac{K \times R}{S} = watts,$$

where R = number of revolutions made by the disk, S = time to make revolutions and K = constant, which is equal to the volts multiplied by the amperes (as marked on the counter) and multiplied by 1.2. When this type of instrument is used with series transformers, and checked without them, K = volts as marked on the counter multiplied by 6. For wattmeters used with series and shunt transformers but checked without them K = 600.

When testing with the standard integrating watt-hour meter connected as shown in Fig. 2, when more than one meter is to be checked against the standard, it should be connected as shown in Fig. 3, but only one meter can be run with the standard at a time; otherwise the meter nearest the line connection will measure the energy taken by the shunts of those nearest the standard.

Type B Single-phase Meter

The formula for this meter is the same as before, but in this case, with the two-wire meter, K = volts × amperes (as marked on the counter) × 2.4. For meters used with series and shunt transformers, but checked without them, K = the rated watts × 5 × 2.4, since these meters have five-ampere series windings.

For Type B three-wire single-phase self-contained meters used with acid transformers, K = constant or volts × amperes (as marked on counter) × 4.8, and for Type B three-wire single-phase meters used with transformers, K = volts (as marked on the counter) × 12.

For Type C three-wire single-phase

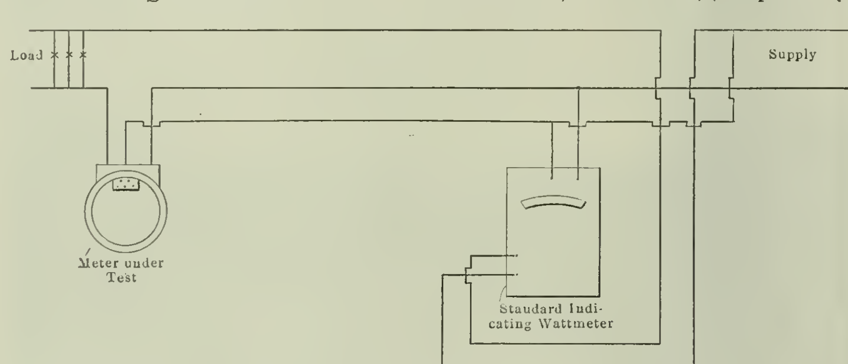

FIG. 1

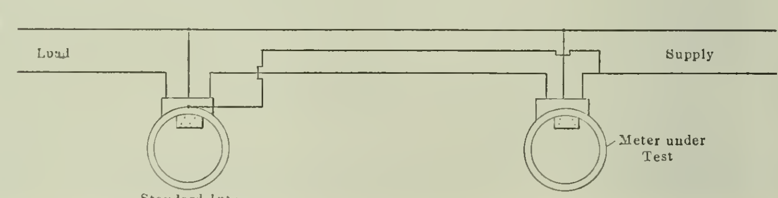

FIG. 2

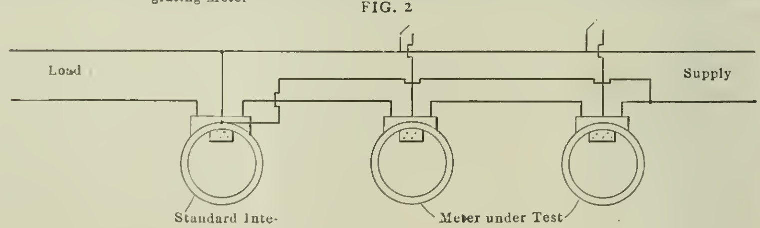

FIG. 3

meters up to 40 amperes capacity, $K =$ volts (between outside wires as marked on the counter) $\times$ 2.4, and for Type C polyphase meters, without series or shunt transformers, $K =$ volts $\times$ amperes $\times$ 4.8; for meters used with series transformers only (but checked without them) $K = 5$ $\times$ volts (as marked on the counter) $\times$ 4.8, and $K = 2400$ for meters used with shunt and series transformers, but checked without them.

In checking polyphase meters it is best to check them as single-phase meters; that is, check over one element of the time. See Figs. 4 and 5.

To check a polyphase meter as a single-phase meter connect the current coils in series and the potential coils in parallel.

Type F Long Scale Indicating Wattmeters for Alternating Current

For accuracy in using these indicating wattmeters the following should be taken into account. In all indicating instruments there are two kinds of error, an initial error independent of the load, which is due to traces of friction, parallax, coarseness of the divisions on the dial, etc., and an error proportional to the reading due to inaccuracies in calibration errors in the standards used, and causes varying the constants of the instruments. In the Type F instrument the former error amounts to five-tenths of one per cent. of the full scale reading, and the latter to five-tenths of one per cent. of the actual reading; therefore, to find the total error at any point within which the readings may be relied upon, the following formula should be used:

$$\textit{Per cent. total error} = \frac{0.005\,A + 0.005\,a}{a},$$

in which $A =$ full scale capacity and a the actual reading. Any visible zero error should be allowed for in reading.

In the lamp-testing wattmeters the initial errors amount to one-tenth of 1 per cent. of the full scale reading and the proportional error to two-tenths of 1 per cent. of the actual reading. Therefore, to find the total error at any point within which the readings may be relied upon, the following formula should be used:

$$\textit{Per cent. total error} = \frac{0.001\,V + 0.002\,v}{v},$$

in which $V =$ full scale capacity and v the actual reading; any visible zero error should be allowed for in the reading.

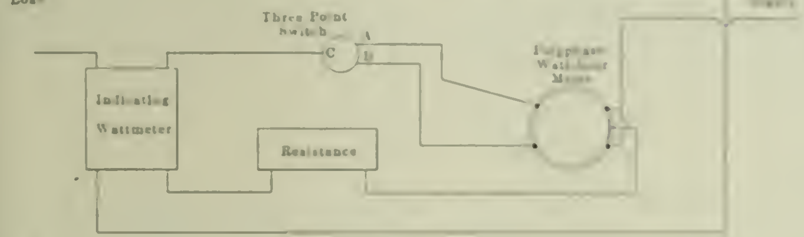

FIG. 4

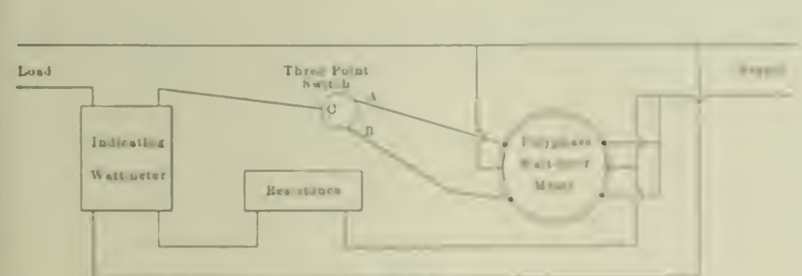

FIG. 5

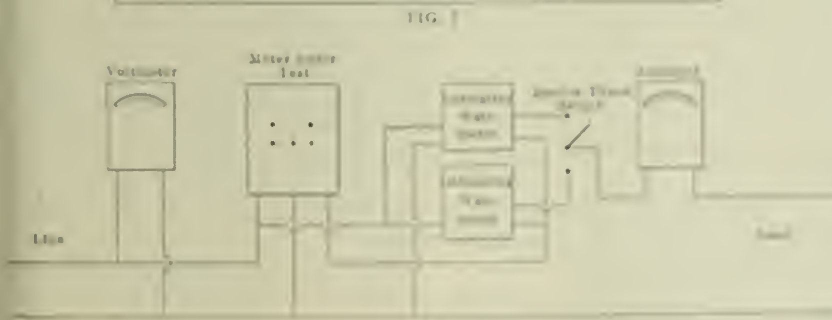

FIG. 6

Portable Long Scale Indicating Wattmeters for Alternating Current

The accuracy of the calibration of this instrument may be stated by saying that the errors of full scale reading amount to two-tenths per cent. and those of the actual reading two-tenths per cent. Therefore, to find the error of calibration at any point the following formula may be used:

$$\textit{Per cent. error} = \frac{0.2\,W + 0.2\,w}{w},$$

in which $W =$ full scale capacity, and w the actual reading. Any visible zero error should be allowed for in the reading. For example take a [illegible]-kilowatt instrument indicating 30 kilowatts:

Per cent. error of calibration =

$$\frac{0.2 \times [illegible] + 0.2 \times 30}{30} = [illegible]$$

per cent.

Wishing to find the number of seconds S in which the disk should make the test number of revolutions with a certain load, use the following formula:

$$\frac{K \times R}{P} = S,$$

where

$K =$ Constant,
$R =$ Number of revolutions in test,
$P =$ Watts indicated by indicating wattmeters.

The value of K may also be found by transposing the formula, thus:

$$K = \frac{P \times S}{R}$$

Connect the polyphase meters as shown in Figs. 4 and 5. This connection shows the meter in a single-phase two-wire circuit with a standard indicating wattmeter. Be sure that the connections are made exactly as shown in the sketch. Both shunt circuits of the integrating watt-hour meter are connected with the main circuit; however, the current passes through only one series coil at a time by connecting the point C to either A or B. When this one circuit of the meter is fully loaded the rotating element will make one-half the number of revolutions which it makes with full load on both circuits. Now pass through the circuit a given number of watts which must be kept as constant as possible while the reading is being taken. After the test has been made on one side the same test should be made on the other side. If C is connected to A in the former test, connect it to B, and vice versa, the shunt connections remain the same as in the first test. The main current is now, however, passed through the other circuit, the first series circuit being entirely disconnected. Be sure that both shunts are connected when testing.

Fig. 6 shows the connections that will be made on a testing board where direct and alternating watt-hour meters are tested by the use of a voltmeter, two indicating wattmeters, a double-throw switch and an ammeter. When testing direct-current meters use a voltmeter [illegible] and an ammeter, and for alternating current use a voltmeter and an indicating wattmeter. Two indicating meters are used, one with a small range and the other with a large range, in order to avoid errors in reading a small load at the lower end of the scale of a large instrument.

Calculating Strength of Riveted Joints*

A New and Original Method Dispensing, by the Use of Diagrams, with the Labor Involved in the Usual Calculation

BY S. F. JETER

The purpose of the present article is to show how most of the labor involved in the calculations of riveted joints, as generally applied to boiler construction, may be dispensed with. The method of doing this is by the use of diagrams, and while those shown in connection with this article are all based on tensile strength of the plate, shearing strength of the rivets and crushing strength of the rivets, of 55,000, 42,000 and 78,000, and 95,000 pounds per square inch, respectively, the methods used in constructing the diagrams will be explained fully and the formulas given, so that those who are concerned with the design of such joints, or who may frequently have to calculate their efficiency, can construct diagrams to suit their special requirements as regards the above mentioned values.

After the principles are thoroughly understood, it will be found a very easy task to construct the diagrams, and the writer has found that the labor involved may be greatly reduced by making use of standard cross-section paper, a very convenient size being 16x21 inches divided in tenths. This can be procured from any dealer in drawing materials for five cents per sheet. It is, of course, not essential to have the form of joint shown in the corner of the sheet, but it was done in the present case merely as an aid in explaining the diagrams; a written description of the joint would answer equally as well. It is impossible to explain the diagrams or the method of their construction without the use of formulas or the aid of analytic geometry; it is, however, not necessary that the reader be versed in either the use of formulas or analytic geometry to make full use of the diagrams in shortening the calculations necessary to determine the efficiency of the various joints considered.

The method, about to be described, of determining the probable mode of joint failure directly without calculation and comparison of values is entirely original with the writer, and as far as he can ascertain it is different from any method which has been previously published on the subject. The principle may be stated thus:

With a given diameter or area of rivet and fixed values for the tensile strength of the plate and crushing and shearing strength of the rivets, straight lines or curves may be drawn, representing values of pitch of rivets or thickness of plate, or both, at which either of the two compared possible modes of failure would be equally probable. Representing the pitch of the rivets by distances on the axis Y and the thickness of the plate by distances on the axis X, or *vice versa,* lines may be drawn representing comparisons between all of the possible modes of joint failure for a given rivet diameter, and the most likely mode of failure, for a given pitch of rivets and thickness of plate, can be determined without calculation by noting the direction in which the point of intersection of the lines, representing the

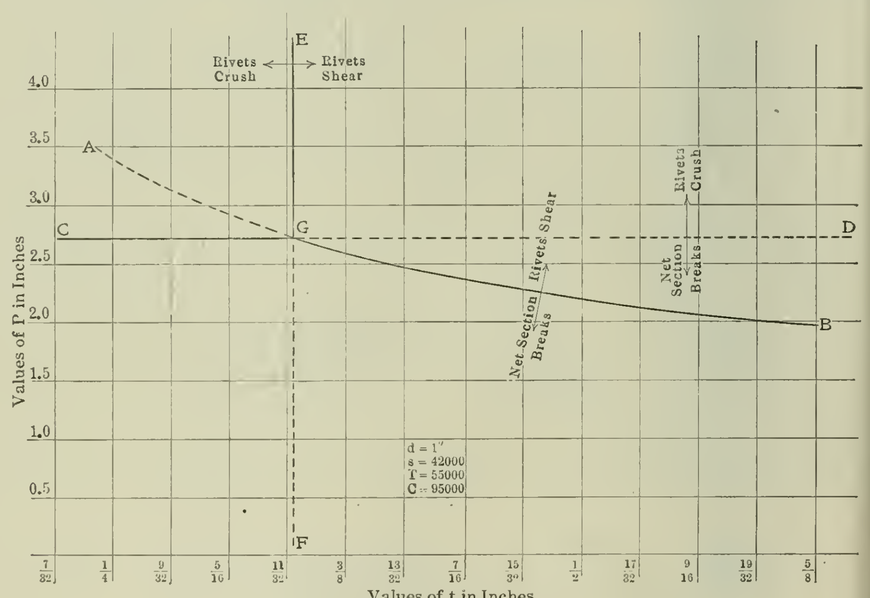

FIG. 1. DIAGRAM FOR A SINGLE-RIVETED LAP JOINT

pitch of the rivets and the thickness of plate lie, with respect to the lines denoting equally probable failure.

In the following explanation for all forms of joint the notations given hereafter will be adhered to.

T = Tensile strength of plate per square inch, in pounds.

S = Shearing strength of rivets per square inch, in pounds, when subjected to double shear.

s = Shearing strength of rivets in pounds per square inch, when subjected to single shear.

C = Crushing strength of rivets in pounds per square inch of projected area of contact between rivets and plate.

P = Pitch of rivets, in inches.

d = Driven diameter of rivet, or diameter of hole, in inches.

t = Thickness of plate, in inches.

In joints that have more than one pitch, P always represents the greatest pitch of rivets. The dimensions corresponding to P, d and t are given on the drawings illustrating the forms of joints in the upper corner of each diagram.

Bearing in mind the notations just given and considering a single-riveted lap joint, the three modes of possible failure, as given in the previous article on page 28 of the July 7 number of POWER AND THE ENGINEER, would be represented as follows:

Breaking of net section between rivet holes

$$t\ T\ (P - d) \qquad (1)$$

Shearing of rivets

$$0.7854\ d^2\ s \qquad (2)$$

Crushing of rivets

$$C\ d\ t \qquad (3)$$

By making (1) and (2) equal to each other and solving for P, the following would result:

$$t\ T\ (P - d) = 0.7854\ d^2\ s,$$

or

$$P = \frac{0.7854\ d^2\ s}{t\ T} + d.$$

Substituting in this equation the values of 55,000 for T and 42,000 for s, it would become:

$$P = \frac{0.6\, d^2}{t} + d. \qquad (4)$$

Now if values for t and P are laid off on the axes of X and Y, respectively, and this equation is plotted with any fixed value for d, a curve would be obtained, and if the pitch and thickness indicated by any point on this curve was used in constructing a single-riveted lap joint, the probability of failure by breaking the net section or shearing the rivets would be the same, and since an increase in pitch would strengthen the net section, without adding strength to the rivets to resist shearing, all points lying above this curve would denote corresponding values for pitch of rivets and thickness of plate that would cause joint failure by shearing of the rivets rather than breaking of the net section of the plate, and conversely, points lying below this curve would indicate breaking of the net section of the plate, rather than shearing of the rivets. Again, if equation (1) is made equal to equation (3), the following results are obtained:

$$t\ T\ (P - d) = C\ d\ t$$

or

$$P = \frac{C d}{T} + d,$$

which reduces to

$$P = 2.73\ d \qquad (5)$$

when $T = 55{,}000$ and $C = 95{,}000$.

This equation represents a line parallel to the axis of X and at a distance $2.73\,d$ above it; a joint designed with this pitch of rivets would be equally as strong to resist rupture by crushing of the rivets or breaking of the net section of the plate with any fixed value for d, and since an increase in pitch of rivets would add strength to the net section of the plate, without adding to the strength of the rivets to resist crushing, all points lying above this line would represent pitches which would cause the crushing of the rivets to be more likely than breaking of the net section of the plate and conversely those values of P lying below it would indicate joints where the net section of the plate would be weaker than the rivets.

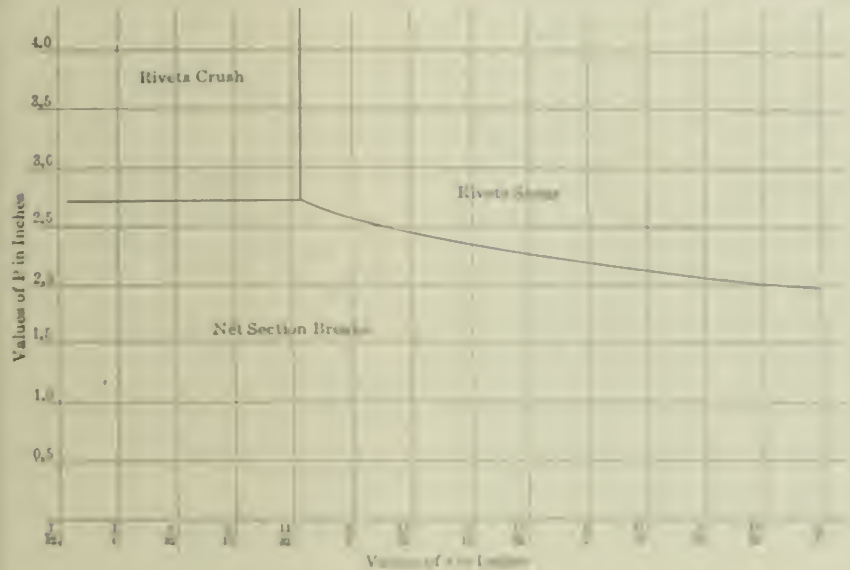

FIG. 2. DIAGRAM OF FIG. 1 SIMPLIFIED

Making equations (2) and (3) equal each other, which is the last comparison possible, the following results are obtained:

$$t = \frac{0.7854\ d\ s}{C},$$

or

$$t = 0.347\ d \qquad (6)$$

when $C = 95{,}000$ and $s = 42{,}000$. This equation represents a line parallel to the axis of Y and at a distance $0.347\ d$ from this axis, and since an increase in the thickness of the plate increases the capacity of the rivets to resist crushing, but does not add to their resistance to shearing, all values to the right of this line would indicate joints which would fail by shearing of the rivets rather than by crushing them, and conversely, those to the left would indicate crushing of the rivets rather than shearing them.

FIG. 1. DIAGRAM FOR THE [illegible]

In Fig. 1 equations (4), (5) and (6) have been plotted, assuming a value of 1 inch for d. Line $A B$ represents equation (4), line $C D$ equation (5) and line $E F$ equation (6). The lower line represents the axis X, while the axis of Y and the origin are $\frac{7}{16}$ inch or seven units of thickness to the left of the last vertical line on the left. As may be noted, the three lines representing the equations intersect in a common point G, and if a joint should be constructed of one-inch rivets and with the pitch of rivets and thickness of plate equal to that indicated by this point, failure would be equally probable by shearing of the rivets, crushing of the rivets or breaking of the net section of the plate and this would also be a joint of maximum efficiency.

The arrows pointing from each side of the three lines denote the mode of probable failure for values of P and t each side of the line in the directions indicated. Since all values lying to the left of $E F$ would give joints in which the rivets would crush instead of shearing, the portion of the line $A B$ denoting comparisons between the breaking of the net section and shearing of rivets, which lies in the area $A G$, can be dispensed with, for in estimating the strength of joints, it is necessary to compare only the strength of the portion most likely to fail with the strength of the solid plate. Since all of the area to the left of $E F$ denotes joints which would crush the rivets rather than shear them, the only comparison which would be of value in this area would be that between the crushing of the rivets and the breaking of the net section of the plate, which is represented by the line $C G$. For similar reasons, the line denoting comparisons of the strength of the net section of the plate with the crushing strength of the rivets, lying to the right of $E F$, or $G D$ can be removed; the lower portion of line $E F$, or $G F$, has no significance, as the area below $C G B$ indicates pitches and thicknesses of plate where the net section of the plate is weaker than either the shearing or crushing of the rivets, and therefore there is no need of determining the relative probability of failure by these two methods in this area. Removing the dotted portions of the various lines, a diagram like Fig. 2 will result, and all corresponding values of P and t which lie in each of the three divisions, would indicate joints which would fail in the manner noted in Fig. 2.

The previous description of the principles involved in making a diagram for a single-riveted lap joint holds good for all forms of joints with one pitch of rivets, as all equations of such joints, giving comparative values between the different modes of possible failure, are of the same form as (4), (5) and (6).

It will be noted that the equation of equality between the breaking of the net section of the plate and the shearing of the rivets, equation 4, is that of a hyperbola, and since it is very tedious to plot such a curve, the value of this method of shortening the labor involved in the calculation of joints would be greatly lessened if there were no way of obviating this difficulty, but a very simple expedient may be made use of, so that all equations may be represented by straight lines. This may be accomplished by laying off the values of t along the axis of X, equal to the reciprocals of the thicknesses instead of directly equal to them, and then equation (4) becomes

$$P = \left(\frac{1}{t}\right) 0.6\, d^2 + d,$$

or a straight line cutting the axis Y at a distance d above the axis X. Since the intersection of the lines representing equations (5) and (6) give another point of this line, it is only necessary to join the two points by a straight line to obtain all intermediate values.

In the accompanying diagrams the origin is to the right of the sheets, and the reciprocals of thickness were multiplied by six, so that the line representing ¼-inch plate is 24 inches to the left of the origin. This scale of thickness for the range covered by the diagrams will be found very convenient. Two different scales are used for the pitch, one twice as great as the other, and the bottom line does not represent the axis of abscissas in all diagrams, because the diagrams could be made more compact and to a more readable scale in the space available by making such variations. The drawing in the upper corner of each sheet represents the type of joint for which the diagram is constructed, and the small diagram immediately below the joint is a guide to aid in the use of the main diagram, which may be illustrated as follows:

Assume that we have a double-riveted lap joint with a plate thickness of ⅜ inch and 13/16 inch diameter rivet holes, pitched 3 inches apart, and that we wish to know what efficiency this joint will have. Starting at the bottom of the sheet for this type of joint (page 00) at the line denoting a plate thickness of ⅜ inch, follow up this line until the line denoting a pitch of 3 inches intersects it, and holding a pencil on this point, look for the line denoting a rivet diameter of 13/16 inch. It will be noted that this point lies in the upper right-hand section of the diagram formed by the lines denoting 13/16-inch rivets, and it is shown by the guide diagram that points in this area indicate that the rivets would shear, so that to find the efficiency of the joint it is necessary only to estimate the shearing strength of the rivets and divide the result by the strength of the solid plate. If the rivet holes had been ⅞ inch in diameter instead of 13/16 inch, the point of intersection of pitch and thickness of plate would lie in the area denoting that the net section was weak, and the efficiency of the joint could be obtained by dividing the length of the net section by the pitch.

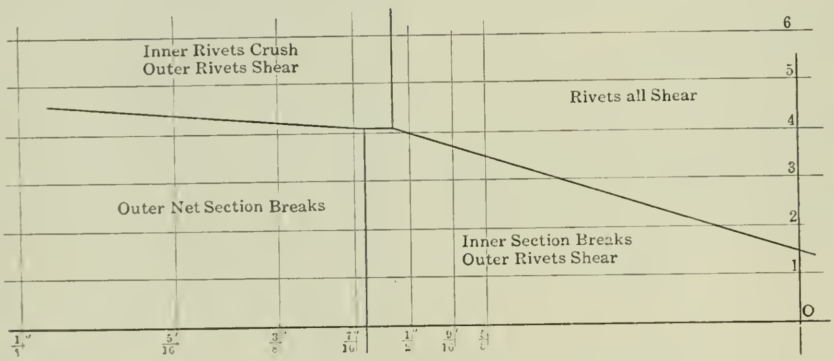

FIG. 4. OMITTING THE DOTTED PORTIONS IN FIG. 3

The following are the equations for the various lines used in the diagrams for joints of one pitch; the letters indicating the lines refer to those shown on the guide diagrams in the corners of the sheets.

SINGLE-RIVETED LAP JOINT

Line O K:

$$P = \frac{C d}{T} + d.$$

Line O L:

$$t = \frac{0.7851\, d\, s}{C}$$

Line O M:

$$P = \frac{0.7854\, d^2\, s}{t\, T} + d.$$

DOUBLE-RIVETED LAP JOINT

Line O K:

$$P = \frac{2\, C\, d}{T} + d.$$

Line O L:

$$t = \frac{0.7854\, d\, s}{C}.$$

Line O M:

$$P = \frac{1.5708\, d^2\, s}{t\, T} + d.$$

TRIPLE-RIVETED LAP JOINT

Line O K:

$$P = \frac{3\, C\, d}{T} + d.$$

Line O L:

$$t = \frac{0.7854\, d\, s}{C}.$$

Line O M:

$$P = \frac{2.356\, d^2\, s}{t\, T} + d.$$

SINGLE-RIVETED BUTT JOINT

Line O K:

$$P = \frac{C\, d}{T} + d.$$

Line O L:

$$t = \frac{0.7854\, d\, S}{C}.$$

Line O M:

$$P = \frac{0.7854\, d^2\, S}{t\, T} + d$$

DOUBLE-RIVETED BUTT JOINT, ONE PITCH

Line O K:

$$P = \frac{2\, C\, d}{T} + d;$$

Line O L:

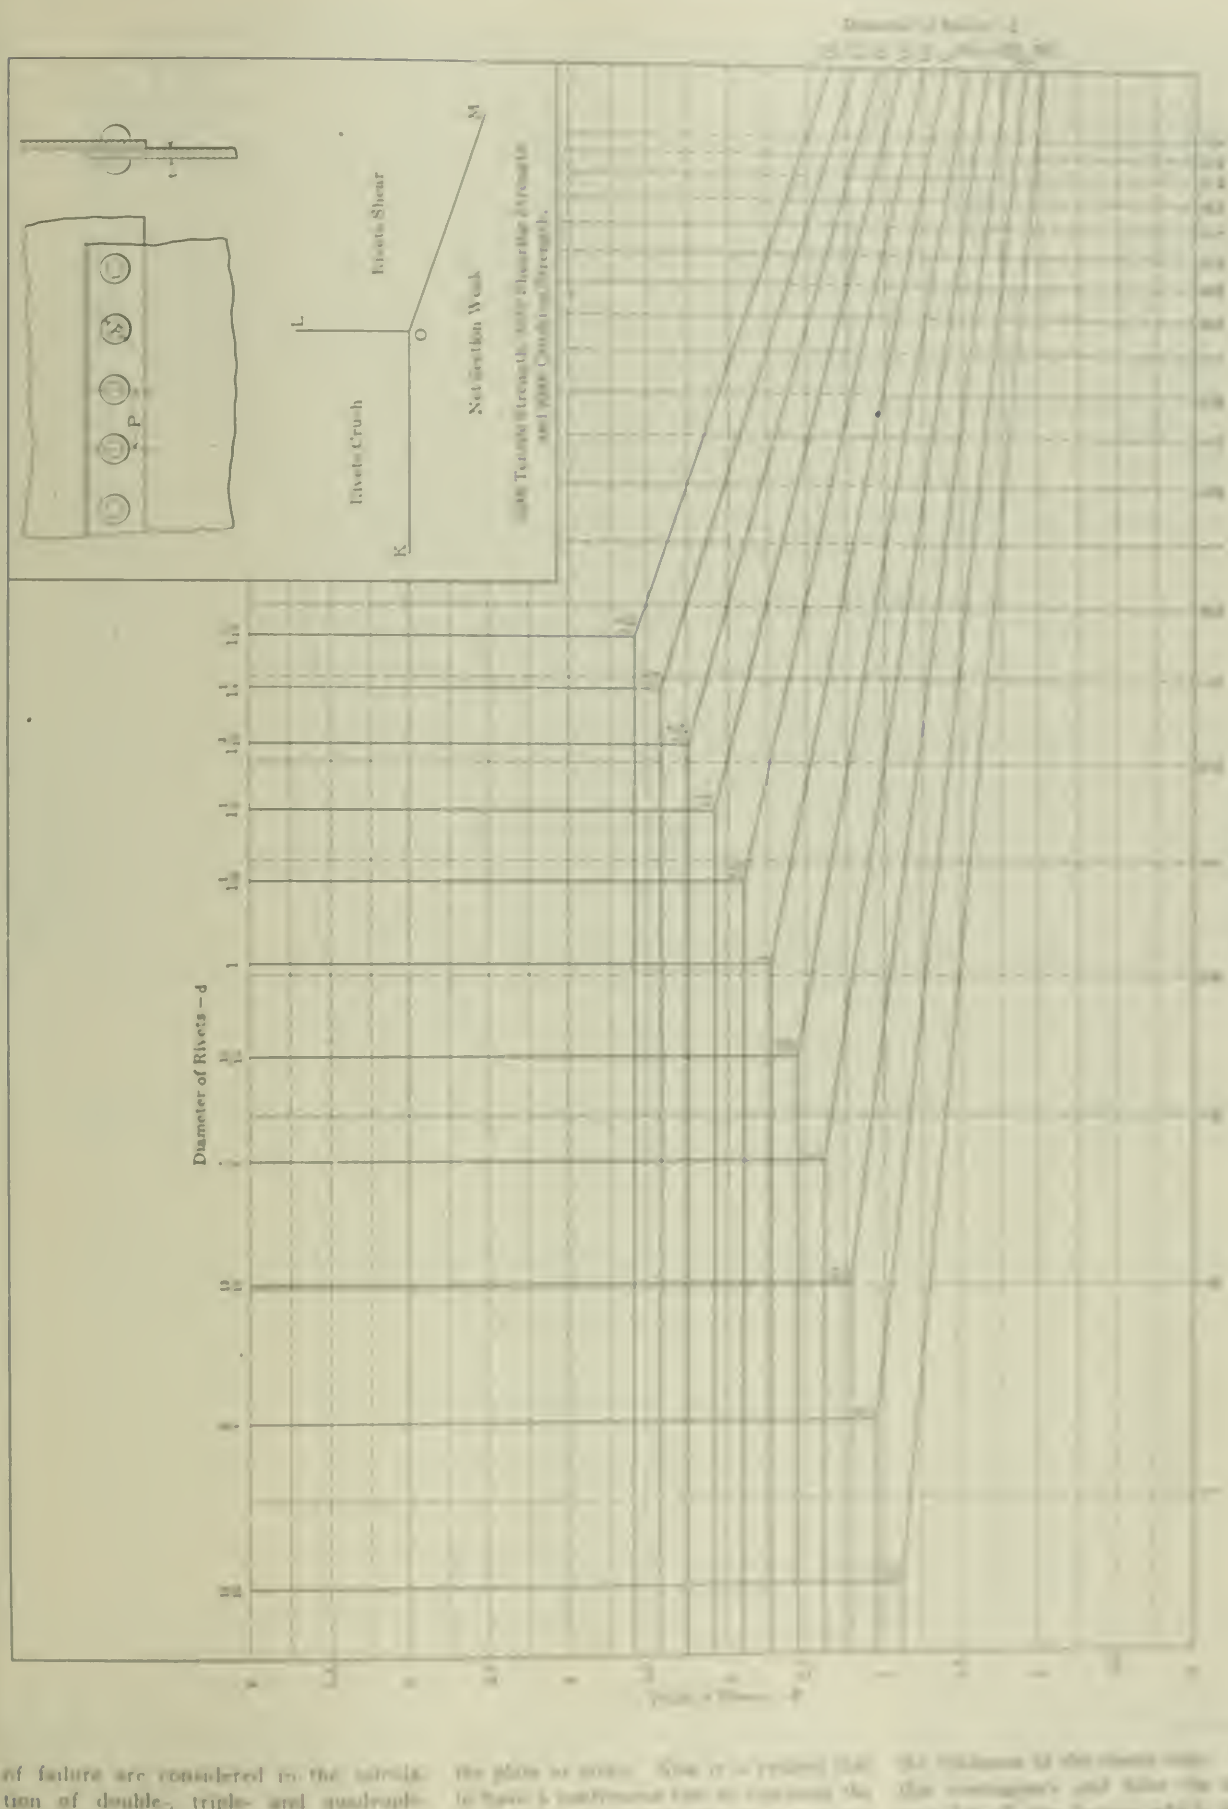
$$t = \frac{0.7854\, d\, S}{C}$$

Line O M:

$$P = \frac{1.5708\, d^2\, S}{t\, T} + d.$$

BUTT TYPE OF JOINTS WITH MORE THAN ONE PITCH

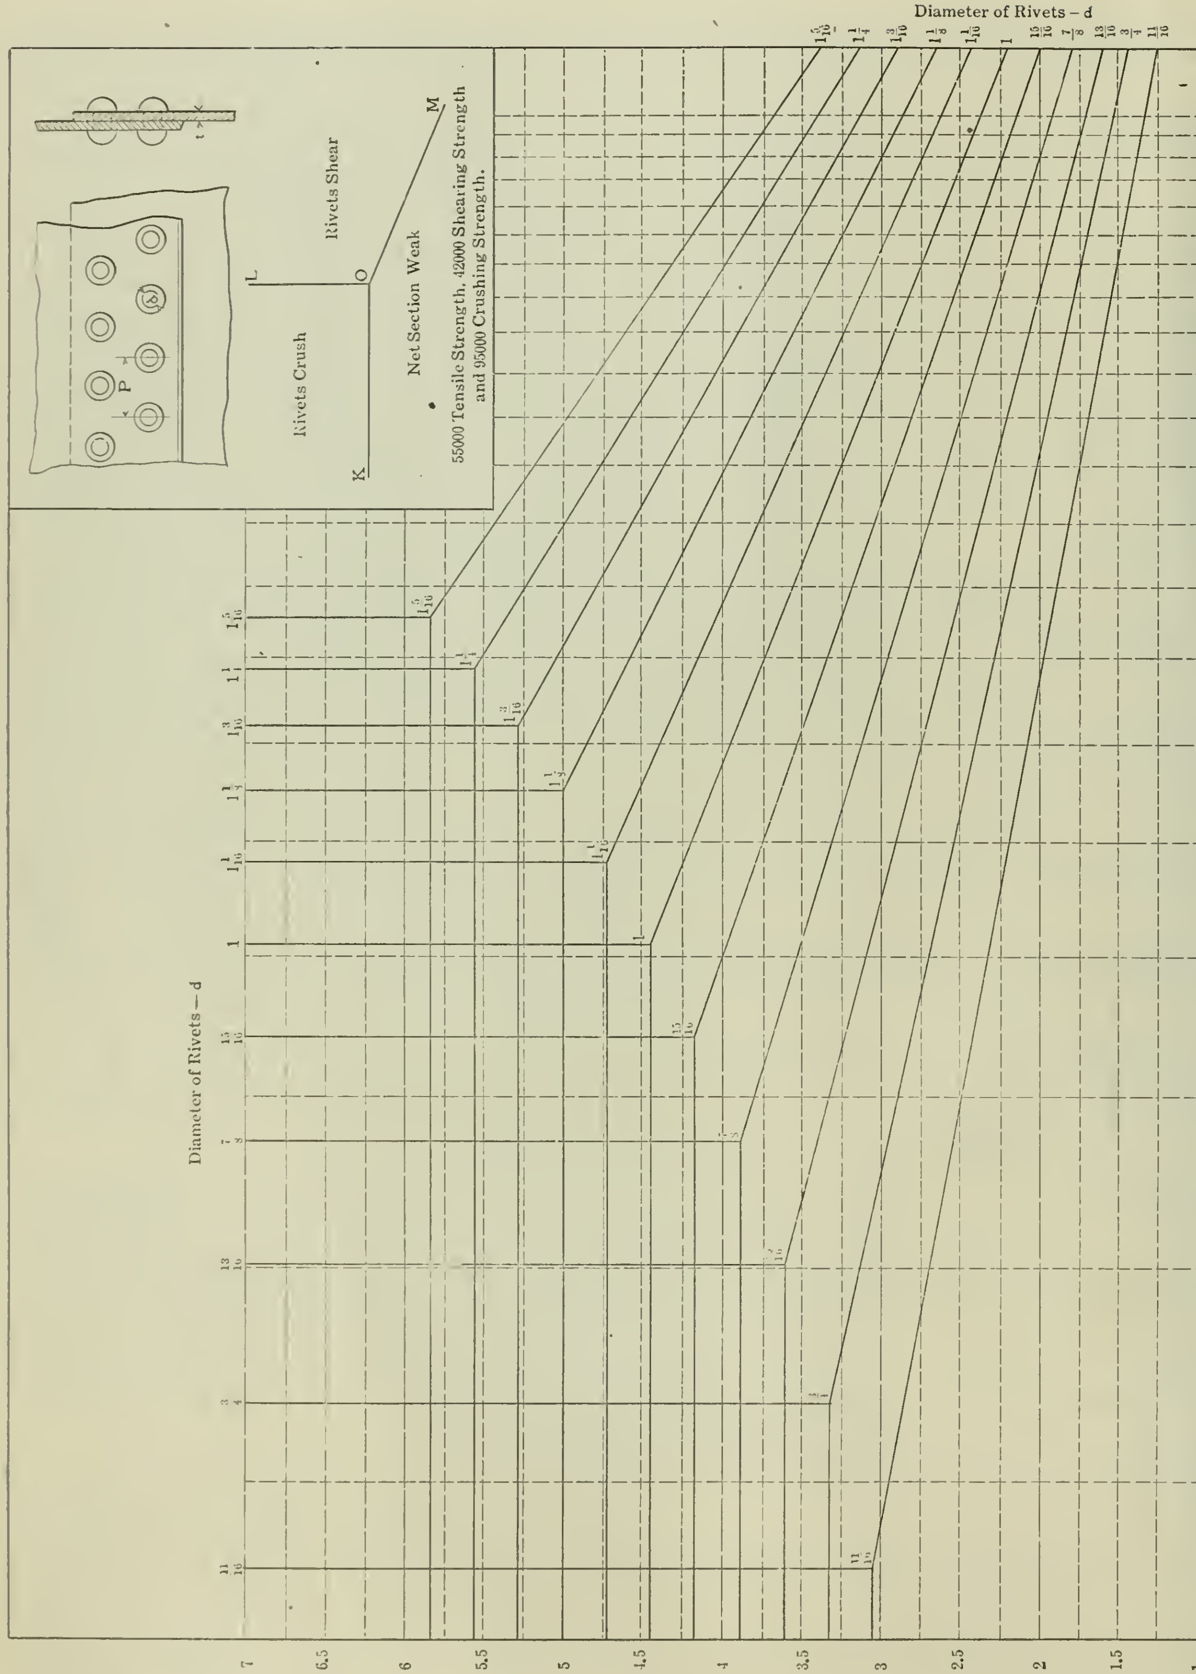
For the butt type of joint where more than one pitch of rivets is used, obtaining the equations and plotting the diagrams is a little more complicated. However, their use is just as simple as for the other joints, and the labor saved by the use of the diagrams is many times greater, as can readily be appreciated by anyone who has plodded through the uninteresting task of obtaining desired results in designing this type of joint by the old cut-and-try method. It will be noted on pages 31 and 32 of POWER AND THE ENGINEER, July 7, that six probable modes



of failure are considered in the calculation of double-, triple- and quadruple-riveted butt joints, as illustrated in Figs. 18, 19 and 20 of that article. Two of the possible modes of failure hinge on the crushing of the rivets in the outer rows in

the plate to crush. [illegible]

[illegible]



DOUBLE-RIVETED LAP JOINT

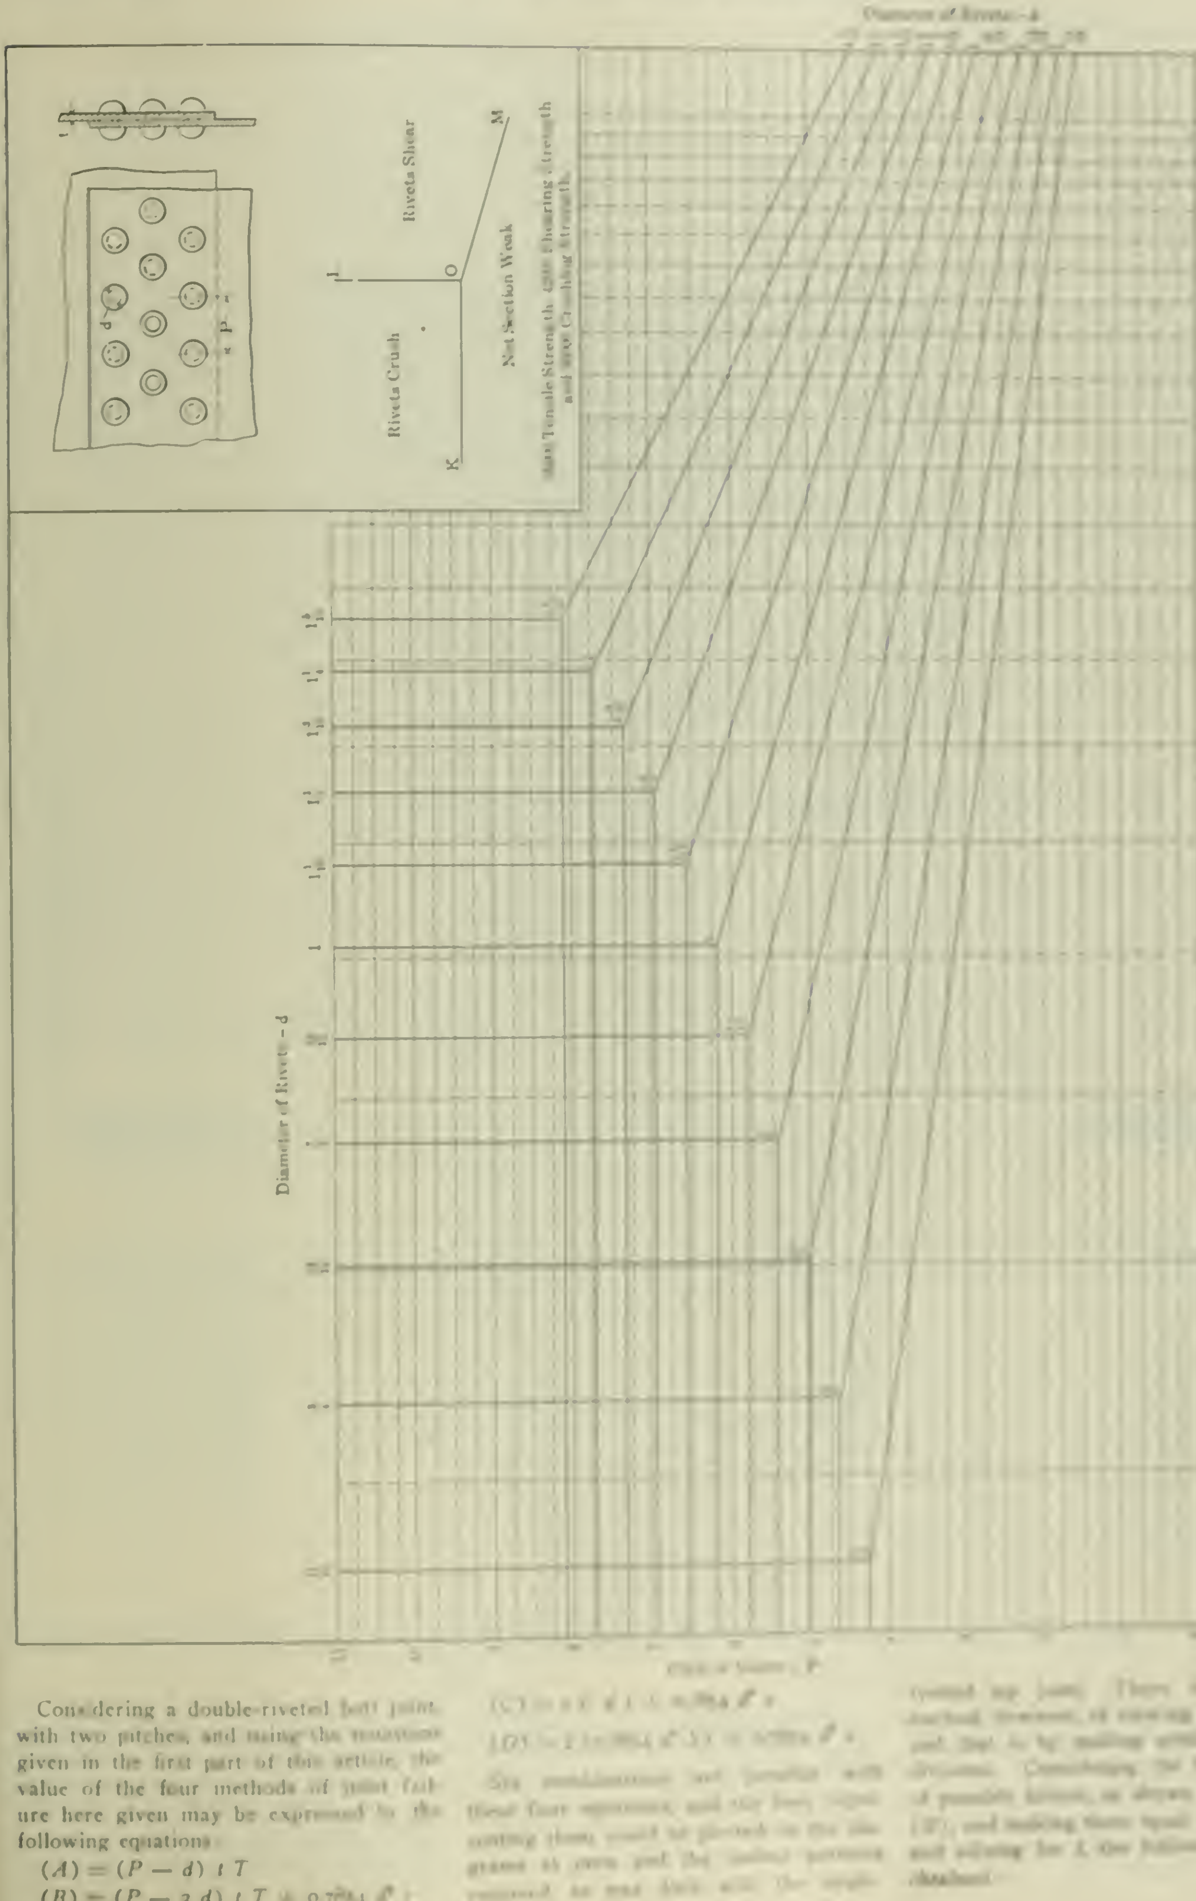
ing of the rivet or shearing in single shear would be equally probable, and as they extend to the right from this point, it is only necessary in using the diagrams to see that the thickness of the straps and plate come within this range, to make the diagrams hold good. It will be found that all practical boiler joints of the double-strapped butt type come well within this range. This expedient also reduces the modes of possible failure to four, which are:

(*A*) Breaking of outer net section.

(*B*) Breaking of the inner section and shearing outer rivets single shear.

(*C*) Crushing of inner rivets and shearing outer rivets single shear.

(*D*) Shearing all rivets, both double and single shear.



Considering a double-riveted butt joint with two pitches, and using the notations given in the first part of this article, the value of the four methods of joint failure here given may be expressed by the following equations:

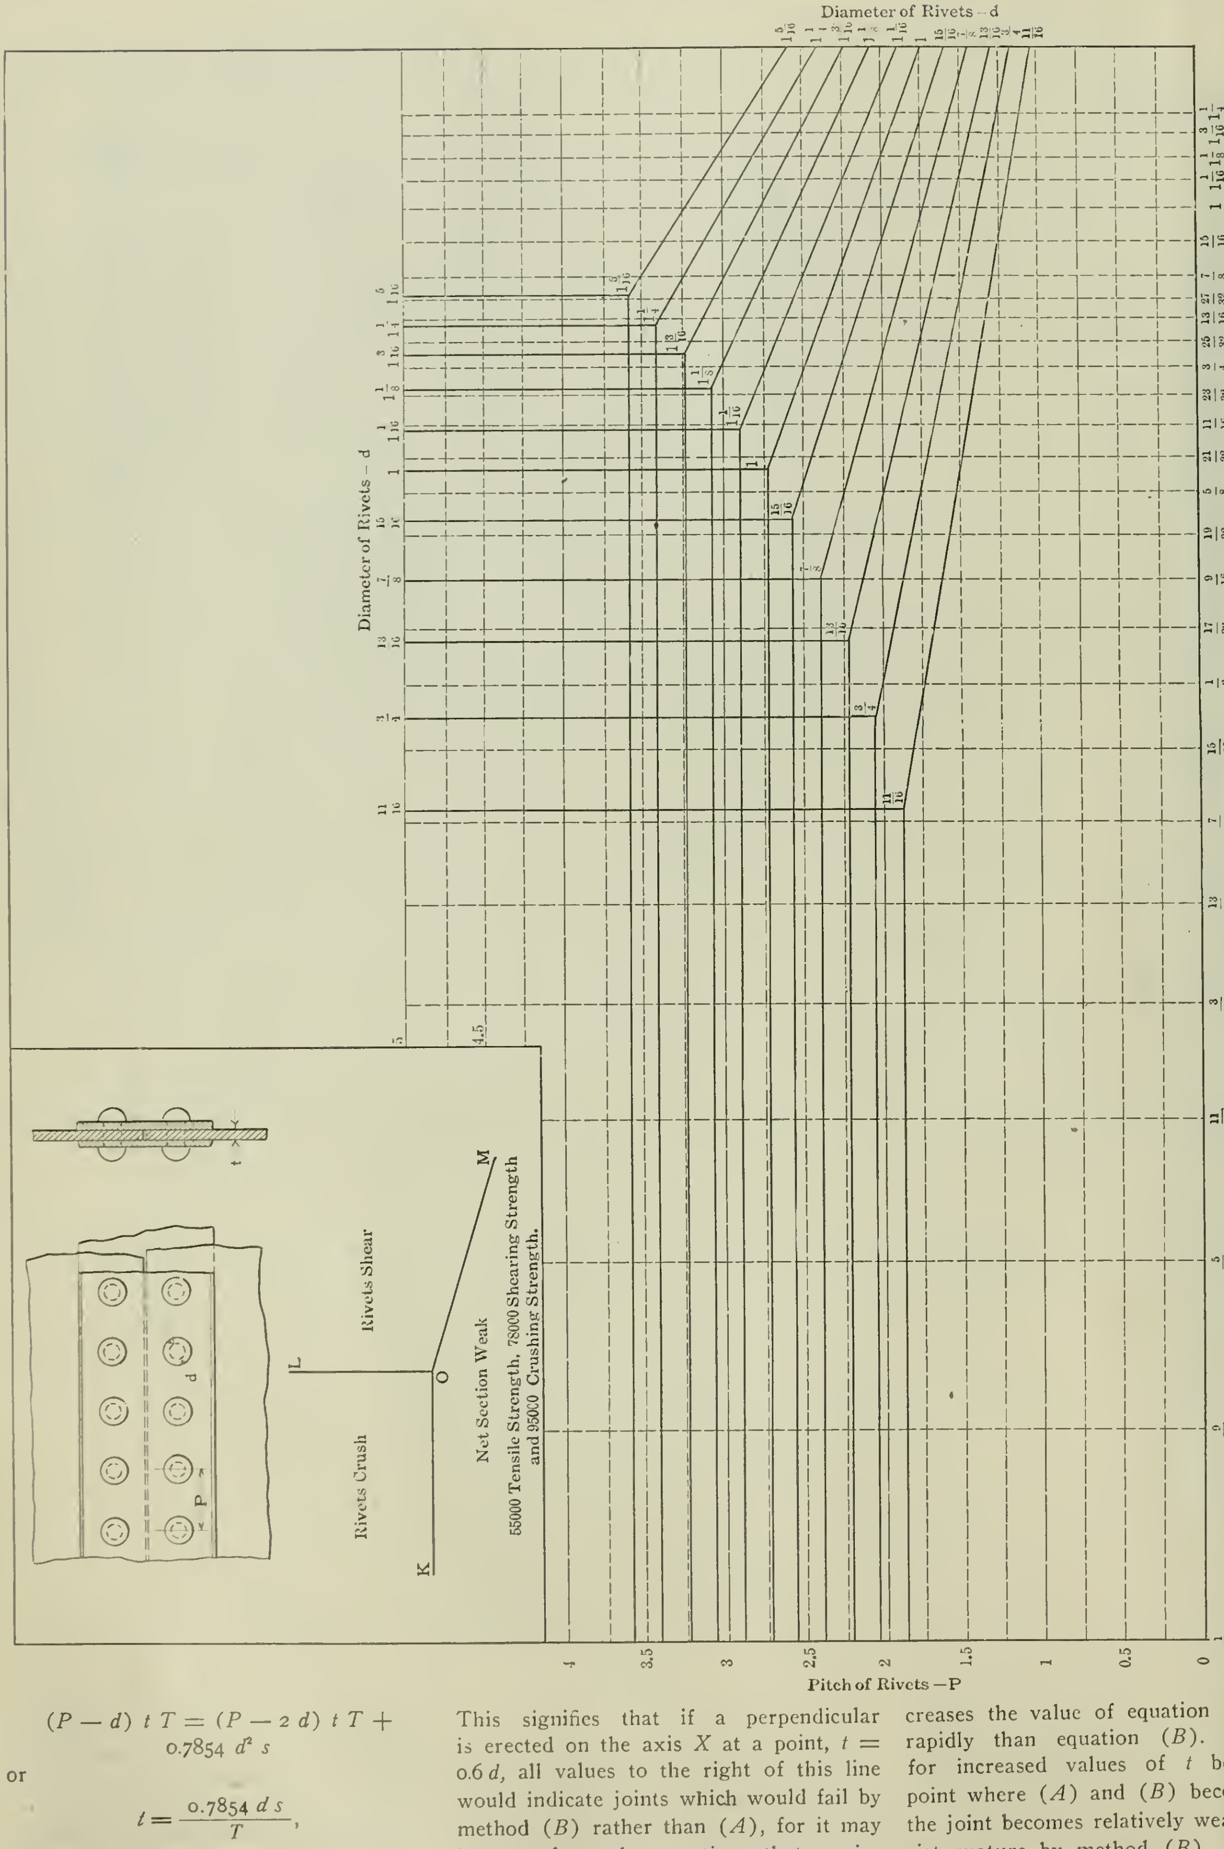
$(A) = (P - d)\ t\ T$

$(B) = (P - 2\ d)\ t\ T + 0.7854\ d^2$ [illegible]

(C) [illegible]

(D) [illegible]

Six combinations are possible with these four equations, and the lines representing them could be plotted on the diagrams [illegible] as was done with the single-riveted lap joint. There is a simpler method, however, of solving the problem, and that is by making [illegible] diagrams. Considering the [illegible] methods of possible failure, as shown by (A) and (B), and making them equal to each other and solving for [illegible] the following result is obtained:



SINGLE-RIVETED DOUBLE-STRAPPED BUTT JOINT

$$(P - d)\ t\ T = (P - 2\ d)\ t\ T + 0.7854\ d^2\ s$$

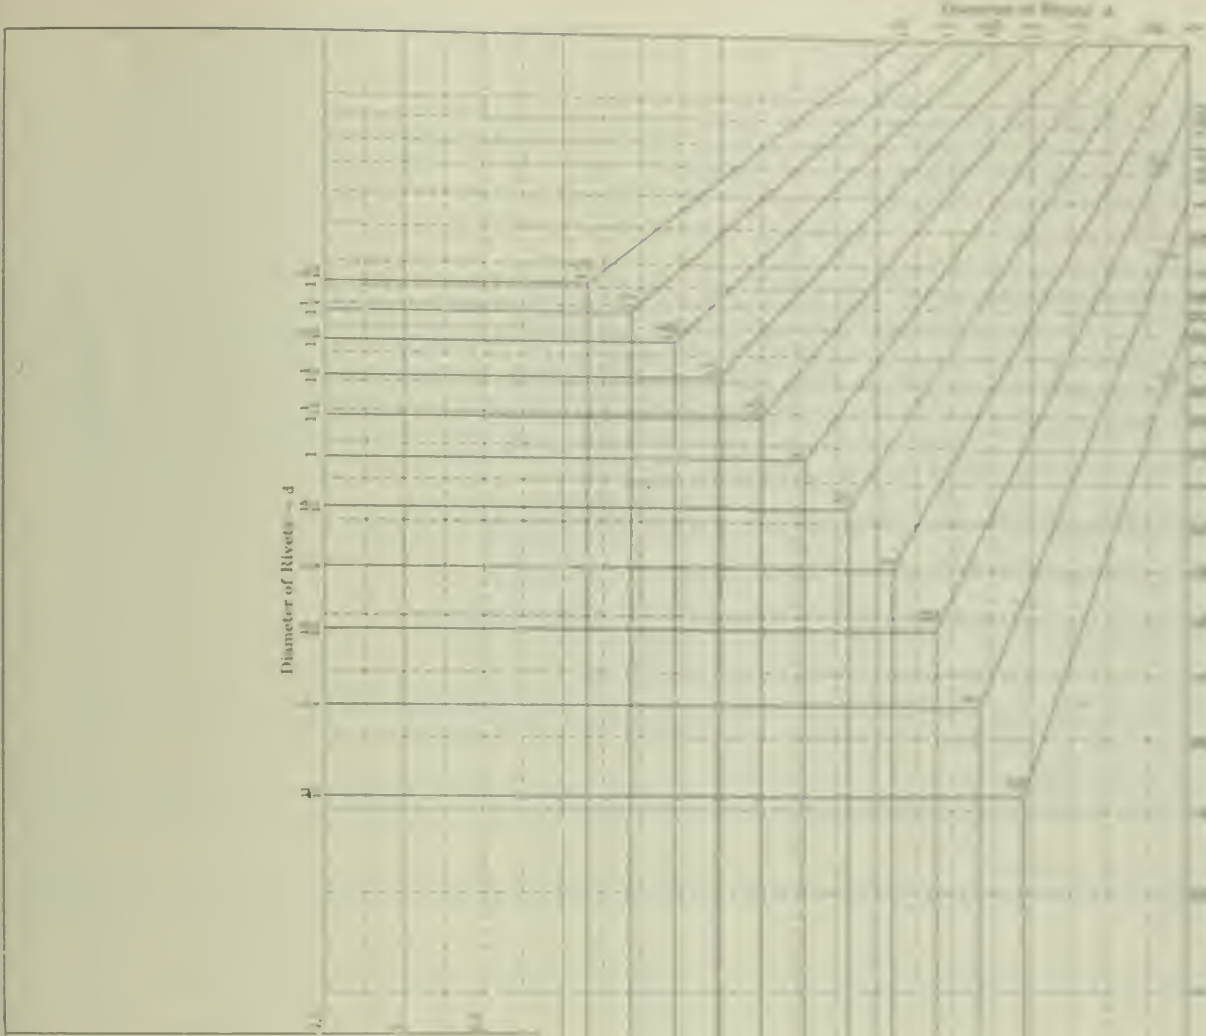
or

$$t = \frac{0.7854\ d\ s}{T},$$

and when $T = 55{,}000$ and $s = 42{,}000$,

$$t = 0.6\ d.$$

This signifies that if a perpendicular is erected on the axis X at a point, $t = 0.6\,d$, all values to the right of this line would indicate joints which would fail by method (B) rather than (A), for it may be seen from the equations that an increase in the thickness of plate, or t, increases the value of equation (A) more rapidly than equation (B). Therefore for increased values of t beyond the point where (A) and (B) become equal, the joint becomes relatively weaker to resist rupture by method (B). Since this is true, the lines denoting the relation be-

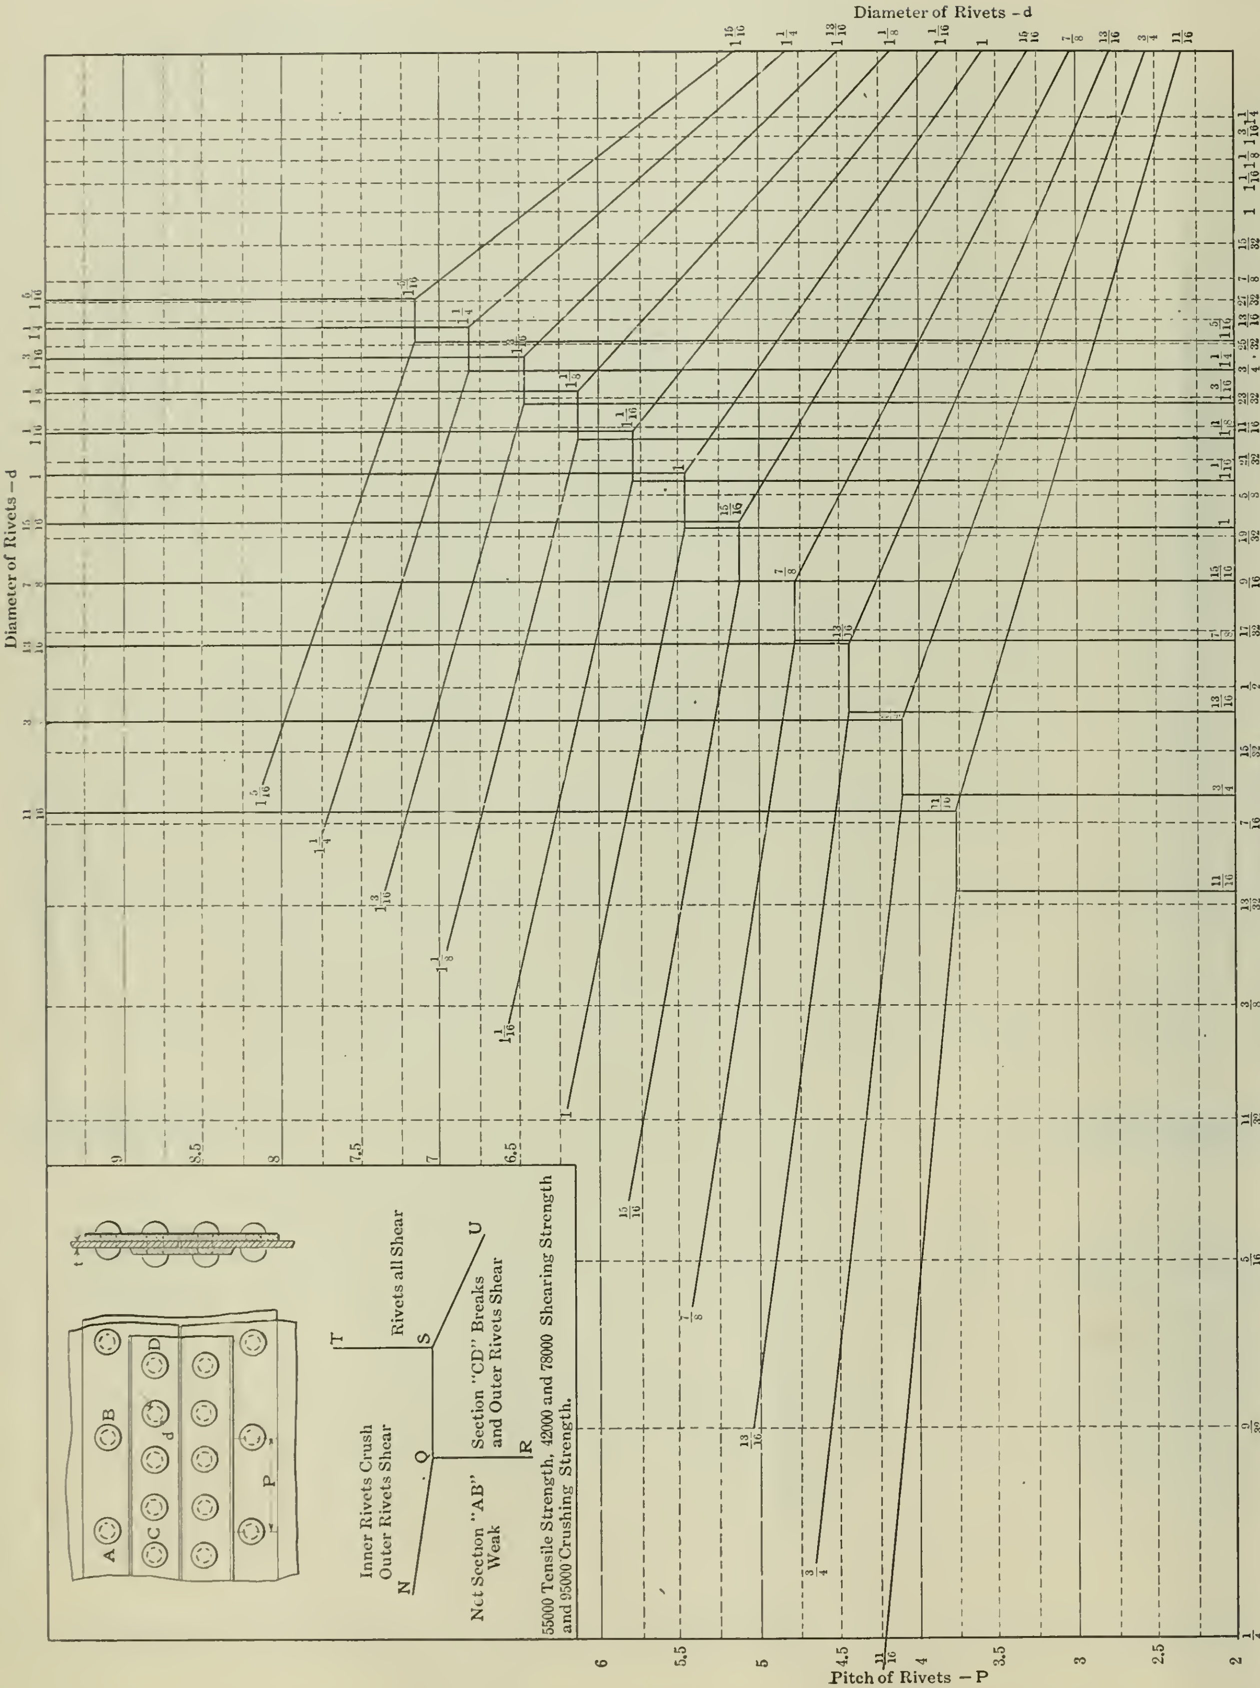


tween the various modes of failure can be plotted in the area to the right of $l = 0.6 d$, without regard to equation (A).

Noting equations (B), (C) and (D), it is seen that the term $0.7854 \, d^2$ is common to them all, so that for the purpose of comparison this term may be dispensed

[illegible]

[illegible]



DOUBLE-RIVETED DOUBLE-STRAPPED BUTT JOINTS WITH TWO PITCHES

origin *O*. The reason for placing the origin at the right is so that increasing values of *t* could be read from left to right, as this is more natural than the reverse.

Comparing equations (*B*) and (*C*),

$$(P - 2d)\,t\,T = 2\,C\,d\,t,$$

and solving for *P*

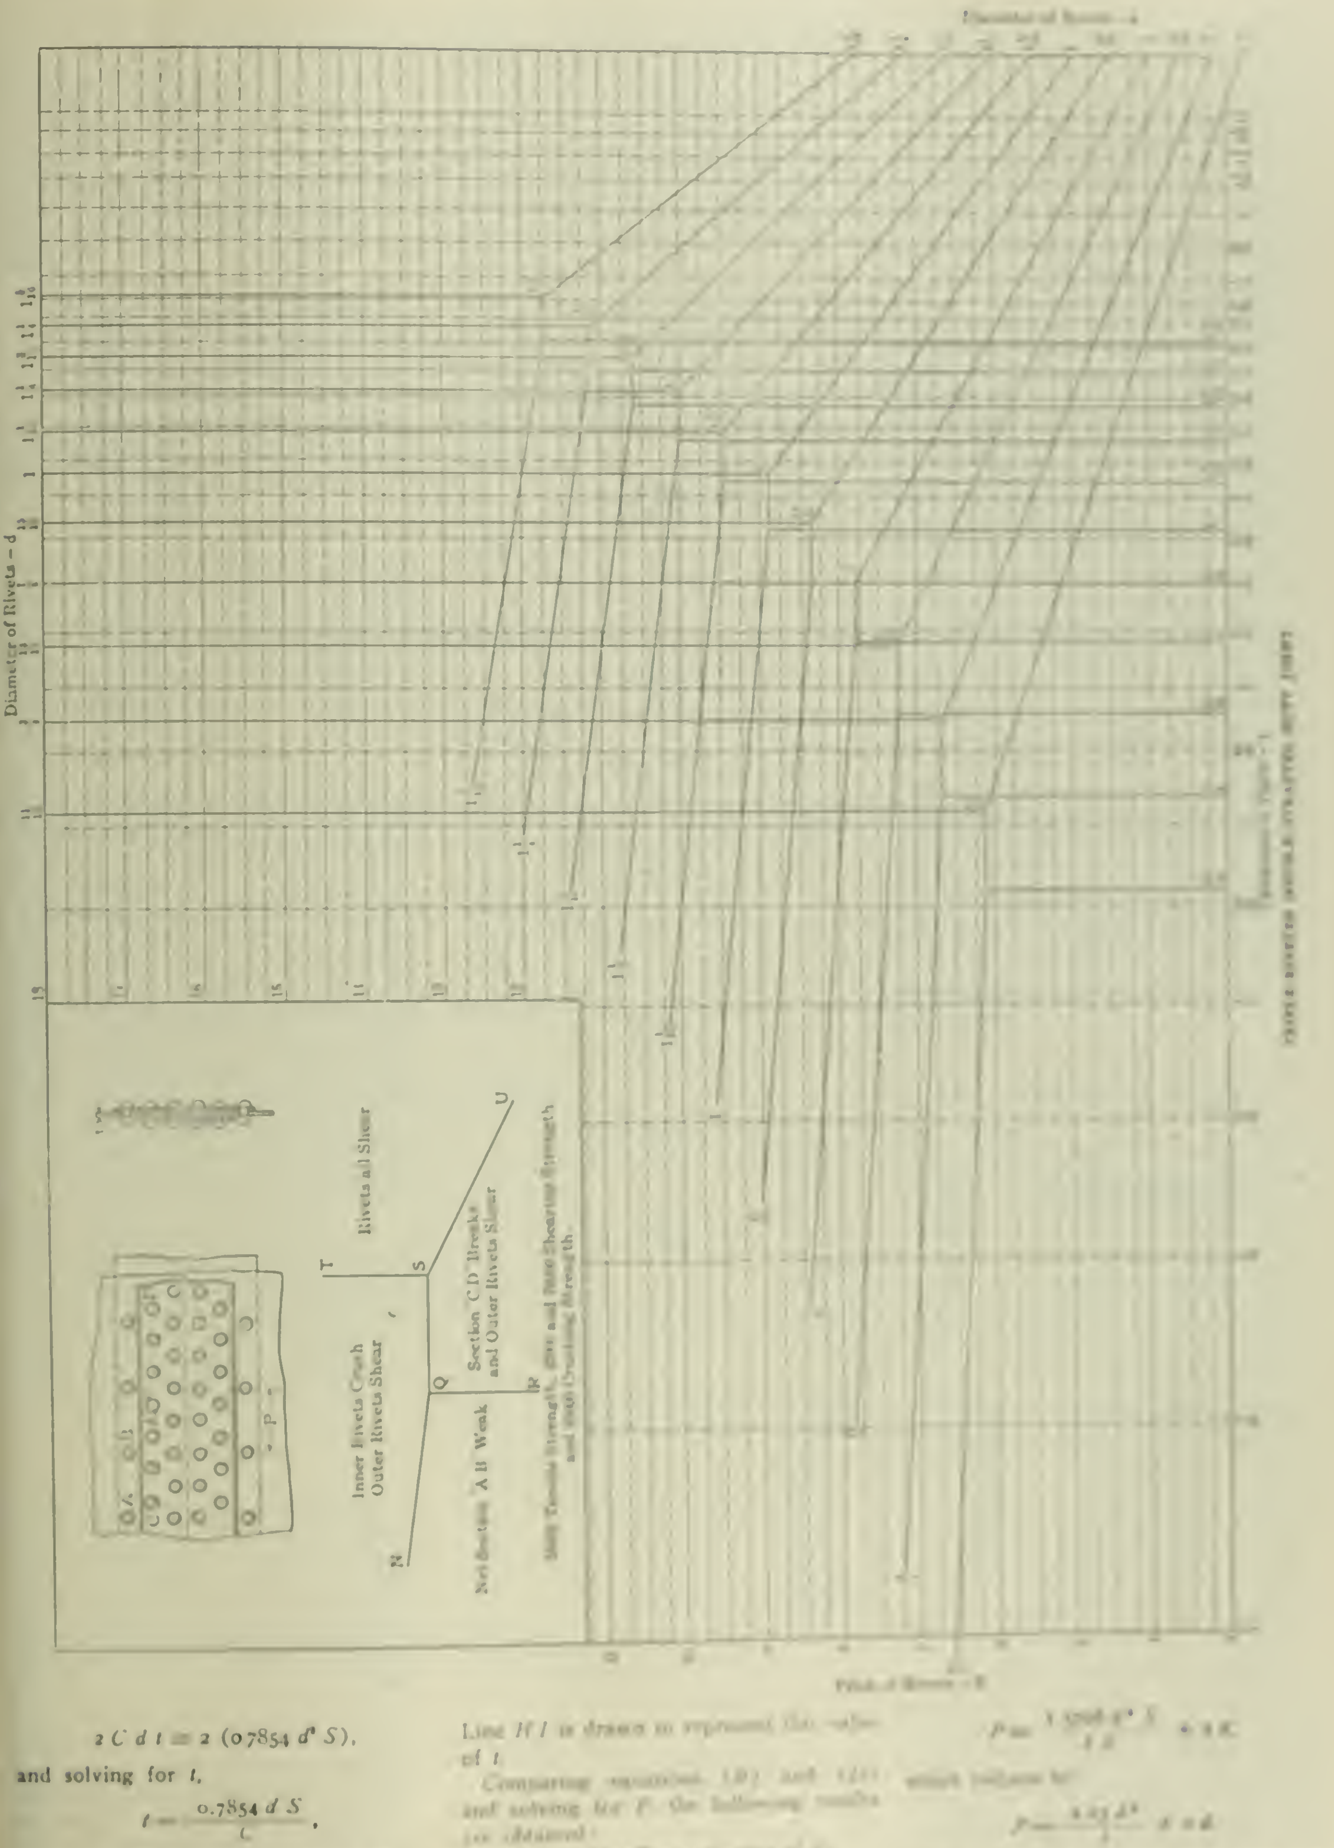
$$P = \frac{2\,C\,d}{T} + 2\,d,$$

or

$$P = 5.45\,d,$$

when $C = 95{,}000$ and $T = 55{,}000$. Line *FG* is drawn at a suitable hight above *X* to represent this value of *P* when $d = \frac{3}{4}$ inch.

Comparing equations (*C*) and (*D*), the following result is obtained:



$$2\,C\,d\,t = 2\,(0.7854\,d^2\,S),$$

and solving for t,

$$t = \frac{0.7854\,d\,S}{C},$$

or when $S = 78{,}000$ and $C = 95{,}000$

$$t = 0.645\,d.$$

Line $H\,I$ is drawn to represent the value of t.

Comparing equations [illegible] and [illegible] and solving for P the following results are obtained:

[illegible]

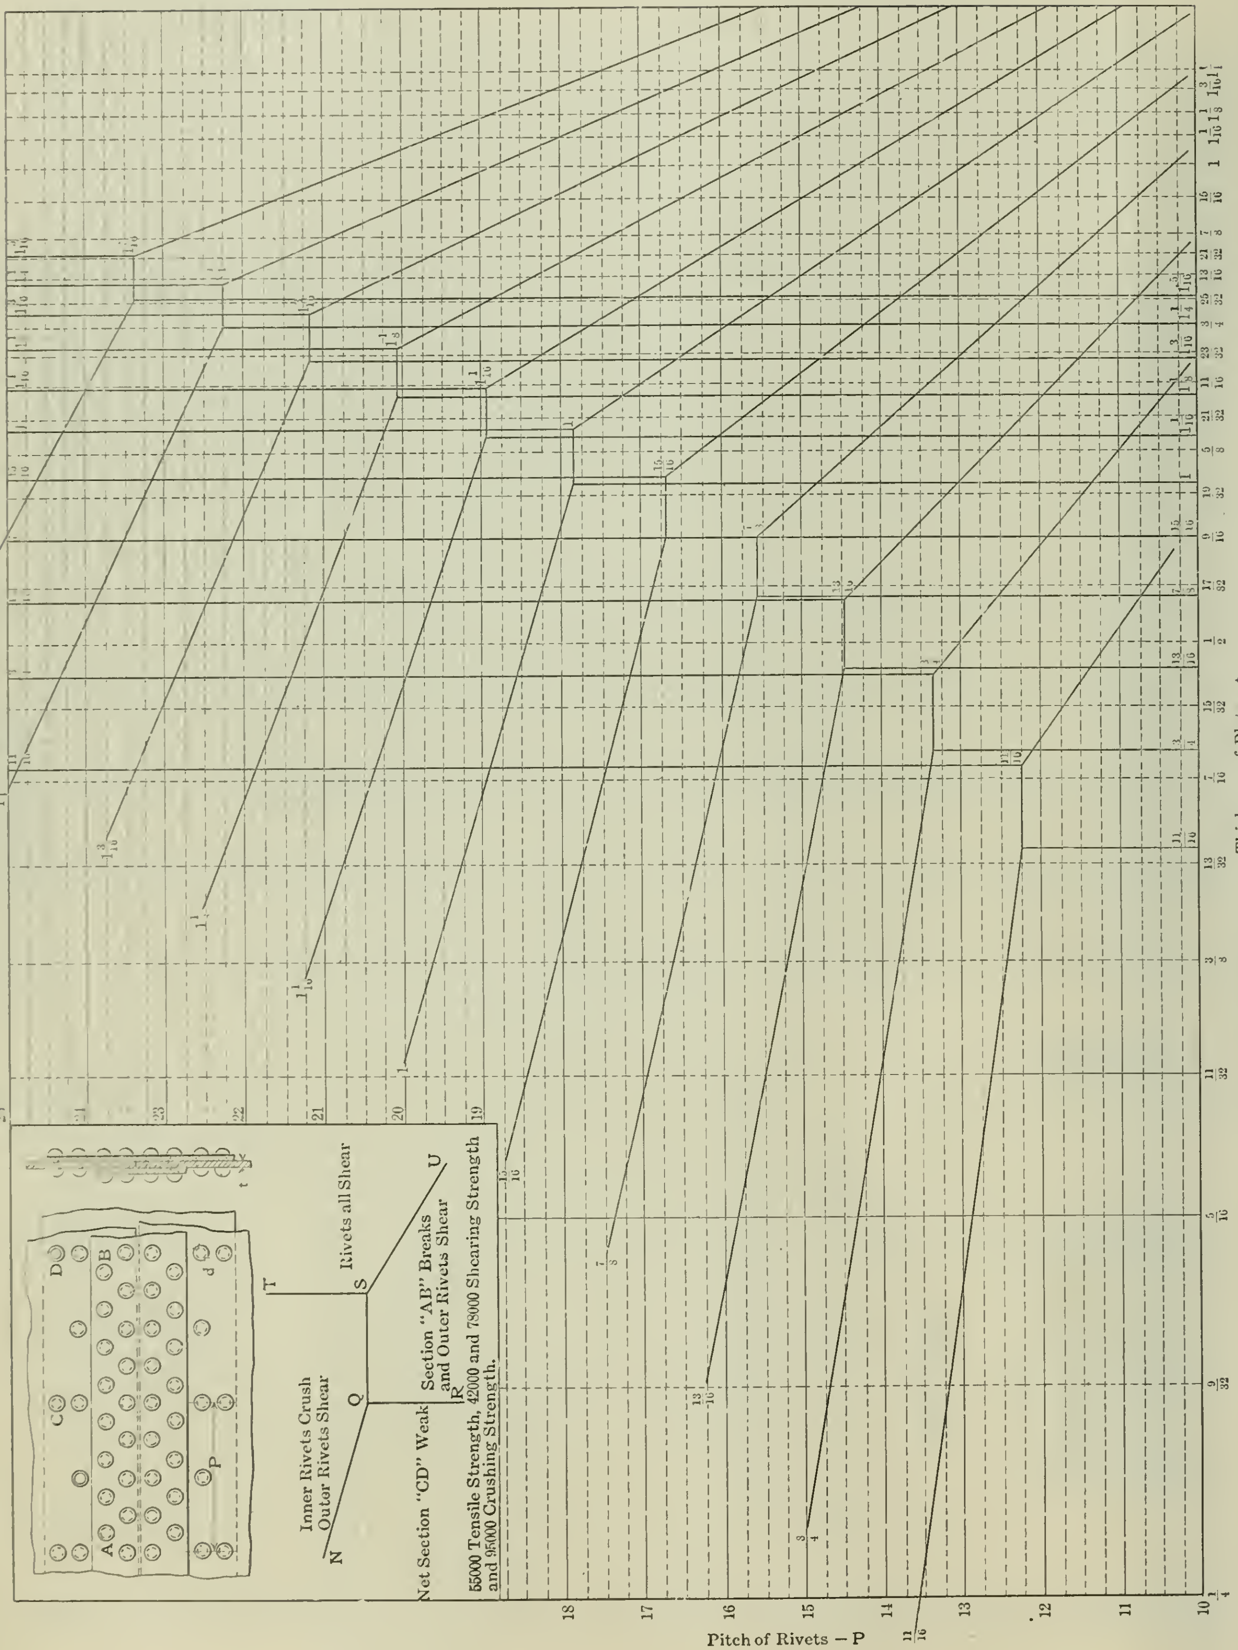
or

$$P = \text{[illegible]}$$

which reduces to

$$P = \text{[illegible]}$$

This line starts the same [illegible]



QUADRUPLE-RIVETED DOUBLE-STRAPPED BUTT JOINT

above the axis X, or at K in Fig. 3. Another point on this line is at the intersection of $F G$ and $H I$ at L, and the line $M K$, drawn through these points, represents the last equation. For the same reasons explained in describing the construction of Fig. 1, the dotted portions of lines $H I$, $F G$ and $M K$ are superfluous.

Returning to the original equations (A), (B), (C) and (D) to plot the diagram to the left of $D E$, the equation (B) is of no further use, since values for it in this area would be high as compared with (A). Now since the line $H I$ represents equal values for joint failure by method (C) or (D), and the value of (C) increases or decreases with that of t, while equation (D) is not affected by variations in t, it is evident that in the area to the left of HI, which represents decreasing values of t, that failure by method (D) need not be considered, and since the area to the left of HI also includes all of the area to the left of DE there remains only one comparison to be made to complete the diagram, which is that between equations (A) and (C) as follows:

$$(P - d)\ t\ T = 2\ C\ d\ t + 0.7854\ d^2\ s$$

or

$$P = \frac{2\ C d}{T} + \frac{0.7854\ d^2\ s}{t\ T} + d,$$

or when $s = 42{,}000$, $T = 55{,}000$ and $C = 95{,}000$

$$P = \frac{0.6\ d^2}{t} + 4.45\ d$$

It will be noted from this equation that when t is given a value of $0.6\ d$, corresponding to line DE, Fig. 3, that $P = 5.45\ d$, or is equal to the value of P for the line FG. Therefore the point F is one of the points on the line

$$P = \frac{0.6\ d^2}{t} + 4.45\ d,$$

and another point is where it cuts the axis Y at N, which lies $4.45\ d$ above the axis X. It is only necessary to join the points N and F by a straight line extending beyond F as NP. The dotted portion of this line FN has no significance, as only comparative values lying to the left of DE are being sought. The diagram is now complete with the exception of explaining that the dotted portion of DE has no bearing on the methods of failure in the area in which it lies, since it represents comparative values between modes of failure, designated by equations (A) and (B), and all values for these equations lying above PF and FG are greater than for (C) or (D).

The line FP is terminated at a value for t which would make the rivets equally as liable to crush or shear, single shear, or in the same position occupied by the vertical lines representing rivet diameters in the lap-joint diagrams, which is

$$t = \frac{0.7854\ d\ s}{C}$$

or $0.347\ d$, when $s = 42{,}000$ and $C = 95{,}000$. The diagram would be correct for all thicknesses of straps or plates above this thickness. For ¾-inch rivets this thickness would be 0.26 inch, or slightly more than ¼ inch; for 15/16-inch rivets and the same values for C and s, this value of t would be between 7/16 and 15/32 inch. It will be found that the proportions between rivet diameters and thickness of plates is such in practical boiler construction that the points will fall well within the limits of the diagrams. Redrawing Fig. 3 with the dotted portions of the lines omitted, the result would be like Fig. 4, in which the probable method of joint failure is indicated in the different sections of the diagram.

The diagrams for triple- and quadruple-riveted joints are derived in a similar manner to the above, and the equations for the several lines in the three types of joint are as follows. As before, the letters designating the lines refer to those on the small guide diagram in the upper corner of each sheet.

DOUBLE-RIVETED BUTT JOINT WITH TWO PITCHES

Line QN:

$$P = \frac{0.7854\ d^2\ s}{t\ T} + \frac{2\ d\ C}{T} + d$$

Line QR:

$$t = \frac{0.7854\ d\ s}{T}$$

Line QS:

$$P = \frac{2\ C\ d}{T} + 2\ d$$

Line ST:

$$t = \frac{0.7854\ d\ S}{C}$$

Line SU:

$$P = \frac{1.5708\ d^2\ S}{t\ T} + 2\ d$$

TRIPLE-RIVETED BUTT JOINT WITH TWO PITCHES

Line QN:

$$P = \frac{0.7854\ d^2\ s}{t\ T} + \frac{4\ d\ C}{T} + d$$

Line QR:

$$t = \frac{0.7854\ d\ s}{T}$$

Line QS:

$$P = \frac{4\ C\ d}{T} + 2\ d$$

Line ST:

$$t = \frac{0.7854\ d\ s}{C}$$

Line SV:

$$P = \frac{3.1416\ d^2\ S}{t\ T} + 2\ d$$

QUADRUPLE-RIVETED BUTT JOINT WITH THREE PITCHES

Line QN:

$$P = \frac{2.356\ d^2\ s}{t\ T} + \frac{8\ d\ C}{T} + d$$

Line QR:

$$t = \frac{0.7854\ d\ s}{T}$$

Line QS:

$$P = \frac{8\ C\ d}{T} + 4\ d$$

Line ST:

$$t = \frac{0.7854\ d\ s}{C}$$

Line SU:

$$P = \frac{6.28\ d^2\ S}{t\ T} + 4\ d$$

Attention is called to a point in the diagrams for butt joints which is slightly confusing, this being that the values of C, T, s and S, for which the diagrams are constructed, are so related that the lines corresponding to tC and sE, in Fig. 5, for ¾-inch and 15/16-inch rivets come in line with each other, and also coincide with the line for 9/16-inch plate thickness. This line is therefore marked ¾-inch rivet at the top of the sheet, and 15/16-inch rivet and 9/16-inch plate at the bottom, but with care in the use of the diagrams, when these particular values are required, no trouble should ensue.

To illustrate the use of the diagrams for butt joints with more than one pitch of rivets, suppose that it was desired to know the smallest size of rivet which would be required in a double-riveted butt joint of ½-inch plate and rivets to be pitched 5 inches apart, so that the net section between the outer rows would be the most likely point of failure; placing a pencil point at the intersection of the lines denoting ½-inch plate and 5-inch pitch on the diagram for this joint, it is seen that a rivet 15/16 inch in diameter or greater would be required, and if a 15/16-inch rivet were used in this joint the crushing of the inner rivets and the shearing of the outer ones would be the weakest mode of possible failure, or if ¾-inch rivets were used the joint would fail by shearing all rivets. It should be distinctly understood that when the diameter of rivets is spoken of, the diameter after driving or the diameter of the rivet hole is the one referred to.

The Country's Fuel Supply

According to the report recently made public of the sections of proceedings of the National Conservation Commission, the available and easily accessible supplies of coal in the United States aggregate approximately 1,400,000,000,000 tons. At the present increasing rate of production this supply will approach exhaustion before the middle of the next century. From the beginning of coal mining in this country down to the close of 1907 there were mined [illegible] tons, and it is estimated that for every ton produced half a ton has been lost or wasted, so that the gross production represents an exhaustion of the coal supply of [illegible] tons.

The first step in extending the life of our fuel supply should be to lessen the waste in mining, handling and burning.

The known supplies of petroleum, natural gas, iron and high-grade phosphate rock cannot be expected to last much beyond the middle of the present century.

One of the advantages attributed to the use of larger boiler units is the reduction in attendance and amount of coal burned and of water evaporated.

How to Use Riveted Joint Diagrams*

Thorough Instructions on the Practical Use of the Diagrams, Illustrated by a Complete Set of Examples, with Answers, on Each Type of Joint

BY S. F. JETER

The following explanation and instructions for the use of the diagrams, given in the article on calculating strength of riveted joints, are for those readers who do not care to follow the mathematical reasoning given in connection with the construction of the diagrams, but who wish to use them as an aid in caluculating the strength of such joints.

It is assumed that the article on page 28 of the July number of POWER AND THE ENGINEER, giving the detailed method of calculating the different joints, is thoroughly understood. In that article it was shown that in all joints of either the lap-riveted or the butt-strapped type, in which the rivets were arranged to give only one pitch, there were three possible modes of joint failure; consisting of breaking of the net section of the plate, shearing of the rivets, or crushing of the rivets. It was necessary to find the numerical value of each one of these modes of failure in order to determine which one was the weakest of the three, and the value of this weakest mode of failure was alone used in obtaining the efficiency of the joint.

DIAGRAMS OF SINGLE-PITCH JOINTS

The purpose of the diagrams is to make it necessary to calculate only the weakest mode of failure, as by their aid this may be selected without calculation as follows: Taking the diagram for a single-riveted lap joint for illustration, it is seen that below the drawing showing the type of joint in the upper right-hand corner of the sheet, there is a small diagram which will be known as a guide diagram, consisting of three lines, *OK*, *OL* and *OM*. These three lines represent any similar set of three full lines in the main diagram, which is seen to contain eleven sets, and each set of these lines represents a given rivet diameter, the particular diameter represented being noted at the intersection of the lines, at the upper end of the vertical lines and at the right-hand end of the inclined lines. In addition to the sets of full lines in the main diagram, it will be noted that there are also dotted and dashed horizontal lines and dotted vertical lines, extending across the sheet in each direction; the former represent pitch of rivets in inches and quarters, the numbers at the left-hand side of the sheet giving the value represented by each line. The lines representing even inches are made with long dashes to permit the eye more readily to distinguish them from lines representing half and quarter inches. The vertical dotted lines represent thickness of plate, and the particular thickness represented by each line is printed under its lower extremity.

To determine the weakest mode of failure for a given joint, it is only necessary to find in which section of the diagram, with reference to the full lines indicating the given rivet diameter, the intersection of the lines corresponding to the pitch of rivets and thickness of plate lie, and when this is found the method of failure printed in the corresponding section of the guide diagram is the one sought. It should be remembered that in using the diagrams in this way for a particular size of rivet, that all other full lines representing other sizes of rivets have no significance whatever, and they should be considered as not existing for the time being. Thus with a rivet diameter of 1 inch, all points of intersection between lines denoting pitch of rivets and thickness of plate, lying to the right of the vertical line for 1-inch rivets and above the inclined line corresponding to *OM* of the guide diagram, would denote that joints composed of such pitches of rivets, thicknesses of plate and with 1-inch diameter rivets, would fail by shearing the rivets. Values of pitch and thickness of plate given by lines on the diagram for a single-riveted lap joint (page 00) whose intersections would lie in this area, would be as follows: 3/8-inch plate, and any pitch of rivets of 2 3/4 inches or more; 13/32, 7/16- or 15/32-inch plate, and any pitch of rivets of 2 1/2 inches or more; 1/2-inch plate, and any pitch of rivets of 2 1/4 inches or more, and so on as far as the diagram extends. All joints containing the above relative values of pitch of rivets and thickness of plate, where 1-inch rivets are used, would fail by shearing the rivets.

Intersections of pitch and thickness of plate, which lie in the area corresponding to that marked "net section weak" in the guide diagram, would indicate that this method of failure would be the most likely one in joints constructed with similar values. Such intersections would be for 1-inch rivets, 2 1/2-inch pitch and any thickness of plate up to and including 3/8-inch plate; or 2 1/4-inch pitch and any thickness of plate up to and including 15/32-inch plate; or 2-inch pitch and any thickness of plate up to and including 19/32-inch plate, and so on. If the intersections lay in the area corresponding to that marked "rivets crush" this would be the most likely mode of joint failure; for 1-inch rivets such values would be represented by any pitch of rivets 2 3/4 inches or greater and any thickness of plate up to and including 11/32 inch.

From the foregoing it is seen that to calculate the efficiency of any joint, it is only necessary to find in which section of the diagram, with reference to the lines denoting the rivet size, the intersection of lines denoting pitch of rivets and thickness of plate lie, and calculate the value of the particular mode of failure printed in the corresponding section of the guide diagram, and divide this by the value found for the strength of the solid plate. The result is the true efficiency of the joint.

For example, assume a single-riveted double-strapped butt joint, in which the rivets are 3/4 inch diameter and pitched 2 1/4 inches apart, and a plate thickness of 3/8 inch. By referring to the diagram for this type of joint, it is seen that the intersection of the lines corresponding to 2 1/4-inch pitch of rivets and 3/8-inch thickness of plate, lies in the area (with respect to the lines denoting 3/4-inch rivets) corresponding to that marked "rivets crush" in the guide diagram. Therefore, the efficiency would be .

$$\frac{\textit{Diameter of Rivets} \times \textit{Thickness of Plate} \times 95{,}000}{\textit{Pitch of Rivets} \times \textit{Thickness of Plate} \times 55{,}000};$$

or since the thickness of plate is common to both numerator and denominator, it would cancel out, leaving

$$\frac{3/4 \times 95{,}000}{2 1/4 \times 55{,}000} = 57.6$$

per cent. efficiency.

If the other methods of failure had been considered, the results would be as follows: Breaking of net section, 62.2 per cent. efficiency; or for shearing of the rivets, 74.2 per cent. efficiency, and since these two latter values are higher than the first, the method of failure indicated by the diagram gives the true efficiency of the joint.

It follows that since the lines representing rivet diameters, which correspond to *O M* in the guide diagram, lie between the area denoting shearing of the rivets, or the breaking of the net section of the plate, that where the lines for thickness of plate and pitch of rivets intersect on this line, joint failure is equally liable by either method. For example, the line corresponding to $O M$ for $1\frac{1}{16}$-inch rivet diameter (in the diagram for single-riveted lap joints) apparently passes through the point of intersection of lines denoting 2½-inch pitch and 15/32-inch plate, and if a joint of this type should be constructed with these dimensions, it would be as likely to fail by breaking the net section of the plate between the rivet holes, as by shearing the rivets, and the value of either of these methods of failure might be used in obtaining the efficiency of the joint. Calculating the value of the two modes of failure would result as follows: For shearing of the rivets,

$$0.8866 \times 42{,}000 = 37{,}237$$

pounds, and for the strength of the net section of the plate,

$$(2\tfrac{1}{2} - 1\ 1/16) \times 15/32 \times 55{,}000 = 37{,}061$$

pounds. It is seen that there is a difference of 175 pounds in these two values, and if the diagram was made to a larger scale and absolutely accurate, the line for 1 1/16-inch rivet would be seen actually to pass above the intersection of lines for 15/32-inch plate and 2½-inch pitch of rivets. However, the diagrams are sufficiently accurate for all practical purposes, for when using the shearing strength of the rivets in obtaining the joint efficiency, it is found to be 57.77 per cent., while by using the strength of the net section of the plate, it is 57.5 per cent., so that practically it would make no difference which method of failure was used in the calculation.

If any value of thickness coincided with a vertical line for rivet diameter, it would indicate that the value of the crushing strength of the rivets or their shearing strength could be used indiscriminately in obtaining the efficiencies of joints made with this thickness of plate and diameter of rivet, where the rivets were spaced so that the lines indicating the pitch crossed the vertical line indicating rivet diameter. There is no thickness of plate shown on the diagram for single-riveted lap joints, which actually coincides with any line representing rivet diameter, the lines for 13/16-inch rivets and 9/32-inch plate coming the nearest. The actual thickness which would exactly coincide with the vertical line for 13/16-inch rivets would be 0.28213 inch, and with this thickness of plate and 13/16-inch rivets, and any pitch 2¼ inches or greater, the joint efficiency could be obtained by using the value of either the crushing or shearing of the rivets, as the value of both would be the same and less than the strength of the net section of the plate between the rivet holes.

If any horizontal line denoting pitch of rivets should coincide with a horizontal line for any rivet diameter, a joint consisting of this particular size of rivet and pitch would have an equal value for joint failure by crushing the rivets or breaking the net section of the plate for any thickness which crossed the horizontal line indicating the rivet size. For example, in the double-riveted double butt-strapped joint with one pitch (page 60), 1⅛-inch rivets were used and pitched 4¼ inches apart, any thickness of plate up to and including 21/32-inch thickness would give a joint which would be as likely to fail by the rivets crushing as by the breaking of the net section of the plate, and therefore either could be used in estimating the strength of the joint.

It follows from the foregoing that if the thickness of the plate and the pitch of the rivets were such that the lines which would represent them should intersect at the same point as those denoting any rivet diameter (as O in the guide diagram), a joint constructed of these values for pitch of rivets, thickness of plate and diameter of rivets, would be likely to fail by either of the three methods of joint failure and this would also represent a joint of maximum efficiency. In the single-riveted lap joint, values of 2¼-inch pitch, 9/32-inch plate and 13/16-inch rivets, come very near fulfilling these conditions, although the crushing strength of the rivets is a little the weakest mode of failure.

The instructions for the use of the diagrams given thus far apply to all forms of joint, both lap-riveted and butt-strapped, in which only one pitch to the rivets occurs, and it will be noted that the diagrams for all these joints are alike in form.

Joint Diagrams with Two or More Pitch Values

The following instructions are for the use of the diagrams constructed for the butt-strapped type of joint in which two or more pitches of rivets occur. The general principles for the use of the diagrams are the same as for single-pitch joints, that is, the area in which the intersection of lines denoting pitch of rivets and thickness of the plate lie, determine the weakest mode of joint failure as indicated by the guide diagrams, and if the intersections happen to fall on the lines indicating the rivet diameter for the given joint, either of the modes of failure noted in the adjacent areas may be used in determining the efficiency of the joint.

Taking the diagram for the triple-riveted butt joint for illustration, it is seen that it differs from the first diagrams in that the full lines denoting rivet diameter divide the space into four sections instead of three, and, as shown by the guide diagram, the two top areas denote joint failure by crushing of the inner rivets and shearing the outer rivets, or the shearing of all the rivets. The two lower areas indicate joint failure by breaking of the outer net section between the rivet holes, or the breaking of the inner net section and the shearing of the outer rivets.

It will be seen that the lines indicating rivet diameters, corresponding to the line $S O$ of the guide diagram, do not extend to the left-hand side of the charts, as was in the case of the 11/16-inch rivet. The explanation for this is, that for mathematical reasons it is required that the two methods of joint failure in which the crushing of the rivets in the outside rows is involved for this type of joint, be eliminated, leaving only the four modes of failure, as shown in the guide diagram. This could be accomplished by making the diagrams apply only to joints in which the thickness of plate and straps are such that the lines indicating the plate thickness cross, at some point, those indicating the rivet diameter used. For example, in joints in which ¾-inch rivets are used, the diagrams would hold good for thicknesses of plate or straps of 5/16 inch or more, but not for thicknesses less than 5/16 inch. If 1⅛-inch rivets were used, the plate and straps must be 13/32 inch or more, and so on, the last vertical line to the left indicating plate thickness, which crosses the full line representing the rivet diameter, being the minimum thickness of plate or straps for which the diagrams are constructed. This limit to the range of the diagrams will not interfere with their usefulness in the least, for the range covered includes all practical boiler joints.

The rivet sizes to which each set of full lines apply are given at the extremities of the vertical lines and the angular lines, and also at the intersections corresponding to the point S in the guide diagram. Using a ¾-inch rivet for illustrating the use of the diagram for a triple-riveted butt joint (page 60), it is seen that if 7/16-inch plate is used with this size of rivet and the rivets are pitched 5¼ inches apart in the outer rows, joint failure would occur by breaking the outer net section; while if the plate thickness had been 15/32 inch, the pitch remaining the same, failure would occur by breaking the inner net section and shearing the outer rivets; if ½-inch plate had been used, the failure would have been equally as likely by the breaking of the inner net section and shearing the outer rivets, or shearing all the rivets both in single and double shear; if 17/32-inch plate were used, the failure would occur by shearing of all the rivets rather than by any of the other possible modes of failure.

If a pitch of 5¾ inches were selected instead of 5¼ inches, and 7/16- or 15/32-inch plate used, the failure of the joint would occur by the crushing of the rivets passing through both straps and the shearing of the outer rivets, while if the plate thickness were ½ inch with this pitch, failure would occur by shearing all of the rivets, both in single shear and in double shear.

In using the diagrams to calculate the efficiency of a given joint it will be found to be most convenient to proceed as follows: Assuming a quadruple-riveted double-strapped butt joint in which the plate thickness is [illegible] inch and the rivets are pitched 15 inches apart in the outer row, their diameter being 13/16 inch, what would be the efficiency of this joint? Commencing at the bottom of the sheet on the line marked 17/32-inch plate, follow up the line until the horizontal line representing 15 inches pitch is reached hold a pencil or other pointer on the intersection of these two lines, leaving the eye free to locate the full lines indicating 13/16-inch rivet diameter, and it is readily seen that the point upon which the pencil is held lies in the area corresponding to that marked "rivets all shear" in the guide diagram.

After using the diagrams a few times the apparent confusion, caused by the numerous lines representing the rivet diameters, will disappear entirely; however, if it was desired, the reader could retrace the diagrams, placing only a single rivet diameter on each sheet, and the diagrams would then have the same appearance as the guide diagram, with the dotted and dashed lines representing the pitch of rivets and thickness of plate added.

There is one point in connection with the diagrams for double-strapped butt joints with two pitches that should be carefully noted, and that is the line corresponding to *Q R* of the guide diagrams, for 15/16-inch rivets, coincides with the one corresponding to line *T S* for ⅞-inch rivets, and therefore the portion lying between the intersection marked ⅞ inch up to the next set of full lines representing 15/16-inch rivets belongs to both rivet diameters, and it also represents throughout its entire length 9/16-inch plate thickness. It will be observed that the correct rivet diameter represented by the upper portion of the line is placed at the top of this sheet, while that represented by the lower portion is placed at the bottom, so that by using these figures to locate the lines, rather than those given at the intersections of the lines given in the center of the diagrams, when ⅞- or 15/16-inch rivets are used, confusion will be avoided.

It should be thoroughly understood that the diagrams shown are only correct for a tensile strength of plate of 55,000 pounds per square inch, shearing strength of rivets of 42,000 pounds per square inch for single shear and 78,000 pounds per square inch when in double shear, and 95,000 pounds per square inch crushing resistance of the rivets. When rivet diameters are spoken of, the driven diameter of the rivet or the diameter of the rivet hole is referred to.

A feature of the quadruple-riveted double-strapped butt joint, which was not brought out in the July 7 article, may be properly mentioned here. This is, that the failure of this type of joint by the breaking of the plate along the second row of rivets and shearing the rivets in the outer row need not be considered, because it can never be weaker than both the failure by breaking of the outer net section and that of breaking the inner net section and shearing the rivets in the two outer rows, but its value will always lie between these two. Consequently when they become equal to each other, it also is equal to them. Thus, if the line indicating the plate thickness for a given joint of this type should coincide with the line corresponding to *O R* for the rivet size used in the joint, failure would be equally liable by either of the three methods, but for all other values of thickness of plate, one of the two latter methods would be the weaker of the three. As may be seen from the diagram, a joint of 9/16-inch plate and 15/16-inch rivets, with any pitch up to and including 16½-inch, would render failure equally liable by either method.

EXAMPLES FOR PRACTICE

The following questions and answers will be found a convenient aid in becoming familiar with the use of the diagrams. The answers are given separate from the questions, but both are numbered alike, and the reader may write his own answers to the questions and then compare them with the answers given, and in this way test his ability to use the diagrams correctly. Eight questions are asked for each type of joint; the first five relating to the use of the diagrams in obtaining joint efficiencies, and the three last to illustrate other uses for the diagrams.

Single-riveted Lap Joint

What method of joint failure should be compared with the strength of the solid plate to ascertain the efficiency of the following joints?

(1) ⅜-inch plate, 2½-inch pitch and 1-inch rivets.

(2) 13/32-inch plate, 2½-inch pitch and 1-inch rivets.

(3) 7/16-inch plate, 2½-inch pitch and ¾-inch rivets.

(4) 7/16-inch plate, 2¾-inch pitch and 15/16-inch rivets.

(5) 5/16-inch plate, 2¾-inch pitch and 15/16-inch rivets.

(6) What is the smallest rivet diameter that could be used, if the pitch were 2¼-inch and plate thickness 9/32-inch, to insure that the joint would fail by breaking the net section of the plate?

(7) If a joint were made with 13/16-inch rivets and 7/16-inch plate, what would be the smallest pitch of rivets that would cause the joint to fail by shearing the rivets?

(8) With 1 1/16-inch rivet diameter, what thickness of plate would make failure by crushing the rivets impossible?

Double-riveted Lap Joint

What would be the weakest mode of failure for the following joints?

(1) 11/32-inch plate, 3-inch pitch and ¾-inch rivets.

(2) 19/32-inch plate, 3-inch pitch and 1-inch rivets.

(3) ⅝-inch plate, 2½-inch pitch and ⅞-inch rivets.

(4) 7/16-inch plate, 2¾-inch pitch and 11/16-inch rivets.

(5) 13/32-inch plate, 2¾-inch pitch and 13/16-inch rivets.

(6) With 5/16-inch plate, what is the smallest pitch and diameter of rivets which would cause joint failure by crushing the rivets?

(7) With 17/32-inch plate and 13/16-inch rivets, what would be the longest pitch that could be used and insure that the joint would fail by breaking the net section of the plate between the rivet holes?

(8) With ⅞-inch rivets, what pitch would be required if the crushing of the rivets was to be one of the possible methods of joint failure? What thickness of plate would this method of joint failure hold good for?

Triple-riveted Lap Joint

What method of joint failure would be most likely in the following joints?

(1) ⅜-inch plate, 3-inch pitch and 11/16-inch rivets.

(2) 11/32-inch plate, 3-inch pitch and 1-inch rivets.

(3) 23/32-inch plate, 3¼-inch pitch and 15/16-inch rivets.

(4) 23/32-inch plate, 3¼-inch pitch and 1-inch rivets.

(5) 13/32-inch plate, 3¼-inch pitch and ¾-inch rivets.

(6) Would it be practical to design a joint with values for rivet diameter and thickness of plate as given in the diagram, in which failure would occur by crushing the rivets?

(7) What would be the least pitch shown on the diagram that would cause joint failure by crushing the rivets, if the plate thickness was ¼ inch and the rivet diameter ¾ inch?

(8) With 21/32-inch plate and 11/16-inch rivets, what would be the least pitch that would cause the rivets to shear?

Single-riveted Double-strapped Butt

What method of joint failure should be compared with the solid plate, in estimating the efficiencies of the following joints?

(1) ⅜-inch plate, 2½-inch pitch and ¾-inch rivets.

(2) ½-inch plate, 2-inch pitch and ¾-inch rivets.

(3) ½-inch plate, 2¼-inch pitch and 13/16-inch rivets.

(4) 21/32-inch plate, 2¼-inch pitch and ¾-inch rivets.

(5) ¾-inch plate, 3-inch pitch and 1-inch rivets.

(6) There are only two possible modes of joint failure for all thicknesses of plate and rivet diameters shown on the diagram up to and including 7/16-inch plate. What are they?

(7) How would all joints with ⅞-inch rivets and 2½-inch pitch or over fail, if the plate thickness were 9/16-inch?

(8) Would rivets crush in any joint made of plate 17/32-inch or over, if the rivet diameters were not over 13/16-inch?

DOUBLE-RIVETED DOUBLE-STRAPPED BUTT JOINT WITH ONE PITCH

What would be the most likely mode of failure in the following joints?

(1) 19/32-inch plate, 3¾-inch pitch and ⅞-inch rivets.

(2) 7/16-inch plate, 3-inch pitch and 11/16-inch rivets.

(3) 17/32-inch plate, 3¼-inch pitch and 1 1/16-inch rivets.

(4) 7/16-inch plate, 3½ inch pitch and ¾-inch rivets.

(5) ¾-inch plate, 4-inch pitch and 13/16-inch rivets.

(6) For any thickness of plate up to and including 21/32-inch, and where 1 1/16-inch rivets are used and pitched 4¾-inch apart, what would be the most likely mode of failure?

(7) If the thickness of the plate were not over 7/16-inch, could joint failure occur by shearing the rivets for any rivet size shown on the diagram?

(8) If 1 inch rivets were used in a joint, what would be the lightest plate that would cause the shearing of the rivets to be a possible mode of joint failure?

DOUBLE-RIVETED DOUBLE-STRAPPED BUTT JOINT WITH TWO PITCHES

What would be the weakest mode of failure in the following joints?

(1) 19/32-inch plate, 4-inch pitch and 1-inch rivets.

(2) 19/32-inch plate, 4-inch pitch and ¾-inch rivets.

(3) 9/16-inch plate, 5 inch pitch and ⅞-inch rivets.

(4) 15/32-inch plate, 5 inch pitch and 13/16-inch rivets.

(5) 25/32-inch plate, 4¾-inch pitch and ⅞-inch rivets.

(6) How would joints fail, having ⅞-inch rivets and pitched 4¼ inches or less and the plate thickness being 9/16 inch?

(7) What would be the maximum thickness of plate, where 1 inch rivets are used, if the breaking of the outer net section must be one of the possible modes of joint failure?

(8) If 15/16-inch rivets were used in 1-inch plate, what would be the least pitch that could cause joint failure by the shearing of all rivets?

TRIPLE-RIVETED DOUBLE-STRAPPED BUTT

What would be the probable method of joint failure in the following joints?

(1) ½-inch plate, 6¼-inch pitch and ¾-inch rivets.

(2) 11/16-inch plate, 7½-inch pitch and 1-inch rivets.

(3) 17/32-inch plate, 8 inch pitch and ⅞-inch rivets.

(4) 17/32-inch plate, 7½-inch pitch and 15/16-inch rivets.

(5) 11/32-inch plate, 6 inch pitch and 1 1/16-inch rivets.

(6) With 1 inch rivets pitched 7½ inches, what would be the maximum thickness of plate that could be used and have the net section between the outer rows of rivets the weakest?

(7) If 1⅛-inch rivets were spaced 8 inches apart, what would be the thinnest plate that would cause all of the rivets to shear?

(8) With ¾-inch plate thickness and 1¼-inch rivets, how would joint failure occur for any pitch up to and including 11-inch pitch?

QUADRUPLE-RIVETED BUTT DOUBLE-STRAPPED JOINT

What would be the most likely mode of failure in the following joints?

(1) ⅝-inch plate, 14-inch pitch and 1⅛-inch rivets.

(2) ½-inch plate, 14½-inch pitch and 13/16-inch rivets.

(3) ½-inch plate, 14½-inch pitch and ¾-inch rivets.

(4) 19/32-inch plate, 15½-inch pitch and 15/16-inch rivets.

(5) ⅞-inch plate, 14-inch pitch and 13/16-inch rivets.

(6) If it was required to design a joint with 1¼-inch rivets pitched 16 inches apart, and have the net section between the rivets of the outer row the weakest, what would be the maximum thickness of plate that could be used?

(7) With a pitch of rivets of 17½ inches, how thick would the plate be to make all rivets shear, when the rivet diameter is 1¼ inches?

(8) What is the thinnest plate to be used with 1¼-inch rivets, to make failure by the breaking of the inner net section and the shearing of the outer rows of rivets one of the possible modes of joint failure?

ANSWERS TO QUESTIONS

SINGLE-RIVETED LAP JOINT

(1) Breaking of net section.
(2) Shearing of rivets.
(3) Shearing of rivets.
(4) Shearing of rivets.
(5) Crushing of rivets.
(6) ⅞-inch diameter.
(7) 1¾-inch pitch.
(8) Any thickness of ½-inch or over.

DOUBLE-RIVETED LAP JOINT

(1) Shearing of rivets.
(2) Breaking of net section.
(3) Shearing of rivets.
(4) Shearing of rivets.
(5) Either shearing of rivets or breaking of net section.
(6) 4½-inch pitch and 15/16-inch rivet diameter.
(7) 4½-inch pitch.
(8) 4-inch pitch or over, any thickness up to and including 9/32 inch.

TRIPLE-RIVETED LAP JOINT

(1) Shearing of rivets.
(2) Breaking of net section.
(3) Shearing of rivets.
(4) Breaking of net section.
(5) Either breaking of net section or shearing of rivets.
(6) No, because the least possible pitch would be too great to permit of a tight joint.
(7) 4½-inch pitch.
(8) 2-inch pitch.

SINGLE-RIVETED DOUBLE-STRAPPED BUTT

(1) Crushing of rivets.
(2) Either shearing of rivets or breaking of net section.
(3) Crushing of rivets.
(4) Shearing of rivets.
(5) Shearing of rivets.
(6) Crushing of rivets or breaking of net section.
(7) Either by crushing the rivets or shearing the rivets, both methods of failure being equal.
(8) 2½.

DOUBLE-RIVETED DOUBLE-STRAPPED BUTT JOINT WITH ONE PITCH

(1) Either breaking of net section or shearing of rivets.
(2) Breaking of net section.
(3) Breaking of net section.
(4) Crushing of rivets.
(5) Shearing of rivets.
(6) Either crushing of rivets or breaking of net section.
(7) No.
(8) 21/32-inch plate.

DOUBLE-RIVETED DOUBLE-STRAPPED BUTT JOINT WITH TWO PITCHES

(1) Breaking of outer net section.
(2) Shearing of all rivets.
(3) Crushing of inner rivets and shearing the outer rivets, or shearing of the rivets.
(4) Crushing the inner rivets and shearing the outer rivets.
(5) Shearing of all rivets.
(6) By breaking inner section and shearing outer rivets.
(7) 19/32-inch plate.
(8) 4-inch pitch.

TRIPLE-RIVETED DOUBLE-STRAPPED BUTT

(1) Shearing of all rivets.
(2) Breaking of inner section and shearing outer rivets.
(3) Crushing inner rivets and shearing outer ones.
(4) Breaking of outer net section.
(5) The diagram does not hold good for this combination of rivet diameter and thickness of plate.
(6) 19/32-inch plate.
(7) 1-inch plate.
(8) By breaking outer net section or by breaking inner section and shearing outer rivets.

QUADRUPLE-RIVETED DOUBLE-STRAPPED BUTT

(1) The diagram does not hold good for this combination of rivet diameter and plate thickness.
(2) Inner rivets crush and outer rivets shear.
(3) All rivets shear.
(4) Inner section breaks and outer rivets shear.
(5) Rivets all shear.
(6) 1 1/16-inch plate.
(7) [illegible]
(8) 11/16-inch plate.

New Turbine Plant at Allentown, Penn.

An Uptodate Alternating-current Plant with Special Facilities for Handling Coal and Ash and an Ideal Location for Obtaining Water

BY JOHN I. BAKER

On account of the increasing demand for light and power and the inadequacy of their old plant, it became imperative for the Lehigh Valley Transit Company to build a new power station. A site near the old plant was selected, and the location is ideal for the receiving of coal and for obtaining water for condensing

FIG. 1. POWER HOUSE FROM THE LEHIGH RIVER

and other purposes. The building is of concrete construction, walls, floors and roof, all reinforced with Thacher bar reinforcement, and is 228 feet 3 inches long, 107 feet 6 inches wide and about 60 feet to the apex of the trusses. A concrete division wall extending from basement to roof forms a turbine room 228 feet 3 inches long by 52 feet 4 inches wide, and a boiler room 228 feet 3 inches long by 55 feet 2 inches wide. The concrete walls are 12½ inches thick from sub-base to roof. The columns supporting the trusses are on 18-foot 3-inch centers, and in order to make the building fireproof in all respects, the doors and window frames are of steel, made by David Luptons Sons Company, of Philadelphia. Wire glass is used throughout; the majority of the panes are 14½ inches long and 22½ inches high. A ventilator, 48 feet wide, having louvres on the boiler-room side and pivoted glass sash on the opposite side, extends the full length of the building.

The Boilers

The boiler equipment consists of ten 525-horsepower Babcock & Wilcox boilers arranged in batteries of two, each battery being 30 feet wide and about 23 feet 5 inches long. A space of 6 feet 6 inches between settings gives ample room for the steam-piping connections to the main header, for operating blowoff valves and for cleaning purposes. The distance from the floor to the top of the steam-outlet flange is 19 feet 9 inches.

Each boiler consists of three drums, 42 inches in diameter and 23 feet 3 inches long, placed above and connected to a set of 21 sections, each section containing 12 tubes 4 inches in diameter and 18 feet long. The drums are three sheets long; each sheet is ½ inch in thickness and all joints are butt-strapped. The superheaters are of the double-loop type; each superheater is made up of 42 groups of four 2-inch seamless drawn-steel tubes and contains 1100 square feet of heating surface. The boilers are guaranteed to evaporate 10½ pounds of water per pound of dry coal from and at 212 degrees Fahrenheit, the coal to contain 14,800 B.t.u. Each boiler contains 5242 square feet of heating surface. The original tubes were hot-drawn and made of No. 10 gage, but on account of occasional rupture, all replacements have been made with No. 9 gage, cold-drawn tubes.

The boilers are equipped with Roney stokers, driven by two 4½x4-inch Westinghouse standard engines. As there is space provided for two additional boilers, the stoker engines are so located that each engine will eventually drive the stokers for six boilers. The line shaft operating the stokers is $1\frac{15}{16}$ inches in diameter and makes four revolutions per minute. An auxiliary engine of the same make is in reserve, and the exhaust from both engines is utilized at the heaters.

Natural draft is furnished by an Alphons Custodis radial brick stack, located directly north of the boiler room, having an octagonal base and an internal diameter of 14 feet at the base with a taper to 8 feet at the top. The total hight of the stack is 226 feet above the foundation, or about 207 feet above the stokers. At the rear of the boilers is a brick flue 9 feet wide and 14 feet high, having an internal area of 126 square feet. Throughout its entire length the flue has these same dimensions. A steel-plate damper is controlled by a Collins damper regulator. The temperature of the flue gases at the base of the stack is 525 degrees Fahrenheit. Structural supports for a future economizer installation were erected with the building and are located above the main flue.

The plant has been in operation since May, 1908, and during that time the greatest overload in the boiler house occurred one evening when nine boilers, for a period of two hours, were operating on a 43 per cent. overload. At the time of the writing Burrows automatic feed-water regulators were being installed.

FIG. 2. COAL HANDLING FROM CAR TO PLANT

Coal and Ash Handling

Coal is received by rail, the main line of the Lehigh Valley Railroad Company passing in front of the power house. If

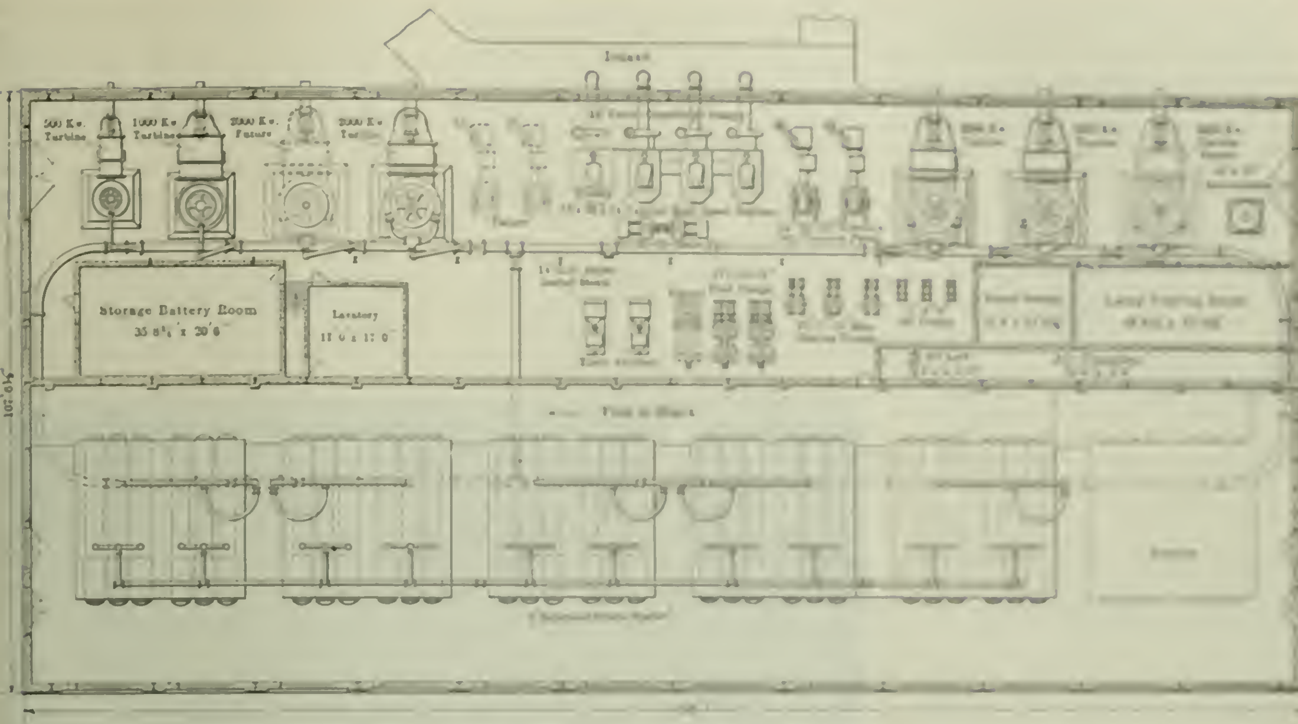


FIG. 3. GENERAL PLAN OF POWER PLANT

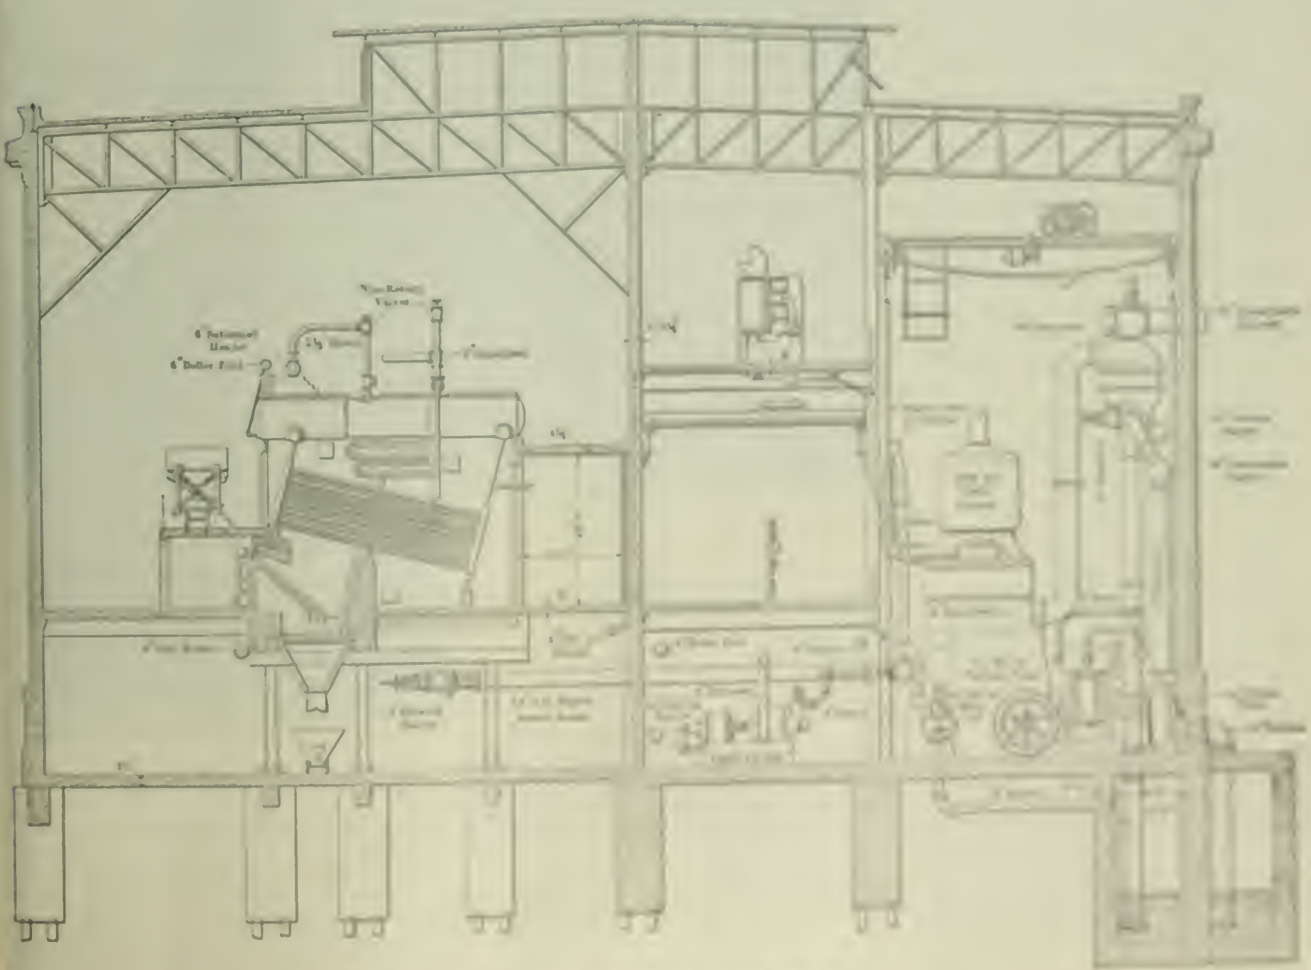

FIG. 4. SECTIONAL ELEVATION OF POWER PLANT

occasion required it, anthracite could be delivered by water, as the Lehigh river and canal are about 500 feet east of the power house. Along Front street there are at present eight reinforced-concrete coal-receiving pits, and the removal of the old power house will give space for three additional pits. Standard-gage railroad cars are run in on a track over a small pit at the side, having a slanting bottom and allowing the coal to slide down into the larger pockets, which are 12 feet wide, 15 feet deep and 19 feet long. Thus the cars can be immediately emptied and returned.

By means of a Gantry crane, built by the Browning Engineering Company, a grab bucket, with a capacity of 2 cubic yards, can take coal directly out of the cars, if necessary, but usually transfers the coal from the large coal pits to a steel-plate hopper attached to the crane, or in the space between the pits and west wall of the boiler room. This hopper will hold about 25 tons, and 6500 tons have been stored in front of the building. One rail for the Gantry crane is along the wall of the coal-receiving pits, while the other rail is supported by a girder at the top of the west building wall. Both rails are 60-pound A. S. C. E. section, and the distance from center to center of the rails is 88 feet 9 inches. One leg of the Gantry crane has a wheel base of 35 feet and the other 24 feet. The crane has a rated capacity of 100 tons per hour.

Extending along the boiler fronts and the west wall of the boiler house, there is a continuous, 19-inch gage track made of 20-pound, standard-section rails. A coal larry, built by the C. W. Hunt Company, and operated by storage batteries, takes coal from the hopper of the Gantry crane and delivers the coal to the small chutes above the stokers. The average capacity of the larry is 5200 pounds. The present coal consumption in 24 hours is from 100 to 125 tons. A bituminous medium-grade Kennerly coal, having the following analysis, is used: Moisture, 1.19 per cent.; volatile matter, 16.41 per cent.; fixed carbon, 70.98 per cent.; ash, 11.42 per cent.; B.t.u. per pound of coal, 13,808.

Motor-driven crushing rolls are located in the large receiving bin attached to the Gantry crane. The operator of the larry fills his car by opening the duplex valves on the hopper, and then runs the car along the front of the building and before entering the boiler room, weighs the coal on a Fairbanks scale having a capacity of 8000 pounds.

In case of accident to the Gantry crane a skip car and hoisting engine, built by the C. W. Hunt Company, have been provided. The skip car empties direct into the larry, and was in use until the Gantry crane was installed. It is now held as a spare.

The ashpits are made of reinforced concrete, and at the bottom of each ashpit there are duplex valves as illustrated herewith. Directly under the ashpits and extending the full length of the boiler-room basement, there is a narrow-gage track, 19-inch gage, made of 20-pound rails. The push-car for handling the ashes has a V-body, 55 inches wide, 40 inches long and 34 inches deep, and is of the double-side dumping type, made by the C. W. Hunt Company. Ashes are used for filling-in purposes, or can be loaded into cars. The narrow-gage track runs up an easy incline to the top of a car. One man takes care of all the ashes and has time to help at other odd jobs.

Prime Movers

The plant has a nominal capacity of 7750 kilowatts. For railway service there are two four-stage Curtis turbines, each of 2000 kilowatts rated capacity, operating at 750 revolutions per minute and delivering three-phase alternating current at 25 cycles frequency. For lights and motors there are one four-stage Curtis turbine, 2250 kilowatts rated capacity, 900 revolutions per minute; one four-stage Curtis turbine, 1000 kilowatts rated capacity, 1200 revolutions per minute, and one two-stage Curtis turbine, 500 kilowatts rated capacity, 1500 revolutions per minute, these three machines delivering alternating current at 60 cycles frequency.

The old plant consists of four 30x48-inch simple Cooper Corliss engines, running 80 revolutions per minute, each engine having a band wheel 20 feet in diameter and 57 inches face and driving by means of a 48-inch three-ply leather belt a 500-kilowatt Bullock generator. Jet condensers of the Worthington type are installed with each engine. For an emergency in railway service, two of these engines are available.

FIG. 5. METHOD OF HANDLING COAL IN BOILER ROOM.

Condensers and Auxiliaries

All condensers are of the barometric-tube type, made by Henry R. Worthington. By means of a reinforced-concrete intake, 7 feet high and 6 feet wide, water for condensing purposes flows from the Lehigh river, 500 feet away, through the intake and up to and along the eastern wall of the turbine room. Three 18-inch volute Worthington centrifugal pumps take water from the intake through 20-inch suction pipes and discharge into 18-inch pipes into the side of a 30-inch water header located directly above the pumps and at an elevation of 51.915. The pumps are direct-connected to 13x22x14-inch Bates vertical automatic high-speed engines, running at a maximum speed of 240 revolutions per minute and equipped with Schutte & Koerting Company angle-trip throttle valves.

[illegible] and to 12 inches at the 500-kilowatt unit. The [illegible] connections to the turbine are 4½ inches, [illegible] inches and [illegible] inches to the 500-, 1000- and 2000-kilowatt units, respectively.

Since the plant has been in operation trouble has been experienced with [illegible] water coming over into the [illegible] [illegible]. The [illegible] connections to the large turbines are taken from the top of [illegible] [illegible]; the [illegible] long-radius [illegible] bends giving flexibility to the line. The [illegible] steam header is [illegible] inches in diameter [illegible] flanges and flanged fittings.

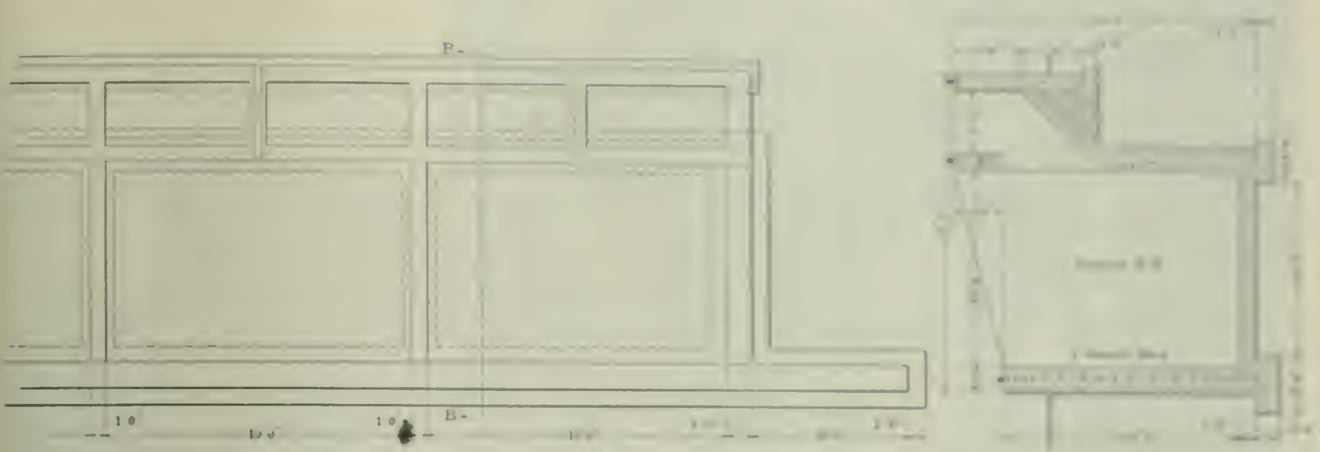

FIG. 6. COAL RECEIVING PITS

The water header extends along the east wall of the turbine room, is supported by brackets attached to the building columns and is 30 inches in diameter where the centrifugal pumps discharge into it, but reduces to 24 inches at the 2000-kilowatt turbine and to 12 inches at the 500-kilowatt unit. From this main header there is a 10-inch injection connection to the 500-kilowatt turbine, a 14-inch injector to the 1000-kilowatt turbine and a 16-inch to the 2000-kilowatt turbine. Ordinary chain passing over

FIG. 7. ASH HOPPER AND CAR

sheaves on the valve stems, and reaching down to handwheels and pedestals on the first floor, allow the attendants to control the injection.

There are two 14x[illegible]x18-inch Worthington steam-driven rotative dry-vacuum pumps attached to a 16-inch [illegible] header, reducing to 8 inches at the 500-kilowatt

pipe, and in order to put a stop to the [illegible] make-up pieces 18 inches high have been put in on every condenser. The exhaust connections from the turbine to the condenser are of steel plate construction with flanges made of steel castings. On the 2000-kilowatt units the rectangular exhaust pipe is 2 feet wide and 8 feet long. The free exhaust pipes are very short, extending just outside of the building with Blake automatic exhaust-relief valves of angle type are used on all units. Bundy steam traps are attached to the exhaust connections of all turbines and vary in size from No. [illegible] for the smallest to No. 104 on all of the 2000-kilowatt turbines. A vacuum of 28 inches is maintained. All steam-driven auxiliaries are running [illegible] [illegible], the exhaust going to the heaters.

The Piping System

The general arrangement of [illegible] steam piping is shown in the plan view of the station. The main steam header is [illegible] inches in diameter and forms a continuous loop extending along the turbine room and beneath the boilers. All flanges are of steel and all fittings are steel castings. Van Stone joints are used throughout. The steam is superheated [illegible] degrees Fahrenheit above the temperature corresponding to [illegible] pounds gage, which would be [illegible] degrees, making the total temperature of the superheated steam at the boilers [illegible] degrees Fahrenheit. Copper and steel gaskets were [illegible] [illegible] and [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] ing Company.

The connections from the header for superheated steam are [illegible] inches in diameter.

[illegible] extra-heavy gate valves are used and a brand of rubber packing called "Torpedo." Saturated steam is used to operate the centrifugal pump engines, rotative dry-vacuum pump, feed pump, step-bearing pumps, oil pumps, turbo-exciters and two of the Corliss engines in the old plant. Connections to the saturated-steam header are [illegible] inches in diameter. Both saturated and superheated connections are equipped with Schutte & Koerting Company automatic-stop check valves, angle type, with bodies of steel castings.

[illegible] Water [illegible]

By means of a [illegible] Worthington duplex-piston make-up pump, water is taken from the discharge conduit and

FIG. 8. [illegible]

delivered to two [illegible] Cochrane feed-water heaters with [illegible] [illegible] in the basement below the boiler room. There is also a [illegible] [illegible] [illegible] [illegible] connected [illegible] [illegible] and located as shown in the [illegible] [illegible] drawing. Both pumps are [illegible] [illegible] [illegible] [illegible] [illegible]. The

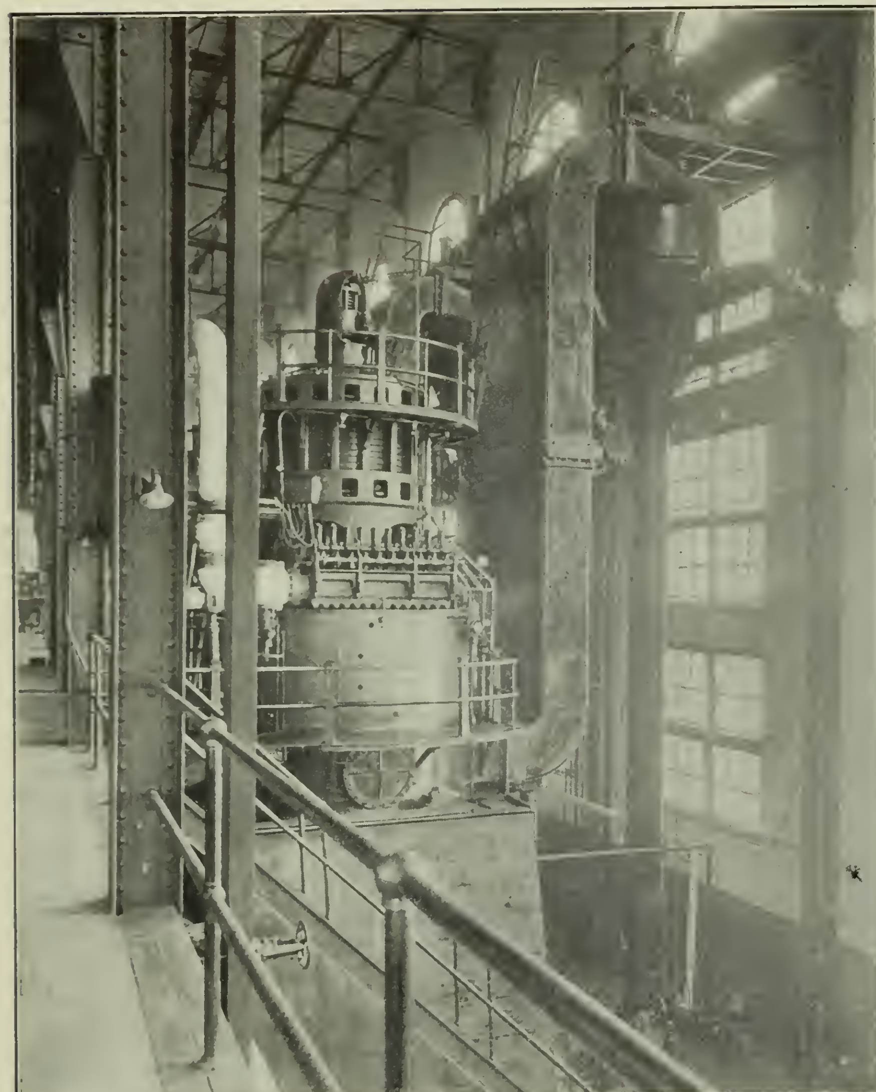

FIG. 9. ONE OF THE 2250-KILOWATT CURTIS TURBINES

feed water, which has a temperature of 208 to 210 degrees Fahrenheit, flows by gravity to two 17x10x15-inch Worthington duplex-plunger feed pumps equipped with Fisher pump governors. The heaters can also take water from an 8-inch connection to the city water line. The boiler-feed header is 6 inches in diameter.

Step-bearing and oil pumps

There are three 12x3x10-inch Worthington duplex-plunger pumps supplying water pressure for the step bearings of the turbines. These pumps are also equipped with Fisher pump governors and so are the oil pumps. The pressure gages show that it takes 200 pounds per square inch for the step bearing of the 500-kilowatt machine and about 435 pounds for the 2000-kilowatt turbine. In case of accident to these pumps a 16x17-foot R. D. Wood & Co. hydraulic accumulator can supply sufficient pressure to keep the turbines running 15 minutes. For oiling the top and middle bearings of the turbines and also the throttles, there are three 6x2x6-inch Worthington duplex-plunger oil pumps.

Electrical Equipment

The two 2000-kilowatt turbine units generate alternating current at 13,200 volts. The old switches between the turbines and buses are located on the second gallery which extends the full length of the power house. To the busbars there are attached five transmission lines as follows: Two on the Philadelphia line, sending 13,200 volts to the substations at Coopersburg, Sellersville, Landsdale and Ambler; one to Siegersville and Slatington, one to Catasauqua and one to Bethlehem and Hecktown.

The southern end of the switchboard gallery contains the substation for the Allentown lines, consisting of nine transformers having a capacity of 185 kilowatts each. The transformers are delta-connected on both high- and low-tension sides, and are air-cooled by two 55-inch Buffalo Forge fans direct-connected to 4-horsepower induction motors running 690 revolutions per minute and guaranteed to furnish 10,000 cubic feet of air per minute at ¾ ounce pressure. At the transformers the current is stepped down to 430 volts. By means of three 25-cycle rotary converters, each of 500 kilowatts capacity and running 500 revolutions per minute, this alternating current is converted into direct current at 600 volts for railway service. The equipments of the other substations are similar to the one just described, with the exception that the voltage is stepped down to 370 volts at the transformers and the converters are of 300 kilowatts capacity each.

For lighting purposes there are three

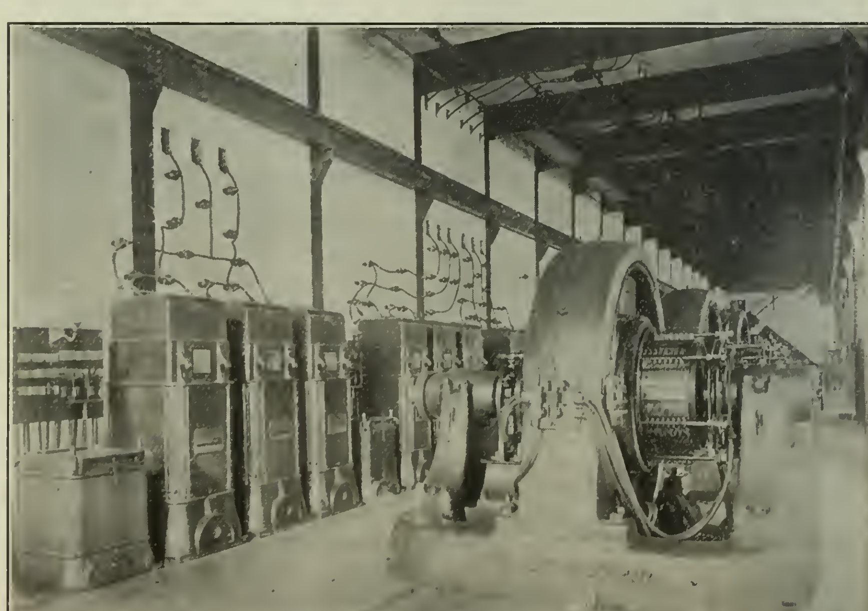

FIG. 10. ROTARY CONVERTERS AND TRANSFORMERS

units of 500, 1000 and 2250 kilowatts rated capacity, generating alternating current at 2300 volts and of 60 cycles frequency. By means of three transformers, each having a capacity of 200 kilowatts, the current is stepped up to 13,200 volts. Transmission lines extend to the towns of Bethlehem and Slatington. A rotary converter of 300 kilowatts capacity and synchronous motors driving arc machines; three generator panels, 60 cycle; two exciter panels; one storage-battery panel, two 2000-kilowatt 25-cycle panels, five 25-cycle 13,200-volt panels, one 300-kilowatt 60-cycle panel for rotary converter, three 500-kilowatt 25-cycle panels for rotary converters, two motor-circuit feeder panels, one motor-circuit panel,

FIG. 11. SWITCHBOARD CONTAINING 57 PANELS

running 900 revolutions per minute converts this current into 600 volts direct current, supplying commercial power and the power for the Gantry crane.

For the 650 arc lamps in Allentown and neighboring towns there are on the second gallery eight Brush arc generators, each having a capacity of 125 lamps. Four 140-horsepower three-phase 2300-volt synchronous motors are direct connected to the arc generators, one motor mounted centrally between two generators.

Exciters and Storage Batteries

On the first floor there are two turbo-exciters operating at 2400 revolutions per minute. These machines are of 75 kilowatts capacity, and one machine can be used as a booster to charge the storage batteries. The storage-battery room, located on the first floor, contains 75 Type G 11 chloride accumulator cells furnished by the Electric Storage Company, and there are always 57 cells floating on the exciter buses.

The switchboard consists of 57 slate panels about 2 inches thick and 7 feet 6 inches high. The total length of switchboard is 81 feet 4 inches and is made up as follows: Ten single-phase feeder panels, 2300 volts; one three-phase panel, 2300 volts; three transmission-line panels, 60 cycle, 13,200 volts; one panel for three low-volt panels, eight [illegible] feeder panels and the remainder are [illegible] to be used when future railway [illegible] are added. The voltage at the switchboard is about 600 volts. The electrical equipment throughout the entire plant was furnished and installed by the General Electric Company.

FIG. 12. BRUSH ARC GENERATORS

General

The turbine room is equipped with one 25-ton Case electric traveling crane having a span of about 47 feet from center to center of the rails. The crane girders are supported on 20-inch I-beams, which in turn are attached to the building columns. The eastern portion of the turbine room contains two galleries. The first has office rooms at one end and a substation at the other end, with the switchboard located about centrally. This gallery is served by a hand traveling crane having a capacity of 10 tons. The plant operates continuously and is run on three shifts per 24 hours. The number of men per shift is as follows: One watch engineer, one pumping engineer, one turbine engineer, one operator and helper on the switchboard (helper necessary on account of the substations on the switchboard gallery), one man, engine only, for arc machines on the second gallery; two firemen who are also water-tenders, one man for ash handling and one man for coal larry, the crane runner on the Gantry crane, and usually one boilermaker and one blower for two shifts.

The company operates 150 miles of electric railway and recently has inaugurated a trolley express service. Some freight cars, resembling outwardly the ordinary freight car, will carry freight to all points along the line. The boiler room of the old plant has been made into an in-[illegible] points. Class cars are governed by official commercial classification.

The plant was designed by the [illegible] Engineering Company, Philadelphia, Penn. The writer is indebted to the superintendent of the power house and other employees for their courtesy and help in gathering the data for this article.

The Three-Wire System with One Dynamo

The Reason Why the Neutral Wire Is Necessary. Methods Used for Compensating Unbalanced Load. Size of Motor Compensator Needed

BY CECIL P. POOLE

If an ordinary dynamo be connected to a group of incandescent lamps arranged in series multiple, as indicated diagrammatically by Fig 1, its voltage will have to be twice that for which each lamp is made, that is, if 110-volt lamps are used, the voltage of the dynamo must be 220 (disregarding line losses for the present). Such a system would be even more economical than the three-wire system, and would have been adopted instead of the three-wire system but for one serious defect—the lamps would have to be installed, lighted and extinguished in pairs. Consequently, a customer who wanted 5 lamps would have to take 6, and he could not control his lamps singly.

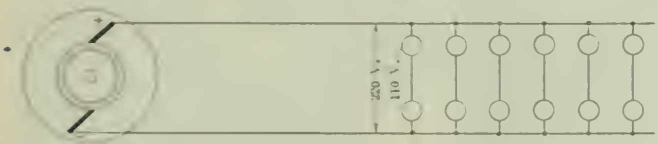

FIG. 1

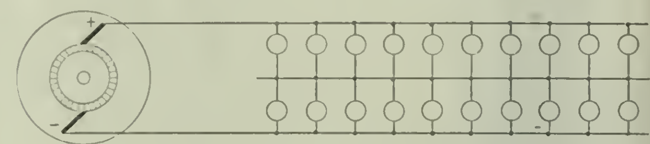

FIG. 2

If, to the arrangement shown in Fig. 1 a third wire were added, connected between each pair of lamps, as shown in Fig. 2, part of the original difficulty of control would be overcome. With this arrangement, any one lamp on one side of the middle wire could be lighted or extinguished, provided one of the lamps on the other side was simultaneously lighted or extinguished. So long as the number of lamps on one side was equal to the number on the other side, it would not matter just which lamps were lighted and which were out. But this would require turning on and off 2 lamps every time, and, worse yet, the consumer would have to know which lamps were on one side and which on the other side of the system, which makes it utterly impractical. The reason for having to keep the same number of lamps lighted on both sides of the same will be evident upon consideration of Fig. 3. Here 10 lamps are shown on one side and 8 on the other. If the resistance of each lamp were 220 ohms, which is a common value for 110-volt lamps, the joint resistance of the group of 10 would be $220 \div 10 = 22$ ohms and that of the 8 lamps would be $220 \div 8 = 27\frac{1}{2}$ ohms. The total resistance of both groups, therefore, would be $22 + 27\frac{1}{2} = 49\frac{1}{2}$ ohms, and the current flowing through the groups would be $220 \div 49\frac{1}{2} = 4.44$ amperes. Now the proper current for the 10 lamps would be $110 \div 22 = 5$ amperes, and the proper current for the 8 would be 4 amperes; consequently, the group of 10 lamps would get too little current and the group of 8 lamps too much.

In order to correct this defect in the arrangement shown, it is necessary to provide means for taking the surplus current from the smaller load on one side and transferring it to the greater load on the other side. This is called "compensating" the lack of "balance" in the circuit. (When the load, or number of lamps on one side of the middle wire is equal to the load on the other side, the circuit is said to be "balanced;" any other condition makes the circuit "unbalanced.") One of the simplest methods of compensating for unbalancing is to connect a secondary battery between the two main wires and connect the middle or "neutral" wire to the middle point of the battery, as in Fig. 4. Here 10 lamps are shown on one side and 6 on the other; the flow of current is indicated by the arrows. Under the conditions shown, the half *A* of the battery will deliver just enough current, if the voltages are suitably proportioned, to supply one-half of the excess or unbalanced load on the heavy side of the system. The dynamo supplies the other half of the excess current, and this half comes in on the neutral with the current supplied by the section *A* of the storage battery and passes back to the dynamo through the section *B* of the battery, charging that section. This proportion holds good for any degree of unbalancing; that is, that part of the battery on the heavily loaded side will send out one-half of the current in the neutral wire and the other half will go through the part of the battery that is on the light load side of the neutral.

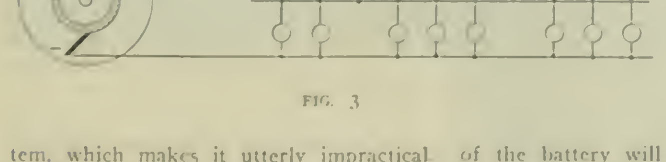

FIG. 3

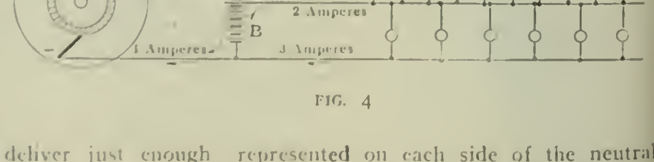

FIG. 4

This arrangement, though apparently ideal in simplicity on paper, is not so attractive in practice because a rather troublesome regulator is needed in conjunction with the battery in order to prevent it from exhausting itself when the load is heavy or drawing too heavily from the line when it is light. Moreover, the two halves of the battery cannot be kept in equal condition, because one side would do more work than the other, unless the circuit could be unbalanced alternately and equally on first one side and then the other. This difficulty can be met, however, by exchanging the two sections at regular intervals, say once a week.

A more practical method of compensation is by means of what is commonly termed a "motor-balancer," but is more correctly a motor-compensator. This consists of two small motors exactly alike in all respects, their shafts rigidly coupled together and their armatures connected one on each side of the neutral wire, as indicated in Fig. 5, where 120 lamps are represented on each side of the neutral wire. Here it is assumed that the motor armatures require one ampere to drive them, or 220 watts (110 watts each), and for simplicity the current required by their field windings is ignored. So long as the load is balanced, the two armatures will take current from the main wires only.

and will revolve idly. If more load is added to one side, however, or some load taken off the other side, the equilibrium between the voltages of the two sides will be upset; the voltage at the brushes of the motor on the lightly loaded side will be higher than that at the brushes of its mate, and it will drive the latter at a speed beyond that due to the circuit voltage, making a dynamo of it, and forcing it to carry the unbalanced part of the heavier load on the circuit. This is illustrated in Fig. 6, where 120 lamps are shown on one side and 60 on the other, each of the circles representing 10 lamps, taking ½ ampere each. What causes the distribution of current shown is this: When the load in the *B* division is reduced the voltage rises, because the losses in the dynamo and circuit wires are reduced; the voltage between the neutral and the negative wires rises more than that between the positive and neutral, because the resistance there is higher—all the reduction of load has occurred in that division of the circuit. The armature *B*, therefore, speeds up, dragging the armature *A* with it until the voltage of the latter increases above that of its side of the circuit sufficiently to carry half of the excess load on that side, minus the power required to drive the two machines. This power was assumed to be 220 watts, the current taken by the two armatures in series in Fig. 5 being one ampere and the total voltage 220. Here, one of the armatures does all the work, so that the whole 220 watts must be applied to it, in addition to an amount of power equal to that being delivered by the armature *A* working as a dynamo. As the armature *B* takes its current now from the unbalanced current coming in on the neutral wire, it works at 110 volts and therefore requires 2 amperes to overcome the losses in the two machines (the losses in the windings are ignored to simplify the problem); the neutral wire must carry 30 amperes because the 60 lamps in the negative division will pass only 30 amperes. Deducting the 2 amperes for motor losses leaves 28 amperes, which divides between the two machines, 14 amperes supplying the motor with the energy necessary to produce 14 amperes from the armature now driven as a dynamo.

Another way to arrive at the division of current is as follows: The main dynamo must supply all of the energy represented in the circuit; all that the compensator does is to transfer the surplus energy from one side of the circuit to the other—it cannot supply any additional energy because it is driven by energy taken from the main circuit. Now the lamps take each ½ ampere at 110 volts, or 55 watts; there are 180 lamps, requiring 180 × 55 = 9900 watts. The compensator requires 220 watts to overcome its internal losses, the watts losses in line being ignored for the present. The lamps and compensator together, therefore, require a total of 10,120 watts. Ignoring line losses, the generator works at 220 volts, and in order to deliver 10,120 watts it must deliver 10,120 ÷ 220 = 46 amperes. Since the lamps in the positive division (*A*) require 60 amperes, the armature *A* working as a dynamo must supply 60 − 46 = 14 amperes. Consequently, of the 30 amperes in the neutral wire, 14 must have been generated in the latter machine, the other 16 to pass through the motor armature *B* to the main dynamo, as previously explained.

The exact figures in practice would not be those here stated because the line losses, the current in the field windings of the compensator and the losses in their armature windings affect the current distribution. The principle, of course, is not affected; the machine on the lightly loaded side of the system always runs as a motor and drives its mate as a dynamo, the latter supplying about one-half of the difference between the two divisions of the load, minus the power required to drive the former. The losses do affect the voltage regulation, however. If the armature windings of the compensator are of very low resistance, the voltages on each side of the neutral will be kept almost exactly equal; if the armature resistances are high, the voltage between the neutral and the outer wire which carries the heavier load will be appreciably lower than that on the other side of the system.

The regulation obtained with series compensators can be much improved by cross-connecting the field windings, as shown in Fig. 7. The result of this is that when the load on the side *A*, for example, is less than that on the other side, the voltage of the side *A* being higher than that of the side *B*, the field strength of the machine *A* will be weaker than that of the machine *B* and its speed will be higher than it would be with a simple field. The machine *B* on the other hand

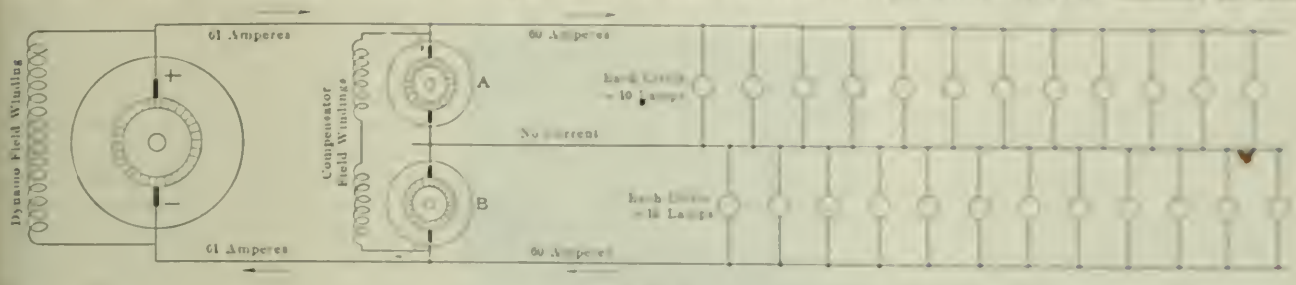

FIG. 5

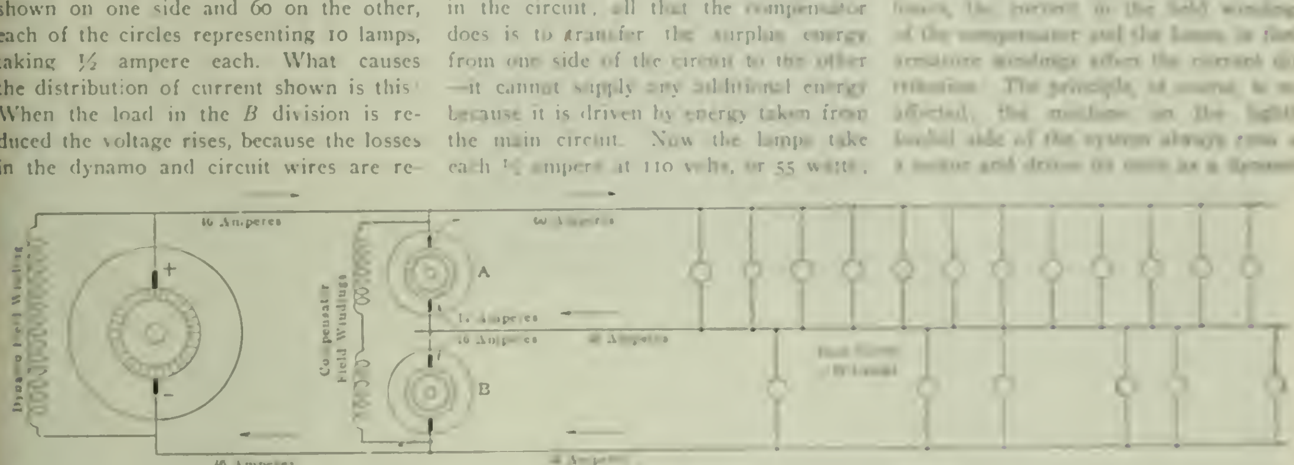

FIG. 6

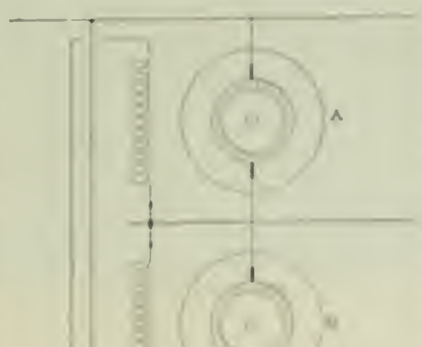

FIG. 7

driven as a dynamo, will have its field strengthened, and will deliver a higher voltage than it otherwise would. In other words, the machine which runs as a motor runs at a higher speed, giving its mate a higher voltage, and the latter will have a stronger field, augmenting its voltage still more, with the connections shown in Fig. 7 than with the more usual arrangement shown in Figs. 5 and 6. If the resistances of the armatures are made very low, however, the improvement in regulation obtained with cross-connected field windings is not great enough to justify the extra complication involved.

The armature capacity of a motor compensator, in amperes, must be equal to one-half of the current that will flow in the neutral wire when the system is out of balance by the maximum amount possible under operating conditions, plus the current required to overcome *all* losses in the two armatures at full load. The losses in small armatures range from 5 to 10 per cent. at full load; therefore, if the compensator armatures can carry 55 per cent. of the maximum current that will ever flow in the neutral wire, they will be large enough.

Reorganizing an Old Water Power

There are doubtless many plants deriving considerable water power from old developments in which both volume and efficiency could be materially increased by a complete reorganization in accordance with the most recent practice. And not only may the power end be benefited thereby, but the good results there possible of attainment may be considered in conjunction with relocation or reconstruction of the manufacturing building or buildings so as to secure the maximum of convenience and efficiency. A typical case of this nature is presented by a reorganization conducted under the supervision of Charles T. Main, of Boston, which successfully embraced both of these advantages as is evident from the following brief description.

The complete plant of the mill in question formerly consisted of three separate installations, each with its own individual dam, water wheels and buildings, all situated within about 1200 feet. The head of water at each dam varied from 10 to 18 feet, according to the changeable conditions. The improvements started with the elimination of the two down-stream dams and the selection of the remaining up-stream dam for service in the new development. By this combination a total head of 40 feet was obtained. From the up-stream location the water was carried through a steel penstock to a modern and comparatively small water wheel somewhat below the farthest down-stream dam. At this point a new manufacturing plant was erected to take the place of the scattered buildings. In this were incorporated many improvements in the way of manufacturing equipment. The old buildings at the other dams were abandoned or used for storage purposes.

The advantages of the reorganization were evidenced in two ways, by the concentration and utilization of a better-conserved water supply under a greater total head and by the grouping of the manufacturing buildings on a single building site. The expense of upkeep of the three original dams was reduced and limited to that upon one, while the loss of head between them, inevitable under the old conditions, was eliminated. By selecting the up-stream site for the single dam and carrying the water by penstock to the new site at a considerable distance down stream, the maximum head was utilized. It is evident that had the down-stream location been selected and the same head provided at the wheels a new dam would have been required. This would have required extra strength to withstand the greatly increased pressure.

The combined power at the best was relatively small, but when divided into three units, as in the original installation, the friction losses were excessive. By the adoption of the new plan it became necessary to keep only one dam tight in order to conserve the water. The excessive leakage through the other two was eliminated, as was also the amount passing by the water wheels during the night. In every way the new plant was more efficient and more easily operated. The power available at the new mill is now sufficient to run the entire plant several months of the year.

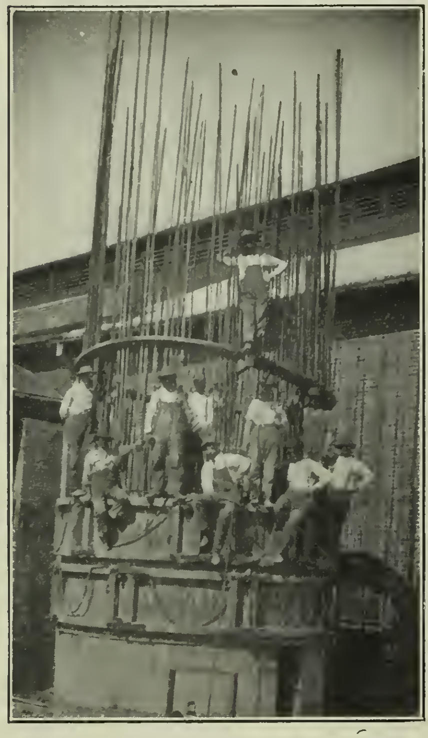

FIG. 1. METHOD OF REINFORCING CONCRETE STACK

Concrete Chimneys

By Ethan Viall

The Illinois traction system, which has a network of interurban electric lines all over central and southern Illinois, has placed concrete stacks at all of its power houses. Up to date eight of these stacks, varying in hight from 160 to 185 feet, have been built or are in the process of construction. These chimneys will average about 12 feet in diameter at the bottom and taper to 10 feet at the top, and are set on a concrete foundation 25 feet square.

Fig. 1 shows one of the chimneys and the entire construction gang, including boss and inspector. The method of reinforcing is well shown in this cut. In addition to the upright rods shown, a 5/8-inch round iron hoop is placed outside of the verticals every 18 inches, and all are firmly imbedded in the concrete. At the bottom are placed 144 uprights, and the number is gradually reduced to 12 at the top.

It will be remembered that one of the chimneys built by this company at Peoria fell with disastrous results, the cause being said to be that the concrete mixture was allowed to stand too long before being placed. Since this accident occurred, quick placing of the mixture and rigid inspection has been the rule. Fig. 2 shows one of the chimneys at the end of the fourth week's work.

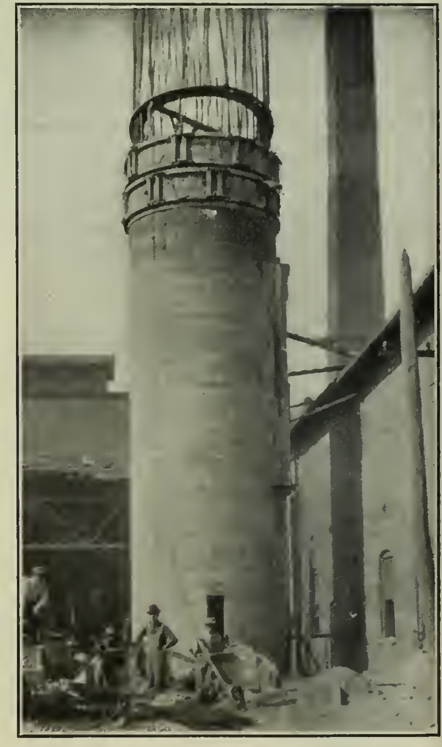

FIG. 2

Supernatural Visitation of James Watt

An Entertaining Presentation of What the "Father of the Steam Engine" Might Do and Say if He Were to Come Back to Earth Today

BY WARREN O. ROGERS

There are many subjects upon which men do not agree, some even going so far as to ridicule the beliefs or opinions of others, although they themselves have never investigated their truth or falsity.

I have no apologies to make for the wonderful experiences I have had with matters which to many may seem supernatural, I shall not attempt to convince anyone that it is possible to communicate with those who have departed this world and passed into the Great Beyond, but will content myself by merely relating my experiences and leave the reader to form his own opinion.

For years I have been a student of psychical research. I have not been content to confine myself to the foolishness of knocking on doors and tipping tables, but have harmonized my mental powers with the influence surrounding many departed spirits. Therefore, astonishing as it may seem, I have been able to enter into the state in which they exist, to some extent, and although possessing my earthly faculties I also partake of their spiritual life, and can see those with whom I am talking, although in phantom form, and converse with them in my own tongue.

The most interesting of these experiences have been those of communing with men whom the world once regarded with honor, although dead and buried for many years. These experiences have been most interesting because [illegible] of their earthly life, and many an hour have I spent in congenial conversation with James Watt, George Stephenson, Robert Fulton, and others. I mention these particularly because I am interested in the subjects they were familiar with more than any others.

My first experience with a resident of the other world was accompanied by sensations not altogether pleasant. I sat one evening, deeply absorbed, reading a treatise on the subject already mentioned. I was alone, and the stillness of the house was broken only by the frequent gusts of wind and rain beating against the window panes. Time passed [illegible]. As the clock on the mantel chimed midnight, I closed my book, with the intention of retiring, [illegible]

I SHALL NEVER FORGET THE APPEARANCE OF JAMES AS HE SAT, ONE SHADOWY LEG OVER THE OTHER, THE FRAGRANT CIGAR SMOKE ASCENDING IN WAVY COLUMNS FROM HIS THIN, BLOODLESS LIPS gineering field since he left us. Absorbed in such speculations, a power which had been developing in me for some months began strongly to assert itself, and being willing to assist, I focused my entire mental energy to bring into my presence in a tangible form that long-departed inventor to whom the world owes so much.

My first realization that another presence was with me was a faint shadow between the light and the wall. It was not a human form, and yet it was. While I gazed, I was seized with a sensation of extreme cold—fear it may have been, I know not. I tried to speak, but my lips were speechless. I tried to move, but was powerless. To add to the horror, the electric lights began to grow dim; the fury of the storm without increased, and a nameless dread possessed me. The form advanced slowly toward a vacant chair on the opposite side of the table. The deep chilly atmosphere of the grave seemed to permeate the room, and as I felt the cold, clammy hands of my visitor grasp my own, my overtaxed mind could stand no more, and I fell into a state of unconsciousness. When I regained my faculties, I heard a friendly voice say:

"Do not be disturbed; you have long wanted a visit from me, and on my part I have been just as anxious to converse with you."

As my vision grew clear, I saw that the one I had been longing to bring into my presence was indeed with me. His genial, smiling face and pleasant voice soon put me at ease, dispelling all sense of fear of the supernatural (which, I may state, has never returned).

In order to make James feel at home, I asked him what he would have, and being told a Scotch high-ball, proceeded to concoct the same, which speedily disappeared. Having thus fortified ourselves, and being comfortably seated in our chairs with fragrant Cuban "perfectos" in our mouths, I asked James to tell me about his early struggles, a subject I was not entirely familiar with.

I shall never forget the appearance of James as he sat by my library table; one shadowy leg over the other, the silver buckles on his low-cut shoes glistening in the rays of the electric light, the half-empty glass on the table (for I had refilled it again), and the fragrant cigar smoke ascending in wavy columns from his thin, bloodless lips.

"I was born," said he, "of poor but, honest parents—"

"Stop, James, stop where you are! I did not ask you to recite the beginning of one of Laura Lean Jibby's novels. I asked you to tell me something that can't be bought on every newsstand in the country. Now, start again."

He recrossed his legs, took another sip, and said in a somewhat dogged tone, I thought:

"Well, they were poor, anyway."

I nodded my approval, and he continued:

"My ancestors were all mechanics and men of genius, so you see it is nothing strange that I was endowed with an inventive turn of mind, or that I lived 150 years before my time. I was born, as you have doubtless heard, at Greenock, Scotland, January 19, 1736. It was a bitterly cold day, and father was so chilled he could hardly measure out oatmeal to his customers. He was a merchant on a small scale. He had lost all his money speculating; that is the reason I always had to work for a living. [Here James gave a sigh of regret.]

"I was a slim, puny kid up to the time I got to knocking up against the world, and then it kept me so busy looking after the £.s.d., I didn't have time to worry about my lack of muscle, and, as a consequence, I picked up."

"I don't care anything about your health, James," said I. "How about your sitting beside the fire speculating on the tea kettle and all that?"

James grinned and winked one eye at me, as he said:

"Don't you take any stock in that yarn. In those days we had the open fire-place, the crane, tea kettle, and all that. The weather in Scotland at that time—I don't know how it is now—was moist, cold and disagreeable at certain seasons of the year, and would pretty near freeze a fellow to a frazzle. [James is evidently a Republican.]

"The back of the room would be like an iceberg, while near the fire one got the other extreme. After I had been out for a few hours cutting up devilments, finishing the chores and eating my bowl of porridge, I felt like sitting near the fire to keep warm. As a general thing an iron tea kettle was hung on the crane to heat water to wash the supper dishes, and as I didn't have anything else to do, I used to sit and watch the steam come out of the cover and spout of the tea kettle, or look at the fire; but as for sitting there and figuring on getting up a steam engine, don't you think of it for a minute, my boy. I was toasting my shins, nothing more. After I improved on the steam engine and got so prominent that people were willing to give me half the sidewalk when we met, some old woman remembered me sitting before the fire toasting my shins and started the tea-kettle story." And James laughed long and loud.

I began to take a fancy to James, for I could see that he was not going to take any more credit to himself than he deserved, and he was proving a pretty jolly companion. Seeing him cast a longing gaze at the cigar box, I pushed it toward him, with an invitation to help himself, which he did. After attempting to light the fresh cigar on the electric-light bulb and evidently much astonished at his inability to do so, he said:

"When I left home I went to London, and became apprenticed to an instrument maker named Morgan. I could stand him only about a year when I skipped out and went back to Scotland, where I hobnobbed with a lot of college professors repairing their kits. Next, I tried to open an instrument-making shop in Glasgow, but the union wouldn't stand for it, seeing I had not served my apprenticeship, although to tell the truth it would have taken a mighty good man who had done better or more accurate work than I did. They thought they were 'it,' but you don't hear much about them now, do you?" And I thought I could notice a slight chestiness about James I hadn't seen before.

"However," he continued, "I was helped along by the college professors, and after awhile found myself established in the college with the cognomen of Mathematical Instrument Maker to the University. What do you know about that? The professor knew I could make instruments, while the practical man thought I was no good, because I had not worked four years for some skinflint for next to nothing while learning my trade." James spoke with considerable vehemence, I thought, considering the occurrence had happened a century and a half ago.

"While at college I made the acquaintance of some pretty learned men and dabbled in philosophy, anatomy, chemistry, electricity, etc. It was my interest in philosophy which caused me to turn my attention toward old Newcomen's engine. I met him only the other day," said James after a pause, "and he swears that he had worked out my scheme of condensing steam, but had been bothered in getting his ideas through the patent office, both at home and abroad, when I butted in. What do you think of that?" James looked at me inquiringly, but before I could answer said:

"Newcomen is only doing what others have done. Few give me credit for what I have accomplished, most people saying that my work consisted of improving what others had started, but I see that they still hold to a lot of my ideas. Now wouldn't that press your pants?"

"Tell me about your first attempt at a condenser," I said, as James flicked the ashes from the end of his cigar with his little finger.

"I am afraid I shall be obliged to postpone that for another visit, as I am not yet advanced enough in the circle of progress in my world to warrant my roaming around on earth during daylight hours, and as it is almost sunrise I shall soon be obliged to bid you 'good morning.' We have had a jolly good time though, haven't we? I'll be only too glad to come back whenever you feel like putting up with such a cold-blooded old fellow as I am."

James arose, and as he reached across the table to shake hands the morning sunlight streamed in through the eastern window, and my visitor of the night immediately faded from my sight.

Practical Letters from Practical Men

Don't Bother About the Style, but Write Just What You Think, Know or Want to Know About Your Work, and Help Each Other

WE PAY FOR USEFUL IDEAS

A Study in Flexibility

The accompanying illustrations show two dry-vacuum pumps, *E* and *F*, connected to so-called "centrifugal barometric" condensers. While this arrangement is apparently simple, it caused no little discussion as to the best means of making the pumps interchangeable on either condenser. A "centrifugal barometric" condenser is a jet condenser of the barometric type, and differs only in that the vacuum is created not by the fall of a column of water but by the suction of a centrifugal pump. Its chief advantages are in the saving of head room and the avoidance of long connections.

Fig. 1 shows the piping as originally laid out, without any particular thought of interchangeability; therefore, it is difficult to understand why the valve *B* was placed in the line and, in fact, why the connections for the two units were not made entirely separate. As the sketch shows, a valve was placed in the drop tee to each vacuum pump, the valve *B*, therefore, could hardly serve any useful purpose except to separate the horizontal run into two parts.

Even had it been desired, by opening *B* and closing *C*, to allow the left-hand pump to operate with the right-hand condenser, the vacuum would still be placed on the left-hand condenser, and even though the valve in the exhaust from the engine, the circulating-water valves, the priming-water valves and the drain valves on the left-hand condenser were all closed, the numerous joints would afford an opportunity for sufficient air to leak in to cut down the vacuum on the right-hand condenser.

When piping has been [illegible] it is much easier to find any mistakes, and in this case it was seen that with comparatively few changes the arrangement could be made much more flexible. Fig. 2 shows how it was done. The valve *B* was removed from the main run, and placed in the short connection between the tee and the condenser; another valve *D* was placed similarly on the other condenser. Then by closing *A* and *D* the right-hand pump operates with the right-hand condenser; closing *B* and opening *D* the left-hand condenser is put in commission. The left-hand pump and condenser may be operated separately by closing *B* and *C* and the left-hand pump operated with the right-hand condenser by closing *D* and *C*.

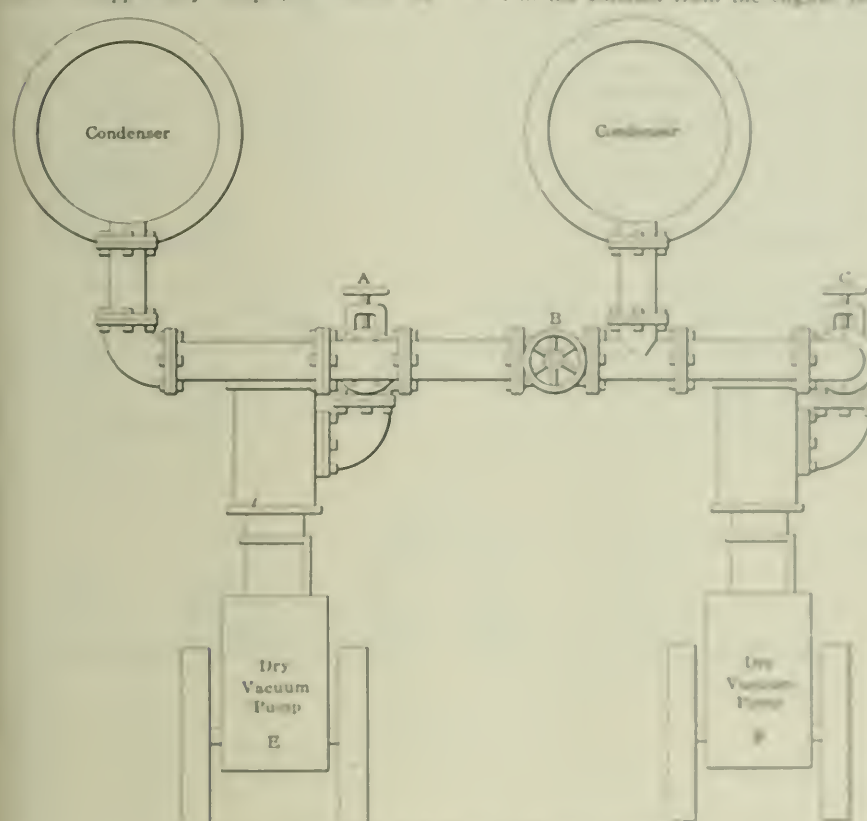

FIG. 1. SHOWING THE ORIGINAL CONNECTIONS

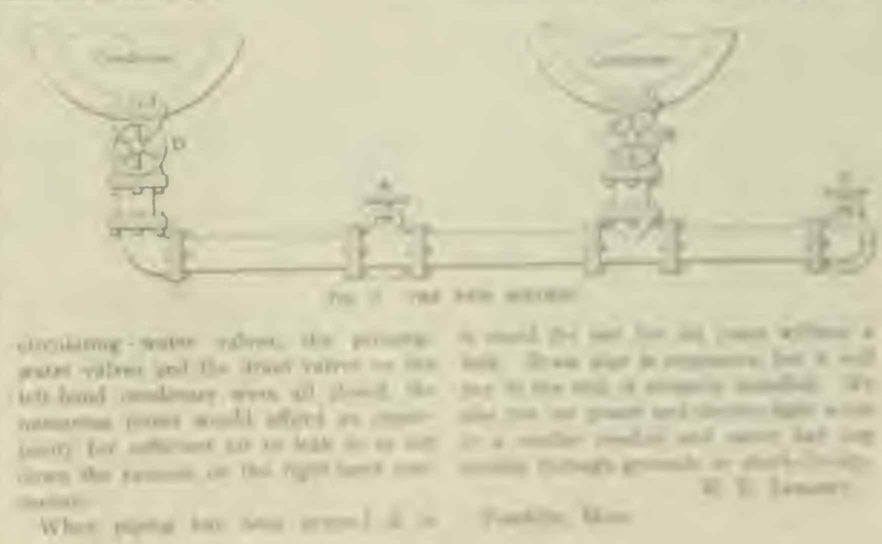

FIG. 2. THE NEW METHOD

Underground Insulation of Steam and Hot Water Pipes

In one plant I had charge of we laid 8-inch common vitrified drain pipe, being careful to have all joints flush and even, so there would be no obstruction on the inside of the pipe. All joints were made tight with portland cement mixed half and half. I used heavy brass pipe from basement to basement, having a union at each end of the conduit, so that if a leak should occur the pipe could be easily disconnected at both ends, pulled out into the basement and [illegible] without much trouble or expense.

By being careful in making joints we succeeded in getting everything tight and it [illegible] for years without a leak. Brass pipe is expensive, but it will pay in the end if properly installed. We also run our power and electric-light wires in a similar conduit and never had any trouble through grounds or short-circuits.

[illegible], Mass.

Exhaustion of Ignition Batteries

R. Manly Orr's query in one of the recent numbers, under the above heading, might form the text for a good deal of theorizing, since ignition batteries are a rather uncertain proposition and form a subject that seems to be but little understood by the average person. Mr. Orr, however, does not state what type of battery he has in mind, whether of the wet, dry, or storage variety.

If he refers to a wet battery, of the Edison-Lalande type, employing a caustic-soda solution as an electrolyte, and zinc and cupric oxide as the elements, he would probably find the life of his battery somewhat prolonged by doubling the speed of the engine, and thus cutting down the time element in the contact.

It could not be expected, however, that the life would be increased in direct proportion to the time element of contact, for the reason that the intermission between discharges is so exceedingly short as to give the battery practically no chance to recuperate to any appreciable extent after discharge. Furthermore, the internal resistance of a battery of this type is very low, permitting of more or less internal action when the battery is on open circuit. In consequence of this the age of the charge in the battery cuts quite a figure.

A battery of this kind generally has a very low voltage, varying from five-eighths to seven-eighths of a volt, and high initial amperage, making it possible for the battery to stand heavy discharges for short periods, with consequent long life on light-discharge service. This type of battery is built in capacities of from 150 to 600 ampere-hours, and is admirably adapted to gas-engine ignition service.

There are, however, three objections to this form of battery: their first cost, cost of renewals and low voltage: the last feature making it necessary to employ a larger number of cells in series to get the necessary six or eight volts generally used in ignition work. Under normal conditions, with no accidental short-circuits, a battery of this kind should give from 10 to 15 per cent. longer service at double the speed of contact.

With the use of dry batteries we are confronted with a different proposition. Practically all American-made dry cells use carbon and zinc as the elements, and ammonium chloride as the electrolyte. This combination results in a dry cell having an electromotive force of approximately 1½ volts, with a high internal resistance. Due, however, to the comparatively high voltage of the cell, and the close association of the active elements in the cell, there is a constant tendency toward internal action on open circuit, which would operate to shorten the life of the battery. In consequence of this, most manufacturers of standard dry cells endeavor to keep the internal resistance of the battery moderately high, and have adopted the practice of dating all their cells, claiming that they should be placed in service within sixty days of date of manufacture, to insure average life.

The idea is pretty general among combustion-engine users that a dry cell in order to be good must have a high initial amperage, and some refuse to accept a cell unless it tests 22, 25 or even up to 30 amperes on short-circuit through an ammeter.

This is all wrong. The initial amperage is merely an indication of the internal resistance of the battery, and has nothing whatever to do with the life of service. A battery showing a high initial amperage is most likely to have a filler of some inert substance having a low electrical resistance, but which serves no useful purpose in the battery. This would make the battery very short-lived, and the service would be exceedingly poor. It is to be noted that quite frequently, when a battery shows an initial amperage of from 22 to 30, if left on short-circuit for a few minutes through an ammeter, the amperage will drop rapidly, going as low in some cases as 10 or 12.

On the other hand, a good standard cell in prime condition, showing an initial amperage of 14 to 20 on short-circuit, will drop back a half ampere or so and remain there indefinitely.

It would hardly be practicable or economical to run a gas engine on dry battery for a period of six months, and get any sort of service out of it. The ideal battery for ignition service is, of course, the storage battery. This form of battery, having an electromotive force of approximately 2 volts per cell, gives an output that is absolutely constant, and under easy control. The first cost is practically the only cost, as the expense for recharging is comparatively light.

Testing Tanks for Steam Turbines

We recently had a test on one of our turbines to determine the steam consumption per kilowatt-hour. Fig. 1 is a cross-section through one of two 4x4-foot

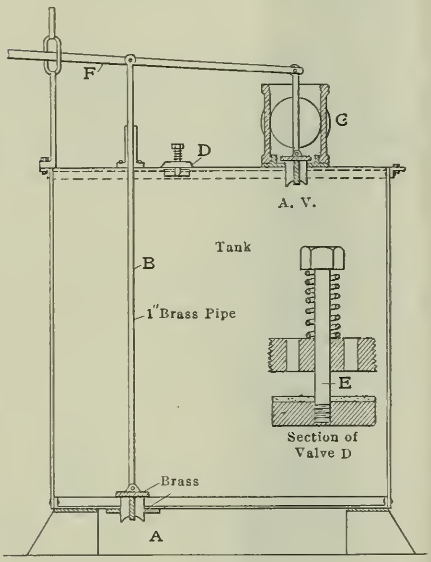

FIG. 1

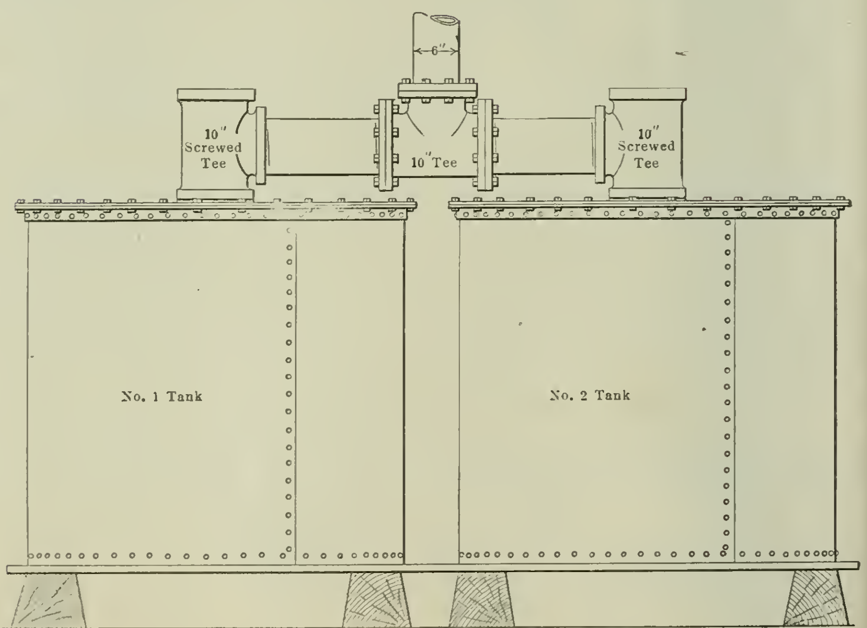

FIG. 2

tanks which were leveled up and filled with water, the water being carefully weighed in 400-pound lots. The tanks each contain practically 3110 pounds of water.

It will be seen from Fig. 1 that only one valve can be opened at a time, each valve stem being the fulcrum, by means of which the other valve is lifted from its seat. The valves are 6 inches in diameter, are made of brass and fitted with a leather washer between the seat and disk. The lower valve seat *A* is a brass plate 1 inch thick, riveted to the bottom of the tank. The valve stems are made of 1-inch pipe. The stem *B* passes up through a 1¼-inch brass pipe which acts as a guide. The discharge valve is shown open, and its construction is readily seen.

The admission valve cannot be opened until the discharge valve is closed, and *vice versa*. The upper, or admission, valve seat has a projecting ring above it, which is threaded with a standard 10-inch pipe thread to which the tee *C* is screwed, its function being shown in Fig. 2, which also shows the connection between the tanks.

The object of the snifting valve *D* is to admit air to the tank when discharging, and also to let the air escape from the tank when filling by simply pressing the hand on the valve stem. The valve opens inwardly and is ordinarily held shut by a spring. An enlarged view of the valve is shown at *E*, Fig. 1. The threaded por-

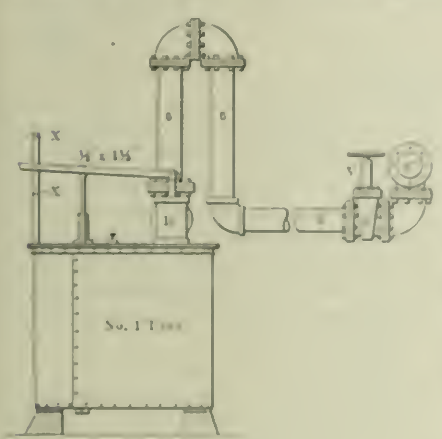

FIG. 3

tion is made of a 2-inch pipe, and the disk has a leather face. The operating lever *F* is provided with a stop, the object being to prevent lifting the valves too far from their seats.

In Fig. 2 each tank is shown connected to a short 10-inch nipple screwed into the tee. A flange on the end of each nipple is bolted to a tee, having the outlet facing upward. The 6-inch pipe represents the turbine wet-pump discharge.

In Fig. 3 is a side view of the tank and the connections to the discharge of the wet pump. The 8-inch pipe shown is a common discharge from two turbines and runs about 20 feet higher than the horizontal pipe. It discharges directly into the heaters. The discharge from the wet-vacuum pump being intermittent, we shut the valves on the heaters and all the water passes through the 6-inch pipe to the tanks. By about half closing the 6-inch valve *V* the pipe to the heaters is made a sort of air chamber on the discharge pipe from the wet pumps, and a steady flow of water is the result.

The "gooseneck" shown is to prevent air finding its way back to the wet pump over the top of the water in the discharge pipe.

While conducting the test a man was stationed at each operating lever to fill the tank, while the other is being discharged. We set the 6-inch valve about half open and shut off the valves on this line above the heaters. Then we let the water flow until the vertical pipe to the heaters was normal, when at a predetermined signal the admission valve was opened. When the man on tank No. 1 closes the admission valve preparatory to opening the discharge valve, the man on tank No. 2 must be ready to open his admission valve. This is, of course, an easy matter, for while it takes 1¼ minutes to fill a tank, the same tank can be emptied in 1 minute 20 seconds.

In closing a test we get one tank full and when the water overflows at the tees, as it did in the start, the last reading on the wattmeter is taken.

Kansas City, Mo.

Valve Problem Solution

Herewith is a solution to George P. Pearce's valve problem, as published in the December 8 issue, page 970. As seen by his illustration, the pressure on top of the valve equals the area of a 5-inch circle multiplied by 100 pounds per square inch equals 1963.5 pounds. The total pressure downward equals

$$1963.5 + 5 = 1968.5 \text{ lb.}$$

The area of passage of seven 1-inch holes is

$$7 \times 0.7854 = 5.4978 \text{ sq.in.}$$

and

$$1968.5 \div 5.4978 = 358 \text{ lb.}$$

pressure per square inch required to raise the valve.

As soon as the pressure exceeds 358 pounds per square inch the valve rises and a much larger area than that presented by the seven 1-inch circles is exposed.

G. A. GLICK.

Madison, Wis.

The pressure is 100 pounds per square inch on top of the valve. Neglecting friction, 100 pounds per square inch on the under side of the valve will balance 100 pounds per square inch above the valve; therefore, the extra pressure is that required to lift the weight of the 5-pound valve.

It makes no difference whether the valve is 5 or 50 inches in diameter, as we are dealing with pounds pressure per square inch and the weight of the water only affects the area of the valve covering the holes in the seat. The area of the holes is 5.4978 square inches, and the total pressure to be overcome or exceeded is

$$100 \times 5.4978 + 5 = 554.78 \text{ lb.}$$

The total pressure per square inch required to lift the valve would be

$$554.78 \div 5.4978 = 100.9 \text{ lb.}$$

per square inch. This would be increased slightly on account of friction of the valve on the stem and also the water in the holes in the valve seat.

J. C. HAWKINS.

[illegible], O.

The receiving pressure will act on the whole area of the valve or 19.635 square inches, and this times 100, the pressure, equals 1963.5 pounds pressure on the valve. The valve itself weighs 5 pounds, so the total pressure acting on the receiving side will be 1968.5 pounds.

It will take this much pressure on the delivery side just to raise it, but the area that this pressure has to act on is only the area of the seven holes or

$$7 \times 0.7854 = 5.4978 \text{ sq.in.}$$

The total pressure necessary to raise the valve will be 1968.5 and the pressure per square inch will be

$$1968.5 \div 5.4978 = 358 \text{ lb.}$$

BURT A. SMITH.

Ithaca, N. Y.

Firing Stationary Boilers

In a recent article, "Firing Stationary Boilers," by F. R. Wadleigh, there is one point which I do not understand. He says: "The fireman should know that the place to regulate or shut off draft is by the stack damper and not by the ashpit doors. The latter are for the purpose of regulating the air supply."

I cannot see why the air supply cannot be regulated entirely by the stack damper, provided its design and the character of the coal will permit. A smoky coal will clog the tubes with soot a great deal more quickly with the damper partly closed than with the ashpit doors closed. It took me a long time to figure out why a certain amount of gases passing through the tubes at a certain time would not have the same velocity under both conditions. I finally decided that with the ashpit doors closed the gases were lighter, due to reduction of pressure and, therefore, had a higher velocity and carried off more of the particles of soot. So far as the simple admission of a certain amount of air to the fire is concerned, I cannot see what difference it makes whether it is regulated at the damper or the doors.

There are two good reasons why the ashpit doors should be kept open. With the doors closed there is more leakage of air above the grates through the setting, while with the ashpit doors open there is more radiation of heat which lowers the temperature of the ashpit and helps to preserve the grates.

J. F. [illegible].

Valparaiso, Ind.

How Compression Saves Coal

The article under the above caption, by M. E. Copley, does not tell why nor how he came to his conclusion. He presents a set of diagrams which I have taken a little time to analyze. The low-pressure diagram shows practically no compression, but does show a great deal of back pressure, due to the fact that there is no compression. If he would overcome the back pressure, he must make his release earlier, which means that the exhaust valve must open and close earlier in the stroke, which will give compression, something Mr. Copley does not want.

The average mean effective pressure of both ends is, say, 0.835 pound, while the average mean effective pressure would have been, say, 0.895 pound, had the valve opened earlier and the area represented by the back pressure been saved, making a saving or additional power of 0.06 pound mean effective pressure. This is worse than lost becaust it represents negative power, or power pushing against the piston tending to stop it, especially at a time when it is most needed, at the beginning of the stroke. If there is a loss of 0.06 pound mean effective pressure through loss of area in the diagram, and that amount is pushing in the wrong direction, the total loss is $0.06 \times 2 = 0.12$ pound mean effective pressure. It is true that some area would be lost through compression, but not as much as the negative pressure would cause.

It is a difficult matter to figure out how a saving is made by cutting out compression and cutting in back pressure.

Another bad feature shown by the diagrams is the great difference in the load between the high- and low-pressure sides. As the size or speed of the engine is not given, I am assuming that the ratio between the cylinders is 4 to 1. The average mean effective pressure of the high-pressure diagrams is, say, 58.29 pounds, while the average mean effective pressure of the low-pressure diagrams is 0.835 pound. Therefore, the total horsepower of the engine would be

$$58.29 + 0.835 = 59.125.$$

Now, if that work were equally divided between the two engines the mean effective pressure of the low-pressure side would be

$$59.125 \div 4 = 14.78$$

pounds, but as the actual mean effective pressure is only 0.835 pound, the low-pressure cylinder is only doing

$$14.78 \div 0.835 = 17.78,$$

or 1/17.78 part of the load. In other words, the high-pressure side is doing nearly 18 horsepower, while the low-pressure side is doing only 1 horsepower. There may be some special reason for distributing the load this way, but if not, it will be a surprise to see what a difference it will make in the coal pile by raising the receiver pressure to 18 or 20 pounds, cutting in a little compression and cutting down the back pressure.

TOTT JENKINS.

De Kalb, Ill.

Connecting Rod Design

In regard to the article on "Connecting Rod Design," in a recent issue, I wish to criticize the crank end of Mr. Willard's rod, which is herewith reproduced in Fig. 1. In the first place it is stated that as flanged brasses are used, it is necessary to have a removable end. A better design is to have the top of the rod open as shown in Fig. 2, the brasses being clamped by a lipped cover plate. In Fig. 1 the end bolt *D* is evidently subjected to the entire stress on the rod on the inward stroke of the engine, while Fig. 2 presents a solid thickness of metal at the bottom and a lipped cap at the top to resist this stress.

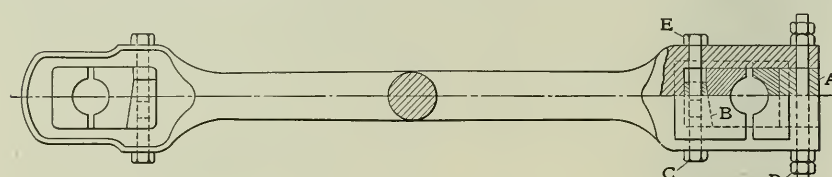

FIG. 1. (REPRODUCED)

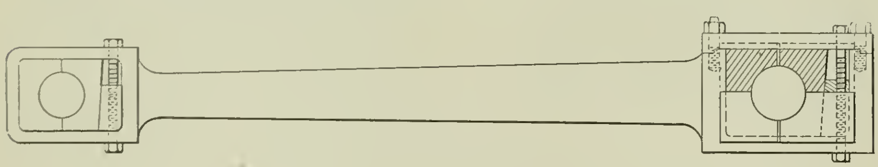

FIG. 2

It should also be noted that in Fig. 2 the adjusting wedge is outside of the the pin, while at the crosshead end it is inside, this end being practically identical to Mr. Willard's form. Such an arrangement of the means of adjustment is very necessary in order to keep the rod of the proper length, and the clearance in the cylinder equal.

In regard to cost of manufacture, it will be seen that the rod in Fig. 1 must have both ends machined on a slotter, while the crank end of the rod in Fig. 2 may be finished in any size on a planer with a corresponding reduction of time. I also differ with Mr. Willard in regard to the adaptability of such a rod to marine engines, though it is the very best type for horizontal engines, air compressors and locomotives.

Hyde Park, Mass.

Method of Calculating Capacity of Absorption Machinery

A very convenient method of calculating the capacity, in tons of refrigeration, of an absorption machine, is as follows: Take the revolutions per minute, or total revolutions, with a counter, of the aqua pump during the time desired for determining the load of the machine; also take the Baumé and temperature of weak and strong aqua at frequent intervals during this time. Note the back pressure on the expansion coils, also.

Determine the capacity of the aqua pump in cubic feet per revolution, taking into consideration the aqua piston rod. Correct from the table the actual Baumé readings of strong and weak aqua for temperature, i.e., reduce both readings to 60 degrees Fahrenheit. From the tables, get the per cent. of ammonia in strong and weak aqua, also the specific gravity of strong aqua, using the corrected Baumé readings.

The weight of a cubic foot of water, 62.5 pounds, times the specific gravity of strong aqua equals the weight of a cubic foot of strong aqua. The revolutions per minute of a pump times the cubic feet per revolution times the weight of a cubic foot of strong aqua equals the pounds of strong aqua pumped per minute, or *M*.

The tons of refrigeration per day of 24 hours equals

$$\frac{M\,(x-y)}{100-y} \times \frac{r}{284{,}000} \times 1440,$$

where

x = Per cent. of ammonia in strong aqua,

y = Per cent. of ammonia in weak aqua,

r = From ammonia tube, equals the value in B.t.u. of one pound of anhydrous ammonia at the back pressure of the expansion coils, allowing for the temperature of the anhydrous ammonia at the expansion valve, and the temperature corresponding to the back pressure.

This method is by no means absolutely accurate, due to slippage in the aqua pump, inaccuracy of gages, etc., but it serves as a handy check on a machine or for daily comparison.

G. A. ROBERTSON.

St. Louis, Mo.

Firing Boilers

In the December 8 number, page 955, F. R. Wadleigh has an instructive article on firing boilers. On page 959 he says, regarding the wetting of coal, "the practical reasons for wetting coal will generally outweigh the theoretical or chemical reasons for not wetting it."

Wet coal will coke better, make a hotter fire and less smoke than dry coal. At one time I held the same opinion as Mr. Wadleigh, but in looking over my table of boiler tests I saw that coal wet so as to make a good fire evaporated about 8 per cent. less water than ordinary dry coal, and I gave up wetting it. The water must be evaporated, and during the evaporation the fire is not hot enough to decompose it.

W. E. CRANE.

Broadalbin, N. Y.

Hard or Soft Condenser Tubes

On the editorial page of the December 8 issue the attention of the reader is directed to the use of hard or soft condenser tubes. Hard tubes are liable to crack, although the process of manufacture may prevent most of it. Cracked tubes are liable to occur, not only condenser tubes, but brass or alloyed pipe of all kinds, even though no work is put upon them. When a pipe is drawn through the die it becomes hard, and to be worked further it must be heated to a low red, which anneals it.

While the tube is in a hard condition a severe strain is placed upon every fiber, and if put into the annealing oven just as it comes from the die it would probably crack. To prevent this cracking, a man lifts the tube above his head and throws it violently to the floor in such manner as to bend it slightly.

When finishing a tube for power purposes it should be left semi-annealed, if not, even the best made tubing may crack in use. With pure copper tubes there is not as much trouble, but they are expensive. Brass tubes are made of different metals with different densities and expansions, and a tube left hard appears to be full of strains which mean its destruction.

With salt water, even pure copper is not free from corrosion, and it could hardly be expected that its alloys would be. It is possible that hard tubes may have incipient cracks which hasten corrosion, and that absence of these cracks may mean longer life to the semi-annealed tube.

Nickel tubes were tried, and for a time it seemed as though the right thing had been found. They could be more heavily annealed than brass tubes and still be stiff enough to work, but they were not proof against corrosion.

W. E. CRANE.

Broadalbin, N. Y.

Composite Power Generation

Recently, in an editorial on "Composite Power Generation Again," it is stated that the writer does not understand how the heat in 40 pounds of jacket water can be concentrated to evaporate 4 pounds. The accompanying sketch shows an arrangement for doing this. The water in the cylinder jacket J will be discharged at, say, 160 degrees Fahrenheit and at a pressure of 14.7 pounds absolute. As the water rises in the pipe A, the pressure, due to gravity head, diminishes until at some point C the pressure will exactly correspond to the pressure of saturated steam at 160 degrees Fahrenheit. Above this point, if no steam were formed at some point E the water would be at 4.4 pounds absolute pressure, and a temperature of 160 degrees Fahrenheit, but this is just as impossible a condition as water at 230 degrees Fahrenheit at atmospheric pressure. Under such conditions part of the water will be evaporated at the expense of the heat in the remainder, so that when the water has risen to point D, its temperature will have been reduced to [illegible] degrees Fahrenheit and it will have given off a quantity of steam.

ARRANGEMENT FOR CONCENTRATING JACKET WATER HEAT

The water at this temperature being returned to the jacket through pipe B by the circulating pump, will again be heated to 160 degrees Fahrenheit and the cycle repeated. Instead of circulating 40 pounds of water per brake horsepower per hour, it would be necessary to circulate [illegible] B.t.u. divided by [illegible] degrees temperature change, which would equal [illegible] pounds per brake horsepower-hour. This would, of course, require [illegible] engine but a short calculation will show that [illegible] pipe would be large enough for a [illegible] horsepower gas engine.

I am not able to follow exactly the reasoning in the last paragraph of the editorial [illegible] of pounds of water that could be evaporated by the exhaust gases. Using the figures given, [illegible] B.t.u. per horsepower, [illegible] per cent. of this would be [illegible] B.t.u. According to the tables of steam in Kent's handbook, the total heat of steam at 150 pounds gage pressure is [illegible]. Subtracting from this the temperature of the feed water, [illegible] degrees, as given, leaves [illegible] B.t.u. required per pound of steam. [illegible] B.t.u. divided by [illegible] equals [illegible] pounds per horsepower-hour, instead of [illegible] pounds. Which is the nearer right?

There is one feature which may make up to some extent for the small output which it is said would scarcely justify the complication necessary for its production. The heat produced by the exhaust can be stored in [illegible] reservoirs during seasons of normal load and utilized on the peak load. This would supply overload capacity, in which the gas engine has always been sadly lacking.

A. L. [illegible]

[illegible], Penn.

Faulty Indicator Diagrams

In a recent number, J. [illegible] shows diagrams taken from a high-speed engine and asks for opinions as to the trouble and for a remedy. As he says, the diagrams show a very one-sided adjustment, the crank end doing practically no work, and I suspect the crank pin suffers because of it. The head-end diagram shows that the exhaust valve closes so early the compression is excessive. On the same end the steam port closes late, giving a release pressure of apparently [illegible] pounds. The crank-end steam port barely opens at all, and the small amount of steam which does get through expands down to atmospheric pressure when the valve is reversed and compression begins.

My remedy would be to lengthen the valve stem for a more equal steam distribution. I think it will be found that the eccentric requires moving ahead in the turning direction, until a nearly equal admission line is obtained.

In the same number, M. C. [illegible] shows a set of diagrams from a [illegible] engine which, he says, is [illegible] [illegible] [illegible] [illegible] very small amount of compression, but is it not at the expense of the condenser?

WILLIAM AULD.

Milwaukee, Wis.

A New Method of Firing

I do not approve of a thick bed of coal on the front end of grates with little or no depth of fire on the back end near the bridgewall. The proper method of coking is to keep a good, thick fire on the back of the grates at all times, as well as on the front. In this way, after being pushed back and replaced by a new charge, the fire will be of equal depth all over the furnace. None but an ignorant or lazy fireman would keep coal piled up just inside the furnace door.

One of the first things a fireman should learn is to keep a good thick fire in the back end of the furnace; otherwise, the cold air, meeting little or no resistance, will rush through the thin layer of coal without becoming heated enough to mix with the gases from the front. The bridgewall, instead of being heated hot enough to assist combustion, will retard it by cooling the gases passing over it.

C. E. BASCOM.

Marlboro, Vt.

Criticism of Turbine Installation

The recent article describing a mammoth turbine for Buenos Aires strikes me as a good one on which to base a discussion. First, I would like to call attention to the amount of water the circulating pumps are capable of delivering per hour. Each pump, it is stated, will pump 112 gallons per second; the two pumps will, therefore, pump 224 gallons per second, providing they are both in condition to run at the same time. This is 13,440 gallons per minute, or 806,400 gallons per hour, and assuming 8.3 pounds per gallon (critics, excuse the figure) this will amount in round numbers to 6,693,120 pounds per hour. The turbine at maximum load develops 14,200 horsepower, which is equivalent to 10,593 kilowatts. It is stated that the machine will develop a kilowatt-hour on 13.86 pounds of steam. This will mean about 147,000 pounds of steam, round numbers, to be condensed per hour. Dividing 6,900,000 by 147,000, we get as the circulating water per pound of steam 47 pounds, nearly.

This is the first point I would like to see discussed. The American practice is to allow not less than 60 pounds of condensing water per pound of steam. I think that a larger circulating-pump capacity should have been provided. The temperature of the water the year round must be taken into consideration, the final temperature of the circulating water, and, last but not least, the temperature of the condensed steam. This last point is one I am very much interested in. At what temperature can the condensed steam be maintained with a 28½-inch vacuum?

The second feature in the plant in question is the cooling surface in the condenser. It is 14,000 square feet, and at maximum load of the turbine the ratio is 1 square foot of cooling surface per horsepower. The latest American practice is to have 2 square feet per horsepower for reciprocating engines and 4 square feet per kilowatt for turbines. This may seem to be a rather liberal allowance, yet I have found in my own experience that it is none too much, for several reasons. Trash may stop up a number of tubes between morning and shutting-down time, and it is not always possible to shut down the condenser and clean them out. In summer the circulating-water temperature may get rather warm, or the circulating-pump capacity may decrease. In the case of a turbine, in order to keep the steam consumption down to 13.86 pounds per horsepower per hour, it is necessary to have about 28½ inches of vacuum, and in order to do this there must be sufficient cooling surface. It has been my actual experience that no matter how much water in put through a tube, the element of time has considerable to do with the amount of heat it can absorb. From the foregoing it would seem that there is not enough cooling surface to this particular condenser.

I also notice that this station is making a bid to be classed among the most economical of power stations, by using electric auxiliaries. I fail to see where these so-called modern improvements are making any more than an apparent saving. Suppose the prime mover has a thermal efficiency of 18 per cent. and the electrical end of the auxiliary has a 90 per cent. efficiency, the combined efficiency is 16.2 per cent. This same plant, if served completely by electric auxiliaries, will probably have a feed-water temperature of 100 degrees Fahrenheit, a loss of 11 per cent. in fuel. How much do they gain by the modern auxiliaries? This latter question applies to a good many modern power stations, in part if not altogether.

E. H. LANE.

Kansas City, Mo.

Repairing a Broken Eccentric Rod

Owing to the heating of the steam eccentric, the eccentric rod of a 14 and 26 by 30-inch high-speed Corliss engine broke in three pieces. The first break happened at the rocker-arm brass, where the diameter was less than ¾ of an inch. Coming in violent contact with the concrete floor, it again gave way near the eccentric strap. The oil guard was demolished and a portion of the automatic oiling system was dismantled. It was imperative to have a new rod in place before 4 p.m. the next day, but to get a rod from the maker inside of 18 hours was impossible. It was a case of hustle, therefore, to make a new rod in time for the evening load. Fig. 1 shows the valve gear; at *A* is shown the position of the steam-valve cranks. There is no valve-stem stuffing box, as a ground joint of a special oval pattern makes it unnecessary, as shown.

On this engine the opening in the steam bracket was so small that half a turn of

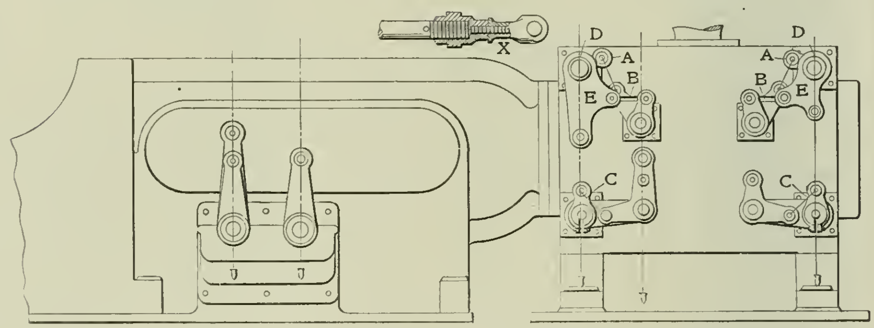

FIG. 1

the eccentric rod one way or the other would cause the valve crank to knock against the edges. Hence, the new eccentric rod had to be the exact length, or we were liable to have another accident in the shape of a broken valve bracket.

With the eccentric rod removed, the striking points of the valve cranks were marked on the box of the rocker arm. The links *B* were then removed and the eccentric rod screwed in for as near its right length as we could determine. The air pump was started and the engine allowed to be turned slowly by the vacuum. The length of the eccentric rod was so adjusted that the mark on the rocker arm traveled slightly inside the marks on the box cover. The links *B* were replaced, the engine brought to speed and load given it, when the job was completed with the aid of the indicator. Some may wonder why the reach rod was not taken out instead of the links *B*. There is only one position of the crank which permits the reach rod on this engine to be taken out, and that position is difficult to stop at. At *X* is shown how the narrow end of the eccentric rod was stiffened and strengthened, by a special nut planned by the superintendent.

At first sight the valve gear looks to be quite complicated, and many would infer that it is difficult to adjust. An inspection of the plumb lines in Fig. 1 shows that the valves are almost as easy to adjust as slide valves. No adjustment is possible on the brass links B of the steam valves and C of the exhaust valves. After adjusting all rods to their proper length, place the engine on the crank-end center, turning the engine in the direction it is desired to run. Then loosen the hub bolts and set screws of the flywheel and revolve the latter on the shaft, until the required lead is obtained at the crank end. On this particular engine the lead is 1/8 inch on the high-pressure side, and 3/16 inch on the low-pressure cylinder. Tighten the hub bolts and set screws on the flywheel, and place the engine on the head-end dead center. The lead on the head-end valve should be practically the same. If it is not, equalize it by means of the steam rod. On the steam-valve bracket washer D, Fig. 1, will be found five marks, the two outer corresponding with the maximum travel of the steam rockers E, the two next with the minimum travel and the middle mark with the central position. These marks should be verified before the steam bonnets are replaced. The maximum travel marks are easily found by rotating the engine.

To find the minimum-travel marks, loosen the tension on the governor springs A, Fig. 2, being careful to count the number of revolutions the springs are turned, and [illegible] the weights W simply against the stops D. Each steam valve should now travel an amount equal to its lap only, i.e., the two marks (the valves are ported) on the circular end of each valve should come line and line with the marks on the valve chamber. This insures that the engine will not run away, should the load be suddenly thrown off. Do not, however, let the valves travel an amount less than their lap, for the governor springs are liable to be overstretched and strained.

When the valve and valve-chamber marks on either side coincide, the mark on each of the rocker arms E will be line and line with one of the minimum-travel marks on each of the two washers, if these marks are correct.

The exhaust valves, when the rocker arms are central, as in Fig. 1, have 3/16 inch lap on the high-pressure side, and 1/4 inch on the low-pressure side. Compression begins when the crosshead is within 3⅓ inches, or 12 per cent., of the end of its stroke. For the benefit of those who might wish to study the action of the governor the layout is plotted in the dotted lines in Fig. 2.

Now place the flywheel in such position that the two [illegible] bolts are downward; loosen and remove them and [illegible] the bolts by a [illegible] and [illegible] replace them. [illegible] with a [illegible] and [illegible]

FIG. 2

a hammer or pegs to set them up; all corrections due to settling will simply take care of that.

Fig. 3 shows the low-pressure governor and the method of changing the receiver pressure. Lengthening the link rod A decreases the travel and consequently raises the receiver pressure. The spring B is connected to the governor weight arm at

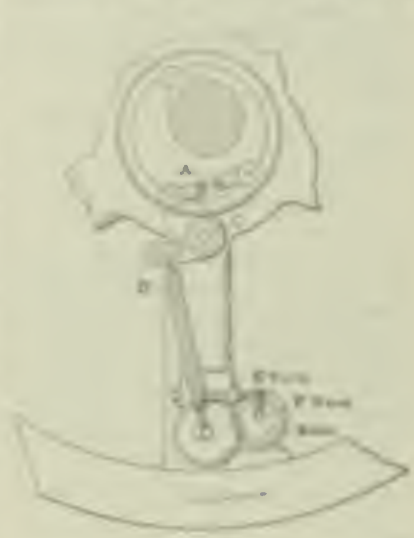

FIG. 3

one end and at the other to the worm gear which is operated by the small motor shown, which is used to make slight changes of speed while synchronizing from the switchboard.

E. O. [illegible]

Framingham, Mass.

Hygrometry

In J. H. Harris' contribution on "Hygrometry," which appeared in a recent number, in the middle of the second column he states: "If moisture is in contact, it in general becomes saturated for that temperature, to precisely the manner that steam becomes saturated in a boiler [illegible]."

I should like to draw attention to the [illegible]. In my opinion when considering "steam" the word "saturation" applies to heat; that is to say, when we state that steam is saturated we intend to convey the idea that it is saturated with heat units. Such being the case, it is [illegible] impossible [illegible] for the steam to [illegible] at all, as any further addition of heat merely [illegible].

Practically, we allow but a certain percentage of moisture being present in saturated steam, and in today's [illegible] we [illegible] the term "dry" or "commercially dry saturated steam" which [illegible] about 2 per cent. by weight of moisture.

W. [illegible]

West Hartlepool, England.

Polish for Brass Steam Pipes

Herewith is a recipe for a polish for brass steam pipes, or other hot-brass work in the engine room, which I have used for years and believe to be the best polish that can be made:

Melt together 1¼ pounds of cake tallow, 2 ounces of spermaceti, 2 ounces of gum camphor and 2½ ounces of beeswax. Then add 8 ounces of raw linseed oil, 10 ounces of coal oil and 2 pounds of tripoli powder.

J. B. Draper.

Kenton, O.

Pump Suction Limit

In a recent issue a correspondent asks why a pump will not lift water a distance nearly equal to the head balancing the atmospheric pressure, say 32 or 33 feet. Leaving out the question of water temperature, for the time being, and assuming that the suction pipe is air-tight, then

A_p = *Total suction limit* =

$$H = \frac{v^2}{2g} + F_p,$$

where

A_p = Atmospheric pressure expressed in feet,

H = Elevation of pump above water level,

v = Velocity of flow in feet in suction pipe,

g = Gravity equals 32.16,

$\frac{v^2}{2g}$ = Velocity head,

F_p = Friction loss in feet, which depends upon the velocity of the water in the suction pipe. This friction factor includes losses in foot valve and elbows.

From this it is seen that the hight to which a pump will lift water by suction can never equal 32 or 33 feet, unless the flow in the suction pipe is extremely slow.

If the temperature of the water is taken into consideration, it still further lowers the lift, as will be seen from an examination of the following table, based on atmospheric pressure at sea level:

Temperature of Water. Deg. Fahr.	Pressure of Vapor in lb. Per Sq. Inch.	Limit of Suction Head, Considering Temperature Only.
70	0.36	32.96 feet.
80	0.50	32.6
90	0.69	32.2
100	0.94	31.4
110	1.26	30.9
120	1.68	29.7
130	2.22	27.3
140	2.87	25.9
150	3.70	24.8
160	4.72	22.5
170	5.98	19.6
180	7.50	16.9
190	9.33	9.9
200	11.52	9.3
210	14.12	1.1

In the foregoing it was assumed that the suction pipe was perfectly air-tight, but as this is hard to secure, due allowance should be made.

John B. Sperry.

Aurora, Ill.

A Homemade Socket Wrench

On taking a turbine pump apart one day, to remove a worn-out impeller, it was found necessary to remove five 1-inch hexagon nuts from the position shown in Fig. 1. A hole in the outside wall was closed by a 2-inch plug, and to reach the nuts a socket wrench was required, and none of suitable size being at hand, it was decided to make one.

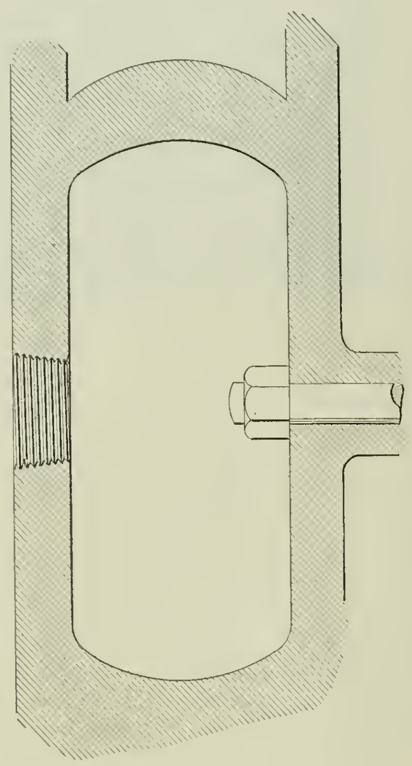

FIG. 1

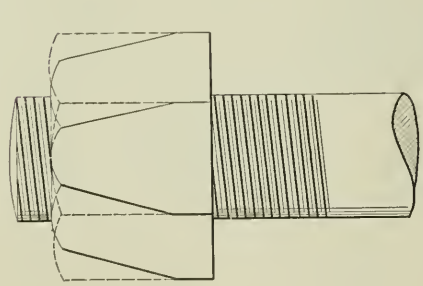

FIG. 2

Picking out a 1-inch bolt and nut from the scrap pile I dressed the nut down to a taper, as shown in Fig. 2, when it was found to just about enter a piece of 1½-inch gas pipe. To heat the end of the pipe and forge it into a hexagon shape to fit the nut was then a simple matter, and it proved an excellent wrench.

In the same manner a 1¼-inch pipe may be made to fit a ¾-inch nut, and 1-inch pipe will answer for a ⅝-inch nut. Socket wrenches of these sizes will always be found handy around a steam plant.

R. Cederblom.

Gary, Ind.

Storage Battery Troubles

In a recent number, J. M. Herwig narrated his troubles with a storage battery which apparently became dead shortly after being charged. The battery has evidently had hard usage, and he will doubtless find that the cells have either short-circuited or accumulated sulphate. Short-circuiting may be caused by sediment accumulating in the bottom of the cell until it reaches the plates. The cells should be cleaned frequently and new electrolyte added to replace that which is lost, to bring the gravity of the solution up to 1.210. If there is any suspicion that there is foreign matter in the solution, new electrolyte should be used.

Care should be taken while cleaning the battery not to allow the negative plates to dry in the least. If they are allowed to dry it will be necessary to charge them again for a period equal to the initial charge.

Sulphating is the most troublesome element to contend with in a storage battery. It is formed when a cell is nearly discharged and is noticeable by the formation of a white coating over the plates. If a cell is discharged and allowed to stand with the electrolyte in place it will sulphate very rapidly. This also causes buckling of the plates, because the formation of sulphate in the active material causes it to expand, forcing the grids out of shape. This sulphate, being a non-conductor, increases the resistance of the plate, and when it is removed carries part of the active material with it. Long-continued charging at a moderate rate will gradually remove all sulphate from the plates.

When the cells are fully charged and in good condition the positive plates should be of a brown or deep red color and the negative plates gray. The battery should never be charged above its maximum charging rate, because it will cause a rapid accumulation of sediment, excessive evaporation of the electrolyte and the life of the battery will be much shortened. A low-reading voltmeter should be used for testing each cell, and a discharge lower than 1.8 volts per cell should not be allowed. The battery should be charged until the voltage shows 2.5, then the charge should be cut to about half and continued until the cells again show 2.5 volts; the battery is then fully charged. As the age of the battery increases the final charging voltage will drop to about 2.4.

The change of temperature affects the final voltage so that it is lowered with an increase of temperature above 70 degrees Fahrenheit and correspondingly increased by a lowering temperature. After the charge is completed and the current is cut off the voltage will drop to about 2.2 volts per cell, and when the discharge is started it will drop to 2 volts.

The temperature of the surrounding air of a storage battery should rise no higher than 80 degrees Fahrenheit and drop no lower than 50 degrees Fahrenheit. If the surrounding temperature is high the wear on the plates is excessive. No harm results from a low temperature except that the capacity of the battery is reduced.

NORMAN S. CAMPBELL.

Detroit, Mich.

If the plates were buckled when received, it would indicate an old battery. Buckled plates would account for the rise in temperature of the electrolyte, and the battery, owing to this condition, has a reduced capacity. The battery in this condition cannot be charged properly, although it will appear to be fully charged and will gas freely, especially if the sulphate forms between the active material and the grid. The active material contracts in the negative plate and closes up the pores; this reduces the active surface, the contact between the active material and the supporting grid is reduced, and when the battery is allowed to discharge too low, and stand in this condition, electrolytic action may take place on the surface of the material next to the grid, which will cause a layer of sulphate to form between the grid and the active material. The expansion of this layer of sulphate crowds the active material farther away from the grid, decreasing the contact and increasing the layer of sulphate, the result is the insulating of the active material.

If the active material in the negative plates has contracted, the separation from the grid can often be noticed. In this case, remove the positive plates and substitute dummy plates, made of thin sheets of lead, about 1/16 inch thick. The positive terminals from the charging leads are connected to the negative plates, the negative leads to the dummy plates. In charging the plates this way the negative plates become positive in effect. By reversing the polarity of the charging current the negative plates are reduced back to sponge lead. This reversing of the direction of the current tends to open the pores and bring the plates back to their normal capacity.

If a layer of sulphate is formed between the active material and the grid, the only way that I am aware of to reduce the sulphate is by burning it off. Charge the battery as rapidly as possible, without raising the temperature above 110 degrees Fahrenheit, and when it gases freely, reduce the charging current to three-fourths or two-thirds of the normal, and continue until the gas bubbles again appear; then again reduce the current to one-half the normal, and continue as before; give the battery a light discharge, and repeat the charging operation. This treatment will have to be performed several times. If the battery has been short-circuited by sediment filling up to the bottom of the plates this charging operation will remedy it. The rate of discharge affects the temperature of the electrolyte, the higher the rate, the higher the temperature. The temperature also affects the capacity of the battery, the higher the temperature the greater the efficiency. It also increases the density. The battery, however, deteriorates rapidly if worked at a temperature above 110 degrees Fahrenheit.

Effect of Superheated Steam on Cast Iron Fittings

Referring to the peculiar effect of superheated steam on cast-iron fittings, one example of which was shown in a recent number, a possible explanation of this action may be in the fact that metallic iron at a high temperature [illegible] has the property of decomposing steam, resulting in the formation of magnetic oxide of iron and free hydrogen. The action is very rapid when the iron is clean, but is retarded and becomes sluggish from the coating of oxide formed over the surface of the iron. I do not know that it has ever been determined whether this action ceases entirely if the temperature is reduced below a red heat, but it seems reasonable to assume that the high temperature of the steam would reduce the affinity of the atoms forming the water molecule, and assist the iron to dissociate them. The action could be very slow and still produce marked effects in the time the fitting in question was in service, i.e., three years.

The increase in the size of the fitting can be accounted for by the oxidation of the iron, but if this is found to be confined to a thin coating inside, another explanation would be the occlusion of the hydrogen by the cast iron. The great tenuity of hydrogen gas gives it great penetrative power, many solid metals, among them iron, being readily penetrated by it. When there is an attraction (perhaps a feeble chemical affinity) between hydrogen and the metal, the gas may become largely condensed in the pores of the casting. Whether this action would result in any increase of bulk in the original metal I do not know, but a careful physical and chemical examination of the metal composing the fitting would show what changes in structure and composition had occurred. In view of the great importance of such information it is to be hoped that a careful investigation will be made and the results published.

Hamilton, O.

Corliss Valve Setting

Following are convenient rules for setting the valves of a Corliss engine: First remove the bonnet covering the ends of the valves. Reference marks will be found on the ends of the valves and seats, giving the positions of the working edges of the valves and ports. Reference marks will also be found on the wristplate and supporting stud. Turn the eccentric around on the shaft, and see whether the wristplate has equal travel on each side of a vertical center line. If it has not, equalize the travel by altering the length of the eccentric rod.

Next place the wristplate in mid-position with the dashpot plungers hooked up. By means of the wristplate rods give the steam valves the proper lap and the exhaust valves a negative lap or opening about as indicated in the following table:

Steam Cylinder, Inches	Steam Lap, Inch	Exhaust Opening, Inch
12	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]

To adjust the length of the dashpot rods place the wristplate in one extreme position, as indicated by the reference marks. Adjust the length of the proper rod until the latch catches, with about 1/32 inch to spare, and repeat for the other extreme position. Should it be necessary to disturb the lengths of the wristplate rods, this operation must be attended to a second time.

Next, connect the [illegible] rod to the wristplate. With the engine on the center, set the eccentric 90 degrees plus the small angular advance necessary for the required lead, ahead of the crank, in the direction the engine is to run. If the lead is not the same with the engine on the other center, adjust with the wristplate rod. Then block the governor balls half-way up and see that the reach-rod lever is clamped at right angles to a line and [illegible] the reach rods. Place the engine on one-quarter stroke from the head end, and adjust the reach rod which trips the head-end valve, until the valve is released. Repeat for the crank end. Final adjustment may be made with the engine running slowly.

Drop the governor balls to their lowest position and adjust the safety cams on the knockoff cams so that, with the governor in this position, the valves cannot be opened by the wristplate motion.

F. L. [illegible]

Hyde Park, Mass.

Waste in a Power Plant

After reading C. R. McGahey's letter in a recent number, I do not wonder that the piping leaks, if the two boilers are connected as his illustration shows.

Regarding the size of pipe for a 28x48-inch engine, running at 100 revolutions per minute, it would be, according to the rule most used, as follows:

$$\frac{(28^2 \times 0.7854) \times 800}{6000} = 821;$$

$$\sqrt{\frac{821}{0.7854}} = 10.2,$$

or, say, a 10-inch pipe.

Nothing is said as to the speed of this engine, but it took the place of a 300-horsepower engine, which, at 100 revolutions per minute, would require only a 7½-inch pipe.

I have often seen a 300-horsepower engine with a 7-inch pipe carrying 500 horsepower, with a very small drop in pressure. I should say Mr. McGahey must be carrying, or trying to carry, a great deal more than 300 horsepower. He has an engine that with a mean pressure of 35 pounds and at 100 revolutions per minute, will carry 530 horsepower.

C. L. Johnson.

Mason City, Ia.

Effect of Scale in Boilers

In the December 8 number, F. Hilton Williams has something to say concerning the effect of scale in boilers. Mr. Williams may be glad to know that very complete information on this subject may be obtained in Bulletin 11 of the Engineering Experimental Station of the College of Engineering of the University of Illinois, Urbana, Ill.

This bulletin discusses the heat-transmission loss due to boiler scale and its relation to scale thickness, and covers a large series of experiments conducted by the experimental station under the supervision of Prof. E. C. Smith.

The statement commonly made that 1/16 of an inch means an increase in fuel consumption of from 12 to 15 per cent. is purely theoretical, and is based on the assumption that that thickness of scale covers the entire circumference of the tube, a condition which is seldom encountered in actual practice. On this subject, the bulletin in question states as follows: "Considering the scale of ordinary thickness—say of thickness varying up to ⅛ inch—the loss in heat transmission due to scale may vary in individual cases from insignificant amounts to as much as 10 or 12 per cent., and the loss increases somewhat with the thickness of the scale. Furthermore, the mechanical structure of the scale itself is of as much or more importance than the thickness in producing this loss."

In actual practice, a boiler with clean tubes will generate almost as much steam with a given quantity of fuel as two boilers of exactly the same size with the tubes coated with scale from ¼ to ½ inch thick.

Buffalo, N. Y.

Removing the Cause of a Hot Crank Pin

The crank pin of an engine gave considerable trouble from heating. The third day after taking the plant to operate the works were shut down, and the writer thought it a good opportunity to look into the cause. Taking off the strap, the boxes still remained on the pin and it required considerable work to separate them. An examination showed that at some time the pin had worked itself loose, making the hole out of round. The engineer had wedged tin around the pin to hold it tight, after which he screwed up the nut at the back of the crank, assisted by a sledge hammer.

Another cause for the pin heating was that when this pin was originally put in there was a counterbore, requiring a collar on the pin to fit in the counterbore. The other engineer had turned the collar off so as to make the pin that much larger in order to fit in the hole better. This left a large opening in the crank. The inner collar on the brasses was also squared off in order to fit the new length of the pin.

In Fig. 1 is shown how the babbitt worked out and filled in the counterbore on the crank. As a consequence, every two weeks or so the brasses required refilling. This kept the pin hot all the time.

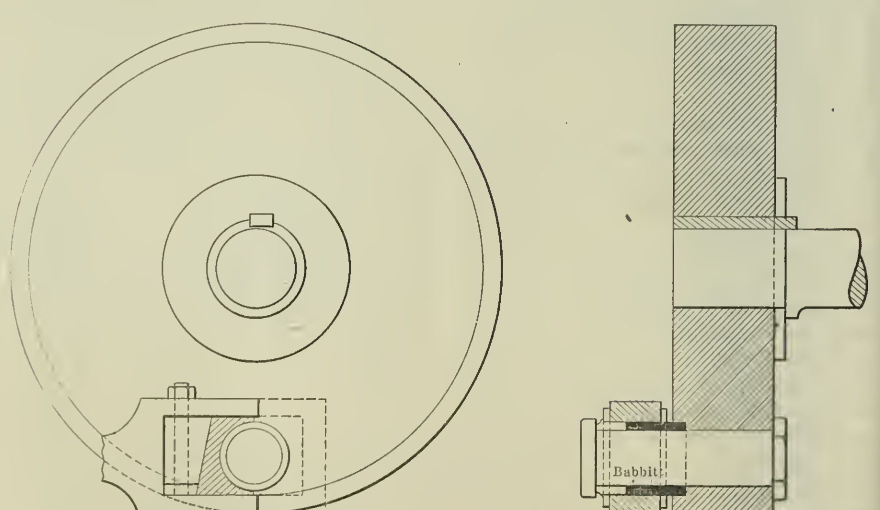

FIG. 1 SIDE AND SECTIONAL VIEWS OF BRASSES AND PIN FIG. 2

I found some ¼-inch copper wire and cut a piece large enough to make a ring to fill in the counterbore on the crank, Fig. 2. Then taking what was left, and putting a half ring in the boxes next to the crank, riveting them to the boxes, prevented the babbitt from working into the counterbore of the crank.

John Tyron.

Lynchburg, Va.

Remedying a Traveling Crane Trouble

Some time ago I had charge of the repair work in a large shop having an old-style crane that did first rate for small work. It was driven from one end, the motor being placed over the cage on the side of the crane.

When we undertook to handle a large casting, the drive end would start ahead of the opposite end and cause the work to sway back and forth, making it dangerous for the men to work on the floor. This ground the flanges off the wheels and sides off the track. As the floor for heavy work was situated directly under the out end, all the lifts were consequently made there. We decided to change the drive to the center, and also to put on a hand brake.

A track ran through the shop, and we had a box car pushed in and ran the crane directly over it. We then built a scaffold on top of the car high enough to work at the job. We took the motor and drive shaft down and laid out the bolt holes for the motor at the center of the crane. We also placed a new hanger to strengthen the drive shaft; also a 15-inch pulley on the shaft over the cage, and a hand brake with a foot lever to work in the cage. When ready, the crane ran a great deal better and without any swing, as both ends started at the same time; and with the brake, the crane could be stopped as quickly as the latest-style crane in the shop. Neither was there a strain on the shaft and gears, nor did the wheels grind and cut on the track.

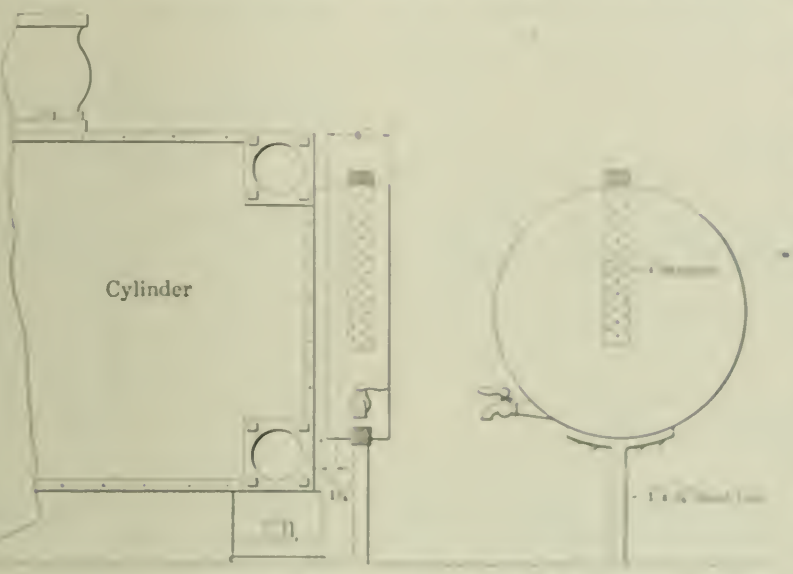
Cylinder Oil Tank Arrangement

The accompanying sketch shows a cylinder oil-tank arrangement I recently came across in a plant in St. Paul. It is attached to the engine cylinder as shown. It takes up but little room and does not



ARRANGEMENT OF OIL TANK ON CYLINDER

disfigure the engine to any extent. It is made of galvanized iron and painted to match the color of the cylinder.

E. O. Jeanson.

St. Paul, Minn.

Eccentric Troubles

Recently a friend called my attention to the condition of one of his cross-compound Corliss engines. The eccentrics on the high-pressure side were clattering badly and running very hot, while the eccentrics on the low-pressure side were running smooth and cool. Oil was being fed at the rate of thirty-two drops per minute, the sight feeds delivering oil directly over the center of each steam valve. The receiver gage showed 27 pounds and never "flickered."

There being a hand-regulated cutoff on the low-pressure side governor, and being asked to see what I could do, I tried to change the receiver pressure, but the gage remained the same. We removed the gage and found it to be stuck fast. After repairing it and setting it with the other engine receiver gage, we replaced it and found that the receiver pressure was only 3 pounds. This was immediately changed to divide up the load. After taking a few cards we evened up the load very nicely, which helped the eccentric a great deal, but did not cure it. At the noon hour we took off the eccentric straps and found the eccentrics badly cut and grooved. The question confronting us was how to smooth them up without taking them off, and I decided to file them while in motion.

We made a blank of No. 14 sheet iron and blanked the flange [illegible] on the high-pressure side of the receiver, or, in other words, the high-pressure cylinder into the receiver [illegible] and the valves on the high-pressure cylinder and ran the low-pressure side with the equalizing valve. The engine was run very slowly and after four hours' work the eccentrics were in fine condition and calipered true. In the meantime the straps were scraped and calipered until they became smooth and true. When the engine was assembled we started off and a better running engine cannot be found.

The plant has in it three 30 and 70 by 60-inch cross-compound condensing engines, direct-connected to 500-volt generators, operating at a steam pressure of 175 pounds.

Marion T. Merrell.

St. Louis, Mo.

Automatic Engine Stops

In an engine house where they were having trouble at the throttle the automatic stop was blamed. Upon investigation it was found that the engineer had packed the throttle-valve stem too tight, with the result that when the stop operated it was necessary to use force to open the valve. We overcame this trouble and eliminated all carelessness of engineers by getting metallic packing for the valve stem.

By having the stop directly connected to the main throttle it is operated every time the engine is started or stopped, thus insuring its being in working order.

When a speed limit is used it should be set to operate at [illegible] revolutions in excess of normal speed. The speed limit should also be tested at stated intervals.

[illegible], Penn.

Moving Heavy Machinery

I [illegible] in one of the [illegible] issues [illegible] A. G. Knight's method of moving heavy machinery on rollers or on skids. As he says, the method of moving heavy weight on rollers is old, but holding it up on inclines with pipe tongs and depending with tackle, jack or block is certainly new to me, and I have moved considerable heavy machinery. Suppose one of the men should fail to get a good grip on the pipe roller, and the others fail to hold it, where would the machinery land, and what would become of anyone who happened to stand in its downward course, if there were no tackle or block to stop it?

My advice would be to adopt some extra precaution in case of the possible slippage of the pipe tongs or wrenches.

William S. Luckenbach.

Leavenworth, Kan.

Commutator Troubles

In replying to the request of Edward A. Young in a recent issue, I advise that the brushes be given the correct tension on the commutator. If the tension is too light the brushes will jump and spark; if too heavy they will cut the commutator, which seems to be the trouble with Mr. Young's machine.

In the case of the D.C. [illegible], the heating of the commutator may be due to overload. Such heating is generally accompanied by excessive sparking, which cannot be remedied, except by reducing the load. The trouble may also be due to the improper position of the brushes. The brushes may not be properly spaced around the commutator, [illegible] all brushes should have the same relative position with regard to the [illegible] line.

A broken connection in the commutator leads or an armature coil broken will produce flashing at each revolution and the bars on each side of the one disconnected will be badly burned. The [illegible] wire should be [illegible], or if broken the commutator bars on each side of it should be soldered or bridged together by a temporary repair. As soon as possible a new coil should be put in.

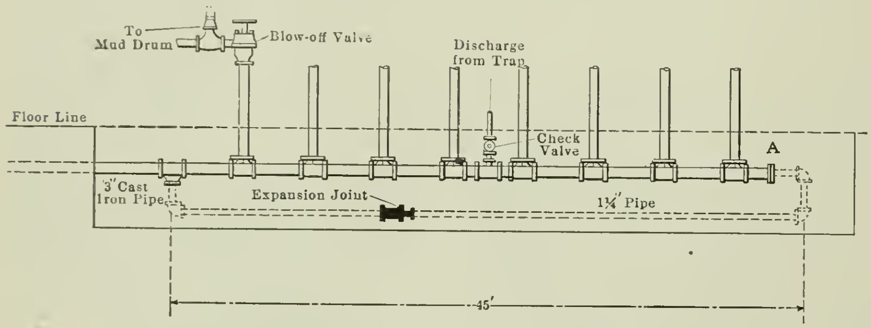
Sparking may also occur in a multipolar machine from the wearing away of the bearings, which produces [illegible] of the armature with respect to the fields and consequently unequal magnetic reluctance at different points. In some cases [illegible] wear amounts to [illegible] a very close consideration to insure true [illegible]. If such is found to be the case, the bearings should be [illegible] up [illegible] [illegible] the armature [illegible] under the pole pieces, thus relieving the bearing strain and probably [illegible] a complete [illegible] of the windings.

[illegible]

[illegible]

Blowoff Pipe Trouble Remedied

By the plan described herewith the writer got rid of at least 90 per cent. of the trouble from a very troublesome blowoff pipe. The full lines in the sketch show the 3-inch cast-iron pipe as first arranged. It was fitted with flange joints and tees to connect to the 2½-inch wrought-iron pipes, two of which connect to each mud-



HOW BLOWOFF-PIPE TROUBLE WAS REMEDIED

drum, there being four boilers. The discharge from two low-pressure steam traps enters about the middle of the pipe. The end *A* was blanked.

For a year this pipe gave all kinds of trouble with broken tees, blown gaskets and, at one time, a split pipe. It was impossible to keep it tight more than two days. After a time, noticing that the breaks nearly all occurred near the closed end, I concluded that our trouble was caused by water hammer, and set out to find a remedy. Taking off the blank at *A*, we piped a 1¼-inch loop, as shown by the dotted lines. This pipe is 45 feet long and an expansion joint was inserted about the middle of its length, to take care of the expansion. This change has almost entirely cured the trouble. We have no more broken fittings, only an occasional gasket has to be replaced and we do not have to touch it for months at a time.

Springfield, O.

To Etch Tools

The best way to mark names or initials on metal tools is to etch them. The mark is ineffaceable and easily done, with a little experience.

The first step in the process is to spread a thin layer of soap over the surface intended to be used. Next, with a sharp stick, or scratch awl, cut the name in the layer of soap, exposing the metal. Then drop into the letters enough of the following solution to commence an oxidizing action on the metal exposed: One ounce salt, 2 ounces copper sulphate (bluestone), and 1 quart of vinegar. A few drops will suffice, and a few trials will teach how long to let the solution work before wiping it off with a cloth.

This also makes a good solution for an open-circuit battery, for electric-bell and telephone work. Use copper and zinc terminals.

J. J. O'Brien.

Buffalo, N. Y.

Using Kerosene Oil in Boilers

In a recent issue a correspondent states that he cannot see any real gain in using kerosene oil for removing scale in steam boilers. Some years ago I had charge of a small steam plant in which was installed a second-hand boiler. It was in good condition, only it was badly scaled. After the boiler was set and bricked in I removed the scale with kerosene oil in the following manner:

All loose scale and sediment were removed from the tubes and shell and kerosene oil sprayed over the interior surfaces of the boiler, so that when the boiler was filled the oil would rise and come in contact with the under side of the tubes.

The top manhole was left open, and after filling the boiler to the proper level a slow fire was started and kept up for about ten hours. The boiler was then left to cool off over night and the next morning the water and loose scale were removed. The operation was repeated until most of the scale was taken out.

More kerosene was sprayed over the tubes and shell and the boiler was put in service for a week, meanwhile feeding kerosene with the feed water. Then the boiler was opened up and the loose scale removed.

When kerosene oil is used in a boiler, never place a torch or candle inside, until it has been thoroughly ventilated; better still, use an incandescent lamp.

Care should be exercised when using kerosene for removing old scale in steam boilers to open up the boiler a short time after using the oil, because the scale is liable to drop down on the fire sheets.

H. Jahnke.

Milwaukee, Wis.

An Emergency Piston in an Air Compressor

The accompanying description and illustration are of an emergency piston used in a disabled air compressor. The piston is from the steam cylinder of an 18 and 18¼ by 24-inch straight-line compressor. The original piston was wrecked when the heads of two follower bolts broke off and fell into the clearance space. The spider was split in two and the follower plate was broken.

The air from this compressor is in constant demand, so a temporary piston was constructed as follows:

We sheared out 12 plates of ⅓-inch tank steel in circles 18⅛ inches in diameter and bolted them together, as shown, by eighteen ¾-inch bolts. These were drawn up as tightly as possible and the piston put in a lathe. The taper hole in the hub was bored out to fit the piston rod and the piston turned down to the proper size. Three grooves were turned in the surface, ⅝ inch wide and 9/16 inch deep, and high-pressure spiral packing was forced into the grooves. The bolt heads and nuts projecting through the outside plates were turned off so as to make the piston 7 inches thick, the dimension of the broken piston.

The piston was then put on the rod, fitted into the cylinder and run for four or five days, when the new piston was put in. The temporary piston, when taken out, was in good shape, excepting the packing, which was pretty well used up.

The steam pressure was 160 pounds, with 100 degrees Fahrenheit superheat. The piston was rather heavy, but it did the work and no damage was done to the

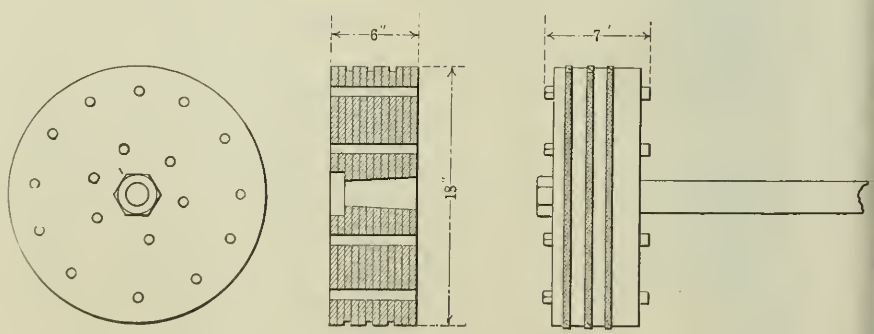

PLATE PISTON FOR AIR COMPRESSOR

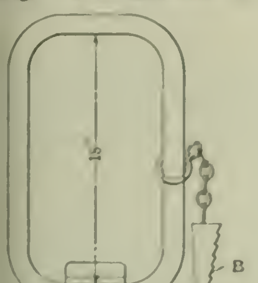
cylinder; in fact, the surface was finely polished when taken out.

G. L. Fales.

Copperhill, Tenn.

Grout Foundation

I am operating a plant containing a 15x22-inch double engine furnishing power to a coal-washing plant. Six years ago the engine was set up on a concrete foundation, and later the top of the foundation crumbled under the bed plate to a depth of 4 inches. It became necessary to reline and level the engines, and at the same time rebabbitt the crank-shaft bearings. We began the job Friday night at



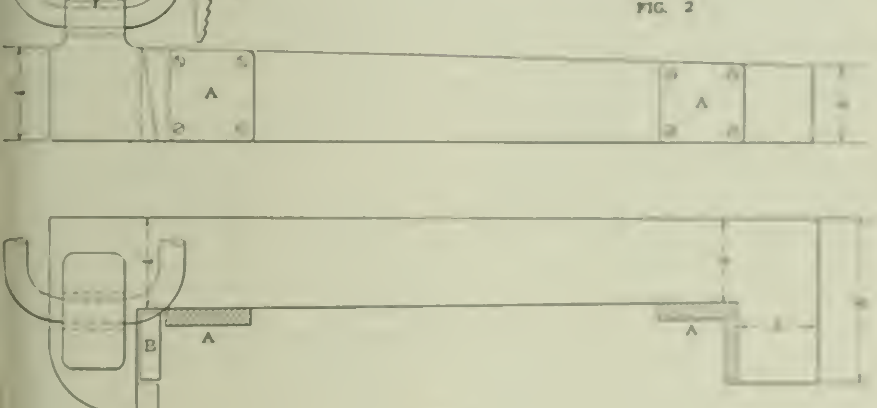


FIG. 1

9 p.m., and had until 6 a.m. Monday morning in which to finish the work.

I used 33⅓ per cent. Vulcanite portland cement and 66⅔ per cent. sand in a grout in a mold 4 inches deep on the foundation, after cutting and cleaning away all loose particles. After allowing 32 hours for the cement to become set we secured the engines with the sixteen 1¼-inch anchor bolts and started up on time Monday morning. After three days we again gave the anchor bolts about one-half turn, and today the engines are in place as solid as a rock.

J. J. Kerr.

Dunbar, Penn.

Scraping Valves and Valve Seats

I desire information regarding scraping and fitting flat valves, of the type commonly known as the "Sweet" valve. Also, the successive steps, tools required, etc., to properly fit these valves.

S. A. Ellman.

Uniontown, Penn.

Engine Turning Device

Following is a description of a [illegible] used to turn the flywheels of a vertical engine. The flywheels are [illegible] feet in diameter, 30 inches face, and weigh [illegible] tons. It was necessary, therefore, to make the hook good and strong. Fig. 1

FIG. 2

FIG. 3

shows side and top views of the rig, the small end of which is 1 inches square, the larger end is 2 inches square. The [illegible] is of 1½-inch iron and 18 inches long. The parts A have leather facings to prevent injuring the paint on the flywheel.

The wedge B, Fig. 3, is [illegible] with [illegible] as shown in Fig. 3,

which slants in the direction of the pull. The wedge is 8 inches long, 2[illegible] inches wide and tapers from 1 inches to ¼ inch. It is shown in position as shown in Fig. 2.

One might suppose the rig would grip the rim of the wheel so tightly that it would stick to the wheel, but such is not the case as it is only necessary to loosen the [illegible] hook, and the wedge will [illegible] loose, thus permitting the rig to slide down on the rim of the wheel ready for a new grip.

[illegible]

Kansas City, Mo.

Nuts and Wrenches

The skilled man [illegible] use a wrench in "any old way," and the other fellow cannot. Did you ever find yourself holding a hot piece of pipe in an awkward position and the other fellow with the monkey wrench in his hurry to secure a threaded union turning the wrench the wrong way, or opening the jaw in setting the wrench to size instead of closing it?

Regarding the standard drop-forged wrenches, why is it that the double-end solid wrench is used so much? The writer has always preferred the single-ended wrench, it being much more convenient.

I notice that a large number of manufacturers are reversing the standard hexagon nut when putting up large steam fittings. I did not take kindly to the change at first, as it looks sloppy, but under the conditions I think it is a good thing to do. In the rush to get work out of the shop there are tons of large gate valves, tees, ells and pipe flanges that are not spot-faced for bolts, which should be done; consequently, the round or chamfered side of the nut adapts itself to the work, rather than the other or finished side.

Charles [illegible].

Hartford, Conn.

Driving Up a Bag in a Boiler

In a recent issue, [illegible] describes an excellent way of driving up a bag in a return-tubular boiler, but the following method can be used where no foundry is handy [illegible] [illegible]

A bag developed and the [illegible] set the boiler out of a [illegible] of steam [illegible]. The [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] The bag was then heated and driven up with a sledge by working around and around the bag, gradually [illegible] the center.

The boiler, which has been inspected several times, has been in use for several years since and is said to be the best boiler in the battery of five.

The plant was not shut down as in the other case, and the boiler was out of use only three days, the expense amounting to the cost of ten gallons of gasolene and a helper for two days.

W. F. Johnson.

Bamberg, S. C.

A Peculiar Lighting Condition

If C. L. Greer, whose letter appeared in a recent issue of the paper, will remove the ground on the negative side of the circuit *C* (see reproduced sketch), he will find that the negative side of circuit *B* is grounded.

I would advise a new extension cord on the lamp used by the boiler washer. Then the lighting system should work properly.

E. B. Austin.

Burlington, N. C.

Concerning C. L. Greer's inquiry, I would say that the following conditions might give rise to his trouble:

Should a dead ground exist at any point on the outside wire of circuit *B*, and a similar ground exist at a point on the outside wire of circuit *C*, the lights on circuit *C* would burn under the conditions he mentioned, namely, with the switch *A* closed on the exciter circuit, switches *B* and *C* closed and the circuit breaker open. The lamps on circuit *C* are then fed as follows: From the positive side of the direct-current machine to the lamps by way of the positive side of switch *C*, through the lamps to the ground, then

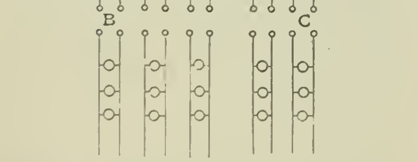

DIAGRAM OF WIRING FOR LIGHTING SYSTEM (REPRODUCED)

from ground on circuit *C* to the ground on circuit *B* and through the negative side of switch *B*, back to the direct-current machine by way of the negative side of switch *A*.

If we put the circuit breaker in it will remain there, the only part it plays is to supply an additional path for the current of the negative side, and the amount of current it will take will be proportional to its resistance and the resistance of the circuit through the grounds. In other words, we have a divided circuit of which one leg includes the circuit breaker and the other leg includes the grounds. If, now, the switch *A* is opened all of the circuit *C* must pass through the circuit breaker; this momentary rush of current may be sufficient to trip the same in the manner spoken of.

Walter G. Mullen.

Gloucester, Mass.

Air Compressor Accident

Quite recently, in one of the largest railroad shops in the middle West there was a serious air-compressor explosion which wrecked the tanks, engine and hundreds of feet of pipe and tore great holes in the walls of the building.

The accident was a progressive one, the first trouble being the explosion of about a hundred feet of underground air pipe in the yards, which so lowered the tank pressure as to cause the engine, which was air-controlled only, to run away and burst the flywheel, which was directly in line with a battery of large boilers. They, however, escaped injury.

The primary cause was undoubtedly oil in the pipes, which became volatilized and fired, either by heat or by electricity, the former being more likely.

There are three lessons to be learned from this accident, of which the most important is that an air-compressor engine should not be controlled by air alone, but should be fitted with an auxiliary governor which will act as soon as the speed rises above a certain point. In this way an accident to the tanks or piping, causing a sudden lowering of the pressure to a dangerous degree, would not cause the engine to race. The lowering of the pressure need not necessarily be caused by an explosion, but the giving way of a pipe, valve or tank from any cause would have the same effect.

The second lesson is one that is being driven home by dozens of accidents all over the country, and that is, *keep an excessive amount of oil out of the system.*

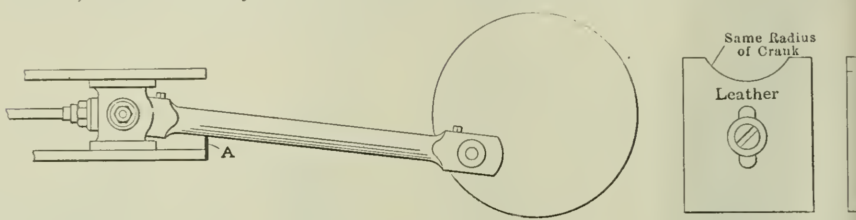
The third and last lesson is one that is seldom needed, but which in this case was disregarded, though fortunately without serious result. It is that no engine should be so set that the bursting of the flywheel would be apt to crush the boilers.

Ethan Viall.

Decatur, Ill.

Preventing a Crank from Throwing Oil

An engineer experienced a great deal of trouble from oil thrown by the crank of a Corliss engine. He tried a number of methods of getting rid of the nuisance, but had not been successful.



OIL GUARD ON GUIDE

The idea of fastening a wiper to a wire, so that it would wipe the surplus oil off as the crank went past the bottom developed. This idea resulted in the application of a wiper, as shown in the illustration. It was cut out of leather and fastened with a screw and washer to the end of the guide. After this wiper was put on and adjusted so that it touched the rod lightly at each revolution, the oil-throwing nuisance completely disappeared.

A Lead Brush

Soon after I took charge of the plant I now have, one of the carbon brushes of a two-brush four-pole shunt-wound motor broke in half. As there was not enough left to be of any use, I got some lead and cast a brush. I then filed it up and sandpapered it to fit the commutator surface. I had no trouble for the rest of the shift and the next morning I replaced it with a new carbon brush.

Exeter, South Australia.

Belt Ruined by Oil

The following experience was a costly one for my employer, although he never discovered the cause. A 6-inch belt gave trouble and the office was convinced that a larger belt and pulleys were needed. After the belt was put in place, the superintendent gave me a gallon of neatsfoot oil and told me to soak the belt with it. Although I knew better, I brushed the oil on until the belt was as limber as a rag. Then it began to stretch, and a heavy idler pulley was put up.

The oil so injured the glued joints that they had to be pegged and riveted repeatedly. Finally the belt parted and wound between the pulley and hanger. It was so badly damaged that a new one was necessary.

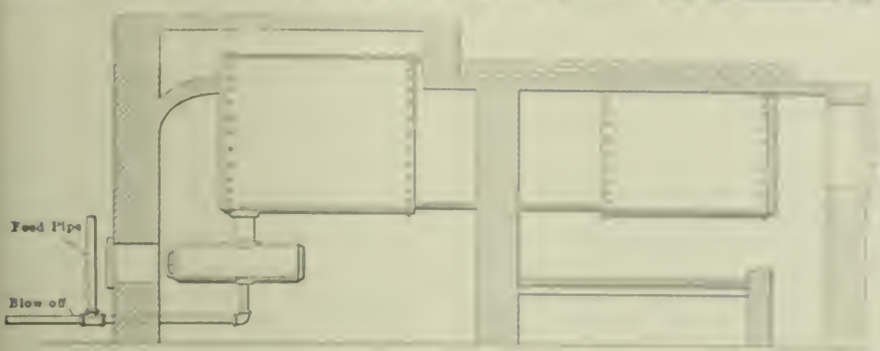
Boiler Setting

S. Kirlin's improvement on Mr Wheeler's idea of a boiler setting as illustrated in a recent number, appears favorable in many respects, although I should arrange details slightly differently The sootblower door, for instance, could be located



MR. CEDERBLOM'S SUGGESTION FOR BOILER SETTING

to better advantage in the opposite end so the flues could be blown out with instead of against the draft. As it is, the soot will be blown out in the fire room if too much pressure is applied.

Where the blowoff pipe now enters the boiler I would have a good-sized mud drum connected to the boiler by a 6- or 8-inch nipple, and pump the feed water into this drum through the blowoff connection, as shown in the accompanying illustration The arrangement would be safe from burning out, and would hold water at such a high temperature that most of the scale-forming matter in the feed water would be precipitated in the drum, where it can do no harm and is easily removed.

R Cederblom.

Repairing Commutators

The "flashing over" or excessive sparking of a commutator may produce a minute cavity in the commutator insulation, which, from time to time, becomes filled with a conductive material from the brushes, particularly where a lubricant has been used When enough has accumulated in the spot to become a fair conductor, and a current passes through it from bar to bar, the mass becomes incandescent, immediately burns out, and with it a certain amount of commutator insulation.

At intervals the process is repeated Often the original cause of this defect is obscure and beyond prevention by the man in charge This condition, however arising, is always recognized by a reddish-yellow spark forming a momentary ring of fire around or partly around the commutator and always recurring at the same place. The damaged spot becomes worse, and unless attention is given will inevitably end in serious damage to the commutator, and often to the armature coils.

In order to properly examine a commutator in this condition ample light must be provided. Each segment must be thoroughly inspected and the faulty parts marked. When a burned spot is found it must be scraped and cleaned out until absolutely no trace of carbonized material remains. This is by no means an easy task, but the same may be facilitated by the use of a special tool which is conveniently made from a 4 inch piece of hacksaw blade, one end being ground to a point similar to a shaper tool. This end is also made just thin enough to enter between the bars. If this tool is given a sharp, square cutting edge no difficulty will be experienced in scraping the mica insulation clean.

After the cavity is thoroughly cleaned it should be refilled with either silicate of soda, or silicate of soda and powdered glass, plaster of paris, or plaster of paris and shellac. A mixture which the writer has used successfully is silicate of soda with calcium carbonate, more commonly called powdered chalk. They are in the right proportions when mixed to a thick paste. The latter is packed into the cavity and a small surplus left on top to be afterward smoothed down with sandpaper. These materials combine chemically, forming calcium silicate and become very hard in a few hours.

Where a burned [illegible] is deep enough, or where it occurs at the end of the commutator, [illegible] may be cut to [illegible] in the part, the cavity coated with moderately thick shellac and the [illegible] tightly driven in, the projecting edges being trimmed off afterward.

Where a machine [illegible] at one time, [illegible] times, but [illegible] applied to [illegible] will hasten the drying and all the [illegible].

Lamp Wiring Diagram Wanted

Can any of the readers suggest a wiring diagram for throwing, say, three battery lamps from parallel to series and vice versa, using only a standard switch or switches?

E. J. Williams.

Cleveland, O.

Laying Out an Eccentric Keyway

In a recent number, John [illegible] gives a simple method of determining an eccentric keyway which, I believe, is not quite correct, as the angularity of the eccentric rod has not been considered.

Let the circle (see illustration) denote the throw of the eccentric and O R the length of the eccentric rod, which in this instance is six times the throw. The arc A O B would be the path of the eccentric rod through the center of the shaft, and the line O A the position of the eccentric at mid stroke, when the valve is in its central position. Mr. [illegible] takes the vertical line C D for this position, and the keyway would be cut as much as the angle C O A, or about [illegible] degrees.

If this was corrected, the keyway so determined would be right only if the rocker arm or [illegible] [illegible] with the center line of the engine. As it is inclined higher or lower, corrections would have to be made accordingly.

If I had the rod and [illegible] surface plate to place them, I would prefer to lay out the keyway with the [illegible]. There is always some part of the keyway near enough to find its position [illegible].

[illegible] LAYING OUT AN ECCENTRIC KEYWAY

Low Pressure Turbines and Steam Engines*

Advantages to be Obtained in a Combined Plant; Flexibility of Application a Turbine Characteristic; Efficiency Ratio Possible

BY J. R. BIBBINS

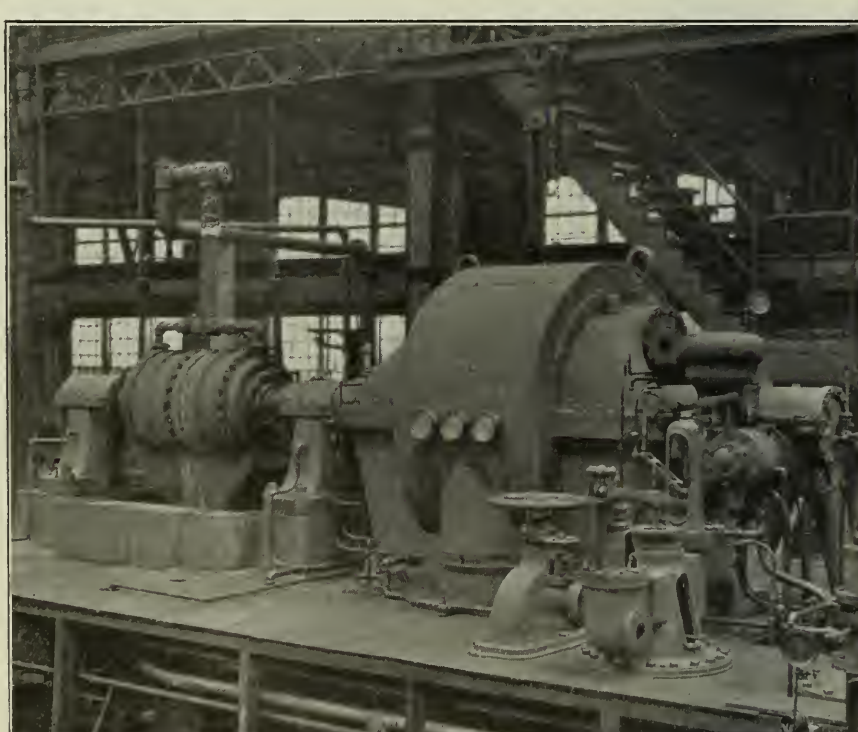
Both the standard types of prime mover, the reciprocating engine and the steam turbine, have distinct fields in which their highest efficiencies are respectively obtainable. The steam engine finds its most efficient territory in the higher pressure ranges above atmosphere, while the steam turbine works to best advantage in the lower stages. This, of course, does not carry the inference that the engine cannot benefit substantially from high vacuum, nor *vice versa,* the turbine from high boiler pressure, for the advantages of each are well known. In the engine, the losses due to condensation and reëvaporation on the cylinder walls during each consecutive cycle are large; in the turbine there is no cyclic change, and therefore no such losses, comparatively speaking, as a fairly constant temperature and pressure obtain at any given point in the expansion range. In the engine the mechanical friction of the enormous sizes of cylinder necessary to accommodate the lower expansion ranges constitutes an effective barrier; in the turbine the lower ranges are obtained with comparative ease and without incurring excessive losses, mechanical or thermal.

A good Corliss engine will give the best efficiency** (72 per cent. at normal load in the case to be discussed later) when operating noncondensing against exhaust pressures of from 15 to 20 pounds absolute. Certainly cylinder ratios of 1 to 2.5 to 3.5 will do so. Similarly, the steam turbine expanding from 15 to 25 pounds absolute down will show a maximum efficiency ratio as high as 73 per cent. for moderate vacuum, and commercial guarantees are today made above 70 per cent., a fact which speaks for itself. Thus, it occurs that the combination engine-turbine plant will show an overall efficiency ratio (65 to 75 per cent. of the ideal cycle) considerably in excess of either an engine or complete-expansion turbine unit running alone, which can hardly do better than 65 per cent. In the case treated later, the Rankine cycle efficiency of the combined unit was found to be 69.3 per cent. at normal load.

The pioneer work (about 1890) of C. A. Parsons, to whom we are all indebted, has brought about so thorough a discussion of the marine problem as to take definite form in the recent decision to equip the two monster transatlantic liners with combined engine and low-pressure turbine plants. Professor Rateau's work in steel mill and mine hoisting has also resulted in the practical application of low-pressure turbines in connection with the steam-regenerative principle, permitting the turbines to operate constantly, using the exhaust steam from engines intermittently operated. His work has been brought to our notice in this country by H. H. Waite, in discussing regenerative turbine application to steel mills.† J. W. Kirkland‡ has introduced the subject of low-pressure turbines in light and power plants. And it is this line of thought that it is desired to enlarge upon in the present paper.

*Paper read before the Canadian Society of Civil Engineers, Montreal, Can., November 26, 1908.

**It is understood that the term efficiency in this case refers to efficiency ratio in per cent. of the Rankine-Clausius cycle, i.e., efficiency in per cent. of available energy in the steam within the range of pressures, not steam consumption.



WESTINGHOUSE DOUBLE-FLOW TURBINE ON TESTING FLOOR

Application

There are two general classes of service in which the low-pressure turbine finds effective field for application:

Class A—Supply of steam intermittent and widely varying in quantity. For example, rolling mills, for blooms, plate, sheet, wire, rail and structural shapes, steam hammers and hoisting engines. All of these involve the regenerative principle, requiring a careful study of the time element in supply and demand, generally resolving into a special problem for each individual installation.

Class B—Nonintermittent supply without regeneration. This class embraces central power stations for lighting, traction or for factory drive, and may be discussed as a general problem of power extension where the widely varying plant conditions may be summarized as follows:

(1) Good engine design; fair operating efficiency. Increase in capacity necessary.

(2) Inefficient engines, condensing or noncondensing, improvement in operating economy or increase in capacity necessary.

(3) Present condensing plant unsuitable or inefficient.

(4) Plant location; where water supply is limited, unsuitable or costly, for example, enforced noncondensing operation.

†American Institute of Electrical Engineers, December, 1907.

‡National Electric Light Association, June, 1908.

(5) High cost of fuel.

Given a reciprocating-engine plant of serviceable construction, along what lines shall needed power extension be made?

(1) By installing more reciprocating units of the same type and operating under the same conditions.

(2) By installing more efficient complete-expansion turbines with suitable auxiliaries.

(3) By utilizing the low-pressure turbine principle to render the present plant more efficient.

Primarily, the problem before us is that of Class B, (1) and (2), *improving the efficiency of a given reciprocating-engine plant*, which may be in the best physical shape, but operating under unsuitable conditions. The importance of this subject will at once be appreciated when we reflect that a plant of noncondensing engines may be changed over to reduce its water rate from 30 or 35 pounds per kilowatt-hour to 15 or 18 pounds per kilowatt hour in comparatively small sizes; in other words, for the same expenditure of coal and water, a net increase in power of from 80 to 100 per cent. may be realized, depending upon the type of equipment. And the resulting cost of power is reduced in the same proportions. In the case later discussed, a minimum water rate of 15.8 pounds per kilowatt-hour (150 pounds dry saturated steam to 28 inches vacuum) is obtainable from an engine giving 28.5 pounds per kilowatt-hour noncondensing, and 20.05 pounds per kilowatt-hour condensing, with an increase in rated capacity of 90 per cent.; maximum, 100 per cent. This is equivalent to 9.9 pounds per indicated horsepower-hour, or an efficiency ratio of 75 per cent. indicated, 66 per cent. brake.

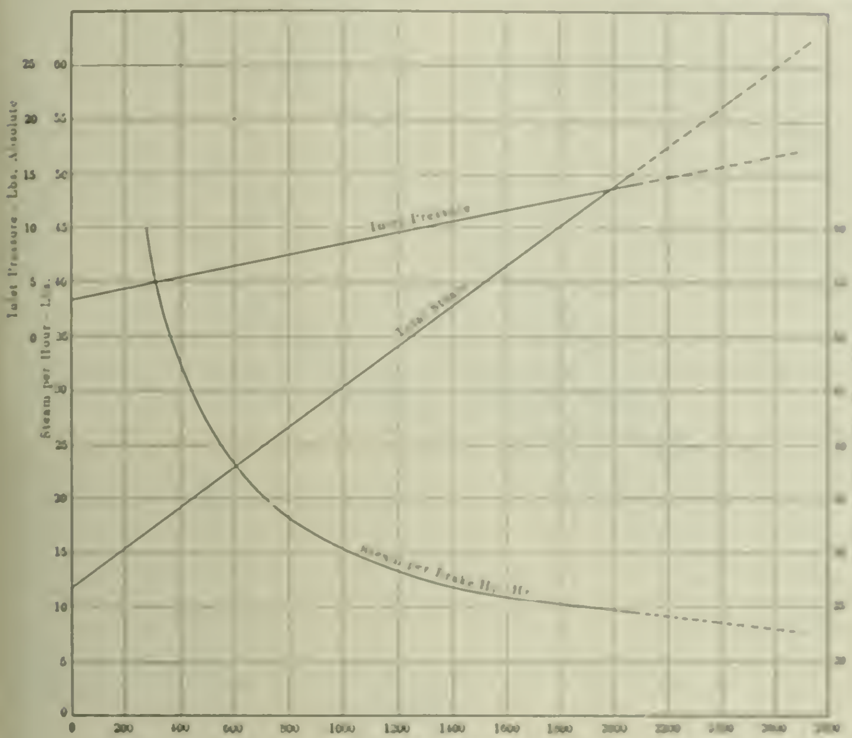


FIG. 1

Turbine Tests

Two series of tests*, Figs. 1 and 2, will serve to illustrate the possibilities of economy and capacity. Fig. 1 represents tests at several different loads and varying inlet pressures, all on approximately dry-saturated steam and 27.5 inches vacuum. Although a few of the original observations were slightly irrational, this was due to the difficulty of maintaining exact vacuum, and when corrected fall well into line. Note that these tests, Fig. 1, were all conducted at inlet pressures below atmosphere, but the characteristic for higher pressures is the same, a straight line, as has been proved by other tests carried as high as 20 pounds absolute. Thus, at 19 pounds inlet pressure, the water rate is approximately 200 pounds per brake horsepower (31.2 pounds per kilowatt-hour) and at 20 pounds inlet pressure, about 21 pounds per brake horsepower (30 pounds per kilowatt-hour).

The effect of higher inlet pressures and varying vacua is well shown by Fig. 2, a series of tests upon the low-pressure section of a 2000-horsepower lighting turbine for the Interborough Rapid Transit Company in 1902. This machine is of the single-flow design, the high-pressure section expanding down to about atmosphere and the low pressure section below. Note that the water lines are virtually straight up to the maximum initial pressure, 30 pounds, and slightly divergent for varying vacua. This range of inlet pressure represents quite closely the actual range of operation in a combined engine-turbine plant. The result of tests on this machine, the first one of the type built for commercial service, shows an efficiency ratio of about 70 per cent. at 15 pounds absolute inlet pressure and 27 inches vacuum. And this may be improved upon if it is considered expedient to design for higher vacuum.

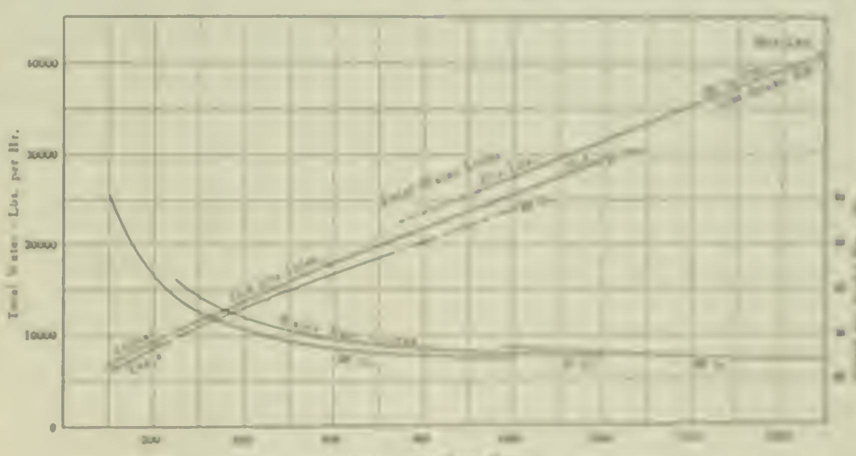

FIG. 2

Characteristics of Low-pressure Turbines

From a thermodynamic standpoint, the low-pressure turbine is the exact counterpart of the complete expansion turbine, and it possesses the same characteristics shown by Fig. 2. As in the high-pressure turbine, the line of total consumption per hour, or water line**, is practically straight, resulting in a constantly decreasing water-rate curve. The power developed by this machine, increased in proportion to the inlet pressure, having the small friction drop throughout the range as at no load. As this type of machine employs no mechanism in the shape of overload or secondary valves, this

*Owing to the author's special familiarity with developments of [illegible], these data refer entirely to results obtained from Westinghouse apparatus.

**Sometimes called the Willans line.

would be expected, and the water-rate curve is necessarily an equilateral hyperbola. The low-pressure turbine may be regarded as the third cylinder of a triple-expansion system, and is equivalent to such cylinder fitted with *fixed cutoff*. In other words, it must have a definite initial pressure to enable it to pass a given weight of steam. This necessitates a careful study of engine-cylinder proportions and valve movements. For it occurs that when direct-connected to an engine, the release pressure in the low-pressure engine cylinder may be well above the initial pressure required by the turbine, or considerably below it, depending upon whether the load is heavy or light. In the first case a large receiver drop would ensue between engine and turbine, and in the second a serious loop in the low-pressure diagram. Therefore, the type of engine, cylinder ratio, the cutoff and the average- and maximum-load demand must be known before any rational decision can be made as to the proper size of turbine to install and the resulting distribution of load predicted. However, should errors be made in the calculations or determinations of the low-pressure turbine characteristics, the same may be easily rectified by a slight change in the angle of the blades, requiring but a very small expenditure.

Engine Characteristics

Assuming a normal design of Corliss compound engine, there are two methods of governing which may come under consideration:

(a) High-pressure cutoff variable; low-pressure fixed.

(b) Parallel cutoff, i.e., both high-pressure and low-pressure variable in the same direction, increasing with the load.

The parallel system is widely employed in Corliss practice to maintain an equalization of work in the two cylinders. It is difficult, however, to avoid loops in the low-pressure cards at light loads (noncondensing), as the low-pressure cylinder expands below the exhaust pressure. In case (a) the low-pressure cutoff is deliberately fixed far enough in advance to eliminate the low-pressure loop in the lower ranges of load anticipated. But this system has the disadvantage of causing a great disparity† in loading cylinders.

A point worth noting is that in lightly loaded plants where large increase is anticipated, the low-pressure loop may be to some degree avoided by omitting a few rows of blades, thus enabling the turbine to pass the same quantity of steam at a lower inlet pressure. Ordinarily two rows will be sufficient and these may be re-replaced later when normal operation is resumed.

†Thus with the low-pressure cutoff fixed at 75 per cent. of the stroke and the high-pressure as short as 15 per cent., the engine would deliver steam to the turbine at 8 pounds absolute and without loop. But on maximum load with high-pressure cutoff at 75 and 25 pounds back pressure, the ratio of work in the two cylinders would be about 2 to 1.

This brief discussion will serve to illustrate the necessity of a careful study of the engine problem. In designing a plant for a given loading factor, say, 75 per cent. average and 150 per cent. maximum rating, the point of rating of the combined unit may be regarded as corresponding to the point where the engine is operating at its best economy, noncondensing, for the combined plant virtually retains the characteristics of the engine equipment.

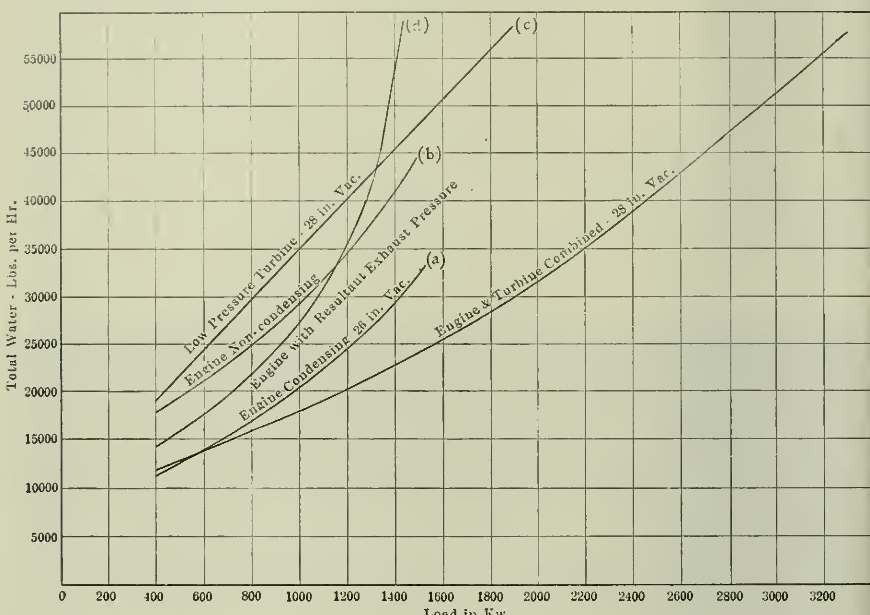

FIG. 3

Combined Plant

The effect of the various factors outlined may be best illustrated from Figs. 3 and 4, which have been prepared to exemplify the principles of design for a 2000-kilowatt installation suited to a 50 per cent. overload, or thereabout. Fig. 3 shows only the water lines, from which are derived the respective water-rate curves, Fig. 4. These water lines cover the following conditions:

(a) Engine alone condensing, 26 inches vacuum.

(b) Engine alone noncondensing, 17 pounds absolute back pressure.

(c) Low-pressure turbine alone, 28 inches vacuum, variable inlet pressure.

(d) Engine noncondensing with variable back pressure, resulting from its connection to the turbine.

(e) Combined engine and turbine system, 28 inches vacuum.

Of the above, (a), (b) and (c) were obtained by actual data. The combined curve (d) must be found graphically from the characteristic curves of engine and turbine, and the final curve (e) by combining (c) and (d). These water lines, Fig. 3, serve to illustrate the difference between the Willans characteristic for turbine (c) and an engine (a) (b) governed by cutoff. One is a straight line, the other a curve. The turbine has no point of lowest water rate other than maximum load; the engine ordinarily does its best at rating or under. It is usual practice to rate an engine at its point of lowest steam consumption. This may be found from the water lines as the point of tangency of a radial line from the origin. Thus, this engine running condensing shows its best economy at about 1000 kilowatts, and noncondensing at about 1200 kilowatts, which is entirely rational. On the other hand, the resultant engine curve (d) shows a best point of economy slightly under 900 kilowatts, due to the influence of the variable back pressure. Therefore, the turbine should be designed to pass just the amount of steam required at a back pressure corresponding approximately to this point of best engine economy, noncondensing. Care must be taken, however, in adapting the turbine to the engine, to avoid any condition that will cause excessive pressures on engine crank pins and bearings.

This point of safe pressures is mentioned because of a tendency permanently to overload the engine in the desire to produce a very low water rate. It should not be considered good practice to operate an engine on pressure much in excess of 50 per cent. of that for which it was designed‡. A recent study of a combined plant that has been widely discussed shows that the engine had been forced to a mean effective pressure of 56 pounds referred to the low-pressure cylinder. In our typical study, Figs. 3 and 4, it has been thought best to take an engine of normal proportions, as found in many lighting and traction plants (cylinder ratio 1 to 3¾) rather than a ratio more suited to efficient noncondensing operation; for example, 1 to 2.5 or 3. There-

‡In average practice, a compound Corliss engine (condensing) would be designed for about 30 pounds mean effective pressure at rating, and should not operate with mean effective pressure much over 45 pounds (referred to low-pressure cylinder).

fore, the results may be considered conservative in this respect. The design is based on, first, an engine rating (best) of about 33 pounds mean effective pressure referred to the low-pressure cylinder, 165 pounds absolute boiler pressure and 17 pounds absolute back pressure, and second, allowing 1 pound drop between machines, a turbine passing the engine room at 16 pounds inlet pressure, 28 inches vacuum. The combined plant, 2000 kilowatts, has an overload capacity of 50 per cent. with some excess margin.

Examining the water-rate curves, Fig. 4, we find that the engine gives an economy of 20.05 pounds per kilowatt-hour condensing, 28.31 pounds per kilowatt-hour noncondensing, for a normal load of 1000 kilowatts in each case; but in combination with the turbine, a maximum water rate of 15.8 pounds per kilowatt-hour.

Curve (c'), Fig. 4, has been derived from (c) for comparison of water rates of combined plant and condensing engine on the *same basis of rating*, i.e., equivalent to curve (c) at half scale. Thus, at rating, the combined plant shows an improvement of 22 per cent. in water rate. At light loads, however (500 kilowatts), the combined plant ceases to be as efficient as the engine running alone condensing. The point of equal economy is, of course, somewhat variable, as it is difficult to locate it accurately with two curves at such an acute angle, but it immediately suggests that in the practical operation of a combined plant, it would be desirable to shut down the low-pressure turbine when the load falls below 30 per cent. rating, for example, and operate the engine alone.

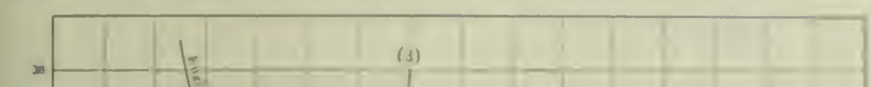

Fig. 4

GOVERNING

For a study of governing the various classes of service may be summarized as follows:

Class A—Turbine electrically locked with engine, that is, serving the same busbars.

(1) Turbine taking all of the engine steam. No governor required. Load on turbine varies with engine load.

(2) Turbine taking part of the engine steam. No governor required. Output remains practically constant with uniform pressure in exhaust mains, due to excess supply of exhaust steam.

In both of these cases atmospheric relief should be provided (if only to enable the engine to operate while the turbine is shut down) and, of course, a hand throttle valve.

Class B—Turbine electrically independent of engine; that is, serving separate bus; for example, lighting only, engines on traction bus.

(3) Turbine taking all or part of engine steam. Governor required in case of intermittent supply.

With momentary deficiencies, occurring only infrequently, a reducing valve need be used for auxiliary live-steam supply, also in case of deficiencies of long duration; but with rapidly fluctuating supply averaging in excess of the demand, a regenerator may become profitable, or its equivalent in electrical storage may be used in direct-current systems.

In all of these cases a safety stop is obviously essential, simply for insurance against possible overspeeding. In Class A (2), for example, should the circuit open with the turbine under load, the safety alone would prevent disaster. The automatic safety stop may operate either a butterfly valve or a positive closing throttle.

GARY INSTALLATION

A typical example of low-pressure turbine application is found in the plant of the United States Coal and Coke Company, at Gary, W. Va. It operates the mining property serving hoists, pumps, blowers, lights, etc. The plant contains two 24 and 44 by 48 Corliss engines, 700 kilowatts, one 1000-kilowatt complete expansion steam turbine and a 1000-kilowatt low-pressure steam turbine, both of the Parsons type. These turbines are served by three cooling-tower units, fan-driven, each 24 feet in diameter and 25 feet high. Two of these units serve the low-pressure turbine and one the high-pressure turbine. The following figures roughly indicate the normal operation of the generating units from readings taken October 7, 1908:

Output of two turbine units	[illegible] kw.
Output of low-pressure turbine	[illegible] kw.
Steam pressure gage	[illegible]
Vacuum, L.P. turbine	[illegible] in.
Temperature of injection	[illegible] deg.
Temperature of air	[illegible] deg.
Cooling in tower	[illegible] deg.

Thus the low-pressure turbine carried nearly half the total load on less than 26 inches vacuum, and would have carried more than 1500 kilowatts on 28 inches vacuum, with better condensing conditions.

AUXILIARIES

Inasmuch as the turbine is so dependent upon auxiliaries, it is pertinent to point out some facts in this regard. If we compare the ideal water rate of a turbine expanding from atmosphere down to various vacua, we shall find that while the ideal machine improves continuously down to the lowest condenser pressures, the actual turbine cannot make as good use of the last inch or two of vacuum as in other parts of the expansion range; in other words, we may expect the highest efficiency in moderate ranges of vacua. This is in strict agreement with high-pressure turbine work, as the author has endeavored to point out many times before. However, assuming that the turbine improves 5 per cent. per inch of vacuum around 27 inches, it is plain that an efficient condenser is very desirable, but with warm circulating water it is not always possible to obtain the vacuum desired. This is due almost always to the inability of the condenser to work with a small enough temperature difference between steam and discharge water. A condenser may be regarded as a heater, and its effectiveness is entirely dependent upon its ability to deliver water heated as nearly as possible to the temperature of the steam. This is of the utmost importance in places where cooling towers are necessary. And at this point may be emphasized the fact that the cooling tower is rapidly becoming less objectionable as a device. This has been brought about by the recent development of more efficient condensing apparatus.

A good surface condenser should operate within 15 degrees difference between the temperature of the steam and discharge water; a good barometric jet within 10 degrees; yet we find that twice this difference is tolerated in modern power plants as supposedly good performance. This is the secret of the poor vacua against which turbine builders are obliged to struggle in designing machines for better conditions.

There are now on the market condensers of the jet type which are able to operate within 2 to 5 degrees of the steam temperature and without unusually bulky or wasteful auxiliaries. This considerably reduces the quantity of cooling water necessary to condense a given amount of steam; in other words, makes possible a higher vacuum with a given temperature of water. For example, assuming a cooling tower able to cool down to the temperature of the air, what vacuum will it be possible to maintain with 75 degrees water? A perfect condenser (with no temperature difference between steam and discharge water) would require about 220 volumes of cooling water for 29 inches vacuum. For 28 inches vacuum it would require 35 volumes. An efficient condenser of the jet type, working within 5 degrees of the steam temperature, can maintain 28 inches with 43 volumes of water. An ordinary jet condenser, working on 10 degrees difference, will require 57 volumes to maintain 28 inches, while the ordinary surface condenser, working for 20 degrees difference, cannot maintain 28 inches except by using an impracticable amount of water, 140 volumes.

The more efficient jet type is thus responsible for reducing the quantity of cooling water to one-third of that required for the average surface type.

In cooling-tower practice, where extra power is required to lift these large volumes, this is evidently of the highest importance, for the increase in auxiliary plant may more than offset the benefits of the increased vacuum. Therefore, the determination of the *most economical vacuum* for a given plant involves a study of the plant economy at various vacua, the power consumption of auxiliaries and the operating and fixed charges against the auxiliary plant. This becomes more and more important as condensing conditions become more unfavorable.

It is important to deliver steam to the turbine as dry as possible, owing to the well known effect of moisture in decreasing the output through friction. The quality of steam from the engines is, of course, indeterminate, but varies between wide limits, averaging 93 to 90 per cent., or less. So that a separator had best be installed in the exhaust main before the turbine. This also serves to remove the water of condensation from a long run of exhaust piping. This necessity suggests the use of a moderate superheat in the engine, sufficient to insure dry steam at the turbine, entirely feasible with the internal type of superheater in common use. This would avoid the resistance through the separator, which may be a serious matter in dealing with large piping and high velocities. The only other alternative is the use of drying coils in the exhaust main. This, however, has proved to be decidedly uneconomical if live steam must be used for this purpose. It could be applied only in cases where some form of waste heat could be used to advantage.

Summary

The most important thoughts presented in the preceding may be summarized as follows:

(1) Low-pressure turbine application is exceedingly flexible, and may work into existing engine plants of good, as well as poor, design to advantage, in conjunction with engines of high- as well as low-expansion ratio.

(2) Regenerative accumulators not always essential in low-pressure turbine work; in fact, average power-plant work does not require their use, resulting in great simplification of plant.

(3) Important to choose proper turbine size so as to permit good economy in engine and maintain exhaust pressures above atmosphere during normal loading, thus preventing air leakage in valves and piping.

(4) During periods of light loads, it may be expedient to run engine condensing, omitting the turbine entirely.

(5) For infrequent or long-continued deficiencies in the steam supply, the turbine may take live steam through a reducing valve to supplement normal supply.

(6) Inherent efficiency of both turbine and combined plant greatest at moderate vacua, 70 to 73 per cent. of the ideal steam cycle.

(7) Condenser problem lies largely in its ability to work on small temperature differences.

(8) Weight and cost of low-pressure turbine unit not far from that of the complete expansion unit. Length of turbine reduced about 30 per cent., unit about 18 per cent.

(9) No governor required if turbine is electrically connected to engine and takes all or part of the steam.

(10) Efficient safety overspeed stop a vital necessity.

Surface Condensers

By Frederick L. Ray

The type of condenser shown in Fig. 1 is practically a salt-water apparatus, as this is the only type that salt water can be used with where it is desired to use the condensation for boiler-feed water; and even with this type it is often impracticable to use the condensation because of leaky tubes allowing the salt water to mix with the water of condensation. If it were possible always to keep the condenser tubes tight, then the surface condenser could be used on the sea coast and salt water used for cooling purposes.

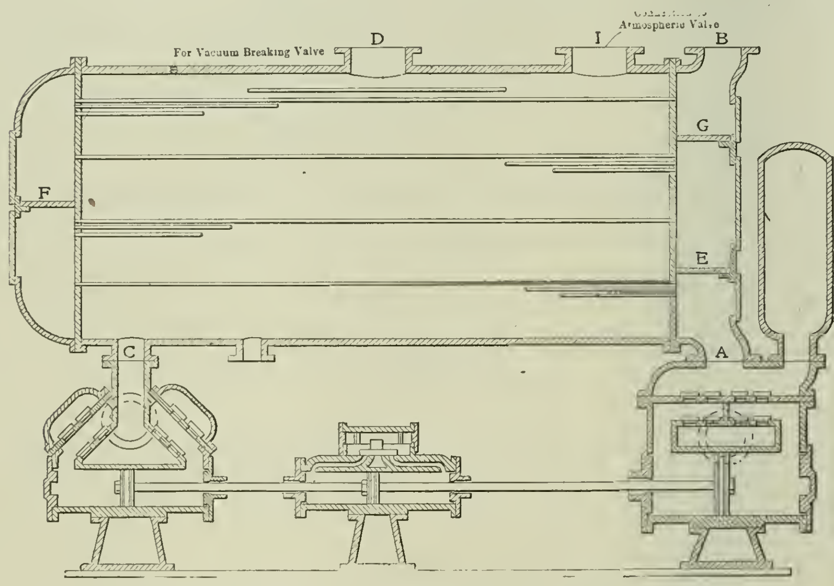

FIG. I. CONDENSER IN WHICH SALT WATER MAY BE USED

Where the circulating water is also used for boiler feed, the surface condenser may be used regardless of leaky tubes. But why go to the extra cost for equipment for such a large cooling surface, circulating and air pumps, where the jet condenser would answer as well and often much better? The surface condenser requires much more attention on the part of the operating engineer, is more complicated and costs much more than the jet condenser.

Care and Operation

As there are many surface condensers in use and more will be installed, regardless of trouble and costly repairs, a few observations on their care and operation are given in the following:

Fig. 1 shows a sectional view of a surface condenser and pumps on one base, in which *A* is the inlet for the circulating water, *B* the discharge for it, and *D* the inlet for exhaust steam which, on entering, strikes a perforated plate, and is distributed over the tubes, thus protecting the tubes from the impact of the steam.

The instant the steam strikes the cold surface of the tubes it is condensed and falls to the bottom of the condensing chamber, from which it flows out at the nozzle *C* to the air pump. The circulating water passes in at *A* and out at *B*, and in its course meets the baffle plate *EFG*, which causes it to pass through the condensers four times. It would appear that this construction would require only one-fourth as much as if the water passed through but once, but this cannot be, as in the repeated passing through the tube, in contact with the steam, it is heated, becomes less efficient and more is required in consequence.

This construction requires that the condenser be somewhat larger, due to the less efficient cooling surface of the tube, but at the same time requires a very much smaller circulating pump. At the left is shown the connection to a vacuum-breaking valve, used to destroy the vacuum before shutting down the air pump, and an automatic atmosphere snifting valve is connected to the outlet *I*. Should the air or the circulating pump break down, or the vacuum be destroyed from any cause while the engine is in operation, this valve will open and relieve the condenser of any excess pressure, and the engine can be run noncondensing.

The tubes of this type of condenser, being quite small, are easily stopped up and considerable trouble may arise from this source, especially when sea water is used, as it always carries more or less seaweed. A strainer of fine mesh is sometimes inserted between the foot valve and the pump, in which case the pump is protected as well as the condenser. This strainer requires cleaning often to insure a proper supply of water.

After a time the steam side of the tubes of a condenser becomes coated with grease carried over with the exhaust steam, and when thickly coated the efficiency of the condenser is greatly impaired, as grease is a nonconductor of heat.

Boiling Out

A process called "boiling out" is effective when animal or vegetable oils are used and is accomplished by fitting the condenser with a soda cock, so that caustic soda can be injected into the steam space upon the grease-covered tubes. The alkali coming in contact with the grease changes it into soap, and in this condition it is easily washed out through the drain cock. This operation is as follows: The steam side of the condenser is filled with water up to and covering the top row of tubes, the alkali is introduced and live steam is let into the condenser, discharging into the water until the water boils. The amount of alkali to be used will need to be determined by experiment, but in any case enough must be used to make the water strongly alkali.

Animal and vegetable oils have been practically superseded by mineral oils for use in the steam cylinder except as they are compounded with mineral oils. Caustic soda has no effect on the grease deposited from mineral oils, therefore the boiling-out process cannot be used. There is no other way but to clean them by hand and to do this the tubes must be removed. It is a difficult and disagreeable task to clean a large surface condenser, as the grease is heavy and sticky, resembling tar. If possible, the grease should be kept out of a condenser and this can be accomplished by installing a grease extractor between the engines and condenser. It should be installed as a matter of economy, making the condenser more efficient and reducing the cost of cleaning and repairs.

Condenser Tubes

Condenser tubes are subjected to great

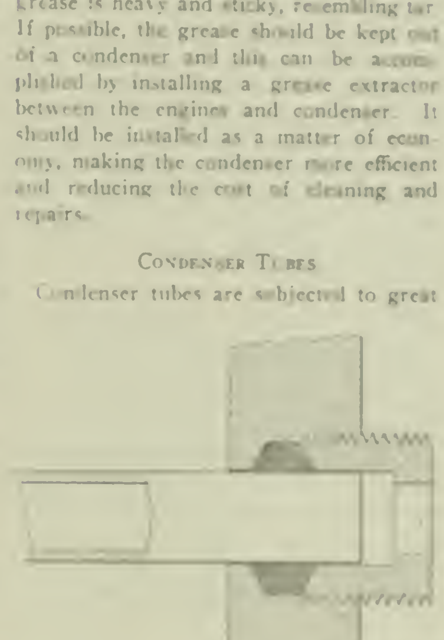

Fig. 2. Special Tube End Construction

extremes of expansion and contraction. In Fig. 2 is shown a method of construction which allows the tube end movement and yet will not allow the tube to crawl out of the packing. This is done by counterboring the screw gland that screws down on the packing which consists of cotton lamp wicking, cotton tape or a rubber ring.

The sources of water leaks in a surface condenser consist of split tubes and defective packing at the tube ends. To test for this leakage, remove the cover plate on the end of the condenser and then by filling the steam space with water, any leaks will be indicated and should be marked for repairs. If temporary repairs must be made, white-pine plugs can be driven into each end of the tube where the tube is split and any packing that is leaking should be replaced with new.

Air leaks will be indicated by a falling vacuum, other conditions being normal, and will be found at the packing on the exhaust-valve stems and piston rods, although it may be in many other places. A lighted candle held to the joint is the best test and where there is a leak the flame will be drawn inwardly. The joints where the tightening of the bolts will not remedy the trouble, the leak may be stopped by plastering over with putty or by driving in hardwood wedges.

When the condensation is returned to the boiler it is very important that the temperature be as high as it is possible to get it, therefore the condenser should be fitted with a thermometer. Under the best conditions it is possible to secure only a certain degree of vacuum, and when more water is circulated than necessary to secure the best vacuum, there is a waste from two directions, i.e., the temperature of feed water is lowered and the circulating pump is using more steam than necessary. Just enough circulating water should be pumped to give the required vacuum, and this will give the highest attainable temperature to the feed water. A reliable thermometer will help the careful engineer to save tons of coal.

Operation of Induced Draft and Suction Producers

By Frank P. [illegible]

It is in the nature of the gas producer, possibly in a wider ratio with reference to plant or unit size than with the steam boiler, that the liability to serious accident increases with the extent of the plant. In the very small producer it may be truly said that there is practically no danger, and no liability to serious destruction of the apparatus from explosions which may occur within its parts. This is not due to any difference whatever in the character or inflammability of the gas, but rather to the relative physical strength of vessels containing gas.

Without exception, we may assume that trained engineers possess a sufficient knowledge, if they only stop and think, to avoid the accumulation of air and gas where the mixture is at all likely to become ignited. The greater the volume of such a mixture, the greater becomes the danger from its ignition and the wreckage it can produce.

There come, sometimes, trying times in the operation of large boiler installations for which no particular person or persons can be held responsible. Invariably an expert boiler attendant is at such times made to face these critical conditions, with readiness to do the right thing at the right moment. So there come, also trying times in the operation of gas-generating apparatus of whatever character and just as with the boiler, the seriousness of the circumstances may be such that a cool head may be the only means of salvation.

Danger of Explosion

The one primary idea to be borne in mind by the operator of any gas-generating apparatus is that whenever and wherever air is admitted into a volume of gas, danger of explosion exists. To illustrate how this point is guarded and feared in the handling of large volumes of richer gases, let me recall an incident of which I was a witness in a large gas works. A single exhauster, direct driven by a steam engine, handled the gas generated by a battery of thirty retort coke ovens of the Solvay type—possibly 130,000 cubic feet per hour. This exhauster delivered a portion of the washed gas back to the burners that heated the system of ovens and through an 8-inch main pipe. The remainder of the gas was delivered into a system of pipes that supplied steel furnaces. On the vacuum side of the exhauster (between it and the ovens) were arranged in series four condensing chambers having a combined volume capacity of probably 7000 cubic feet.

The first warning that something had gone wrong came in the form of an explosion in the 8-inch gas main delivering to the oven burners. The blanked end of this main and a tee at that point were disrupted and blown away. Immediately following this came a series of explosions resembling heavy cannon discharges, occurring at intervals of a few seconds and continuing, it seemed to me, several minutes. The last water seal between the exhauster and the ovens was located near the ovens. Each ignition of the gas burned all that had accumulated since the last explosion back to this seal, and an automatic rapid-fire artillery performance was set up as long as the exhauster continued to deliver an explosive mixture.

Now, you say, why didn't they shut down the exhauster?

With the first report every man sought his post, of course, and the shutting down of the exhauster was the first move the operating engineer would have made, with the permission of the man in charge, but the man in charge had other ideas. There is no doubt that he was doing some rapid-fire thinking, and there were other considerations than the mere stopping of a noise after the one small damage had been done.

The source of trouble would be much more readily located with the exhauster in motion, to say nothing of the serious liability of the combustion to reach backward through broken seals with the lessening of pressures in front and of vacuum behind the exhauster; and, furthermore, depending upon the location of this leakage of air into the system might have been the demolishment of the whole condensing system.

While the shutting down of an exhauster without due warning to everybody concerned meant serious delay and damage to operation, obviously this thing must end somewhere, and the man on whom the burden rested was thinking and acting in sharp blue streaks, though it may take a long time to tell the story. The exhauster was shut down in the end, and no direct cause was located in actual evidence for the derangement, yet there was no mystery about it. Either a seal had been broken admitting air, or one of the operatives had made and corrected an error—taken off and had replaced a cap or plug in one of the many inspection openings.

This incident only serves to show how exciting a situation may become, and how essential to safety and a minimum of property loss is a cool head in the handling of the richer gases, and yet there do not arise any such emergencies that may not be paralleled in frequency and gravity by serious boiler-plant situations. Indeed, in the same plant I can recall that our most frequent and serious anxieties were for our boilers, which were heated by the spent gases from the oven-heating systems. The water supply was not reliable at all times, nor were the dampers controlling or shunting the flue gases, and since the temperatures were high and steam plentiful this became a rather serious combination.

What a Careless Attendant Did

Another incident in producer operation: The attendant had prepared a suction producer for starting up. The producer was of 300 horsepower capacity and the space beneath the grates was of considerable volume, possibly 40 or 50 cubic feet. He had blasted the bed of new fuel to the point of making good producer gas and everything was in prime condition for a prompt start on the engine operator's signal for gas. The two men, working together, understood each other perfectly and all the conditions and liabilities that were involved, but the producer attendant had become a little careless. So, when the signal was given from the engine room, he shut off the blower, threw over the three-way valve and folded his arms, anticipating an immediate start of the engine. After a dozen seconds this start had not been made. Now a dozen seconds at a time like this are sufficient to make a gas-producer operator thoughtful, and the attendant suddenly remembered that his ash doors were all clamped up tightly, and that if just a few more seconds elapsed before the starting of the engine, there would be trouble. Not serious trouble, the producer not destroyed, nobody killed, but probably a door-bar snapped or a producer lining loosened up.

Of course, the first thought would be to open a door *quickly*, but self-preservation being the first law, etc., a cool-headed operator will never attempt to open a door at a time like this. If the engine should start just at the time of laying hold of this door, it may mean, at the worst, a broken arm or leg, and the sensible thing to do is to leave the producer alone and find out what may be wrong at the other end.

The engine man had thought he was all ready to start, but an auxiliary cam would not shift, or a battery switch had been forgotten, or even worse, as a result of which it might be three or four minutes more yet. What then? Go back and open the ash doors and let the producer stand in communication with the engine until ready to start? If the producer is in a room communicating with others where the polluted atmosphere may reach a sensitive constitution, no.

Supposing the producer to be in a fireproof room of only the needed dimensions, let us assume the extreme possibility. This room might become pretty well filled with gas in a few minutes, and when the engine starts up, not only the producer may sustain a shock, but the whole room as well. This last has not occurred, to the writer's knowledge, but a cool head and a careful man will take even such remote contingencies as this into consideration, and act accordingly.

Well, what would be the right thing to do at such a moment, throw back the three-way valve into communication with the purge pipe? Not just yet. *Be sure to open an ash door first; then throw the three-way valve,* because an ignition of the gas below the grates will occur three times out of five under such circumstances, and the one always safe and sure thing to do is to unfasten, or partially open, a base door *just before the blower is stopped.*

And why will these base explosions occur? Why, simply because when the three-way valve is thrown into engine position, the only exit for the gas distilled from the hot fuel is backward, beneath the grate and through the draft conduit. Live fire is resting on the grate bars, and when the engine starts, or the reversal of the three-way valve gives the less active draft by the vent pipe, air is drawn in, partly displacing the gas beneath the grates. When sufficient gas has been displaced by air the remaining mixture ignites from the live fire through which it cannot avoid passing. This contingency is not provided for by the producer builders, because it is not considered sufficiently serious as a danger; nevertheless, a careful attendant will always avoid it.

Flame Arresters Desirable for Test Cocks

In large producers test cocks that are to be lighted, when located anywhere else than on the fuel chambers, should be provided in all cases with gauze flame arresters. In this connection, it is the writer's contention that every operator of a gas producer should have the common judgment, or the training, to enable him to operate his plant right along without resorting to test flames at any point other than on his fuel chamber or vent pipe. This is the one safe means of handling producers without incurring the dangers due to this practice.

When a plant is once put in service and is reasonably free from leakage, the gas left in the vessels at shutting down is better than any new gas which may be made to displace it, so why not start up on it? Here, too, there is one precaution to be taken. New coke fillings in gas scrubbers will absorb considerable volumes of the gas, and if this absorption takes place during a considerable period of layover, even though the engine may have been operated for a short time, and if there is even a small leakage, a considerable volume of air will be drawn in, and there is danger in the application of a test flame. An operator, knowing this, will take no chances, but will blow over a new supply of gas to his engine for the first few times starting up. But he will not need to apply a test flame at the engine. He will have someone to turn his blower for him, if it be a small plant, for these first few starts, and he will know from what he has been told, or from common horse sense, how long will be required to pass this new supply of gas over to the engine. It is evident that the liability to ignition of an explosive mixture is less through the inlet-valve port of an engine normally operating or starting than by the application of a flame to an open jet. The writer has in mind one plant which has been in operation for more than a year. No test flame has ever been applied at the engine; there is no provision for it, and none is sought, the attendant having been instructed to get along without such means.

An incident is recalled of a suction generator of some 200 horsepower capacity under starting blast in which from one poke hole inflammable gas was issuing, while from a poke hole on the opposite side of the fuel bed apparently pure air issued. This is a rare occurrence, of course, but in no way unaccountable. An old bed, after some days' layover, is not as thoroughly cleaned as it should be, because to do so involves the loss of all the fire, and to start a new fire outright takes longer then to blast in the old fire than remains. One side of the bed contains a mass of old clinker which is to be removed as soon as the conditions will permit. It seems quite likely that an improper handling or understanding of this extreme case might cause an explosion.

Finally, a little diligence on the part of the plant operator to acquaint himself with the few simple laws that make for the safety of operation will be worth much, as well as all the talk he can absorb, yet it is unfair to expect him to get all the little details of precaution instilled into his methods by running the liability to danger that so many writers and authorities allow to go undirected in their discussions. He will soon learn, in practice, that in the operation of suction and induced draft producers the admission of a small volume of air into the system between the producer fire and the source of draft is not a serious matter, and no chance or risk at all is sustained. But this volume must be small relative to the volume of gas passing, else serious disturbance, at least, may occur. Herein lies justification for advising the use of a tamping bar with a rod on the bed quite sparingly in the operation of a small suction producer.

A 1-inch opening in the top of the bed chamber of a 100-horsepower producer running with a 4-inch (water) vacuum will do no damage; it will scarcely be appreciable for the length of time required to bar that portion of the fire or inspect the bed. But the same opening into a 10-horsepower producer fuel chamber working at the same rate is almost sufficient to cause an explosion and, if ignited, will at least shut down the engine being supplied.

We are arriving at the intensely practical stage of producer work which demands attention to details, and as time begins to see results we are and have been prone to neglect some of these details that are important.

Improved Pressure Oiling System

By William [illegible]

The improved pressure oiling system herein illustrated and described will be found a very handy equipment in the dynamo plant, office building, hotel or factory engine room. It can be constructed and erected at a very moderate cost and will be found highly economical in the use of oil, as all of the waste oil can be returned, filtered and used again, so long as the oil contains lubricating qualities. In a plant where numerous units are to be oiled and an oil-return and filtering system is not in operation, considerable oil is lost, thus adding to the expense of operation; but where a plant is equipped with a system such as described in this article, the oiling expense should be reduced nearly 50 per cent., not to mention the saving of the labor necessary to do the oiling by hand.

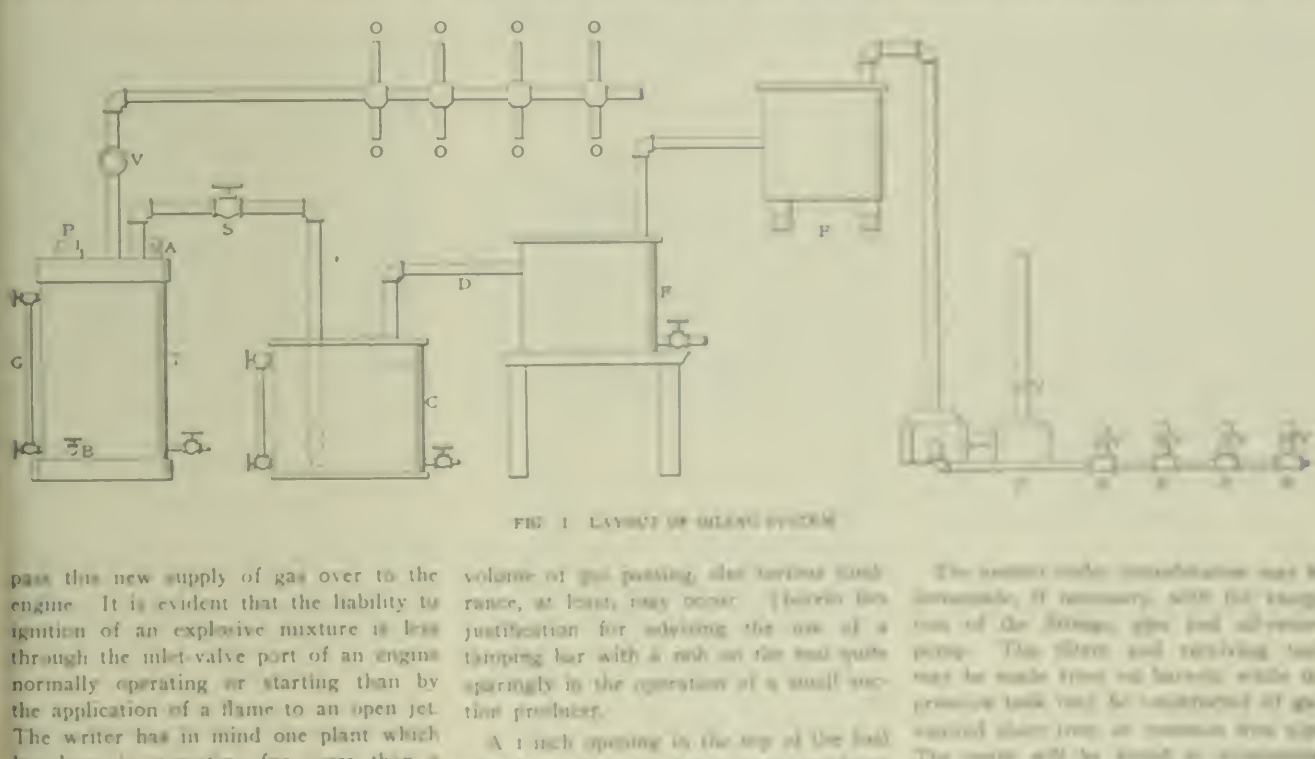

FIG. 1. LAYOUT OF OILING SYSTEM

The system under consideration may be homemade, if necessary, with the exception of the fittings, pipe and oil-return pump. The filters and receiving tank may be made from oil barrels, while the pressure tank may be constructed of galvanized sheet iron or common iron pipe. The outfit will be found so economical, however, that it will be a good investment to have the equipment properly installed and arranged to handle all of the returned oil from the various units.

Fig. 1 illustrates the entire system. The oil-return pump P draws the waste oil from the different units through the oil-return pipes R R R R and then discharges the waste oil into the receiving tank T, where the water is rapidly separated from the oil. The oil will flow from T into the main filter G, then through the pipe D into the receiving tank C, where a pressure pump [illegible]. The oil is taken from the receiving or storage tank F either by a pump or water siphon and discharged into the pressure tank *T*, from whence it is fed to the various units, under a pressure equal to that of the water, if water is used, or, if a pump is used, under any desired pressure which can be maintained on the oil in the tank *T*. The oil flows from *T* through the various outlets shown at *O*, which connect with the oil cups or bearings of the dynamos, engines, or whatever bearing is to be lubricated, the amount of oil flowing into each cup or bearing being controlled by means of a valve placed conveniently over each bearing or cup. In the drawings the location of the valves is indicated by *V*.

The size of pipe to employ in erecting this system will depend on the amount of oil required for each bearing. The main or trunk lines may be any required size from 3/8 inch upward, but the branch

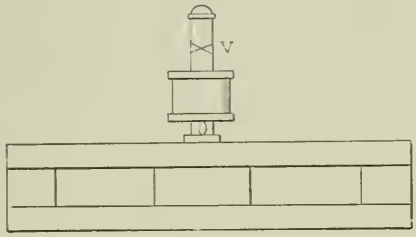

FIG. 2

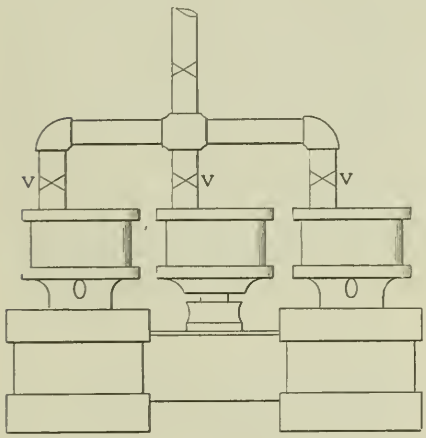

FIG. 3

lines leading into the bearings or cups may be 1/8 inch, and if made of brass will present a neat appearance.

Fig. 2 shows how the pipe carrying oil is attached to the crosshead-slide oil cup, and Fig. 3 is an end view of Fig. 2 and shows plainly the piping for slides and crosshead wipers. Fig. 4 shows oiling connections for main bearings and the crank-pin wiper; Fig. 5 illustrates a sectional view of the "dry" filter, and Fig. 6 is a sectional view of the "wet," or water filter, either of which may be used in this system of oiling. If the pressure on this system is maintained by means of water, the tank *T* should be large enough to contain sufficient oil for a continuous run of, say, from 36 to 60 hours; but if a pump is used to maintain the pressure, the tank *T* need not be so large because the oil supply can be constantly maintained.

The pressure to operate this system will depend in a great measure on the distance it is located from the engine room and the number of bends through which the oil must flow. In actual practice 30 pounds pressure is found sufficient to do the work at this plant, although the system is located more than 50 feet from the engine room.

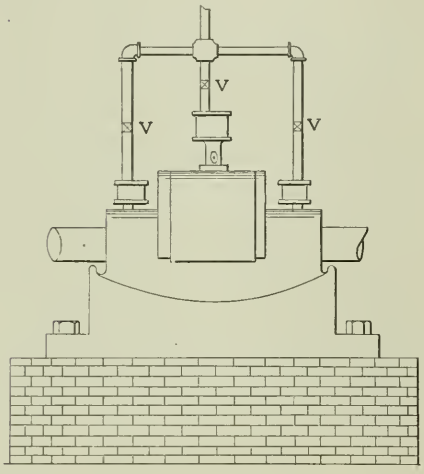

FIG. 4

To operate the system with water, assuming that there is no oil in *T*, fill *T* with water and when water appears at the air vent at *A* shut the water off and close *A*. Open valve *B* and allow the water to run off to the sewer, then open valve *S*, which connects the oil supply in tank *C* with the pressure tank *T*; the oil will be siphoned into *T*, and as the water lowers or runs off, oil will take its place and the amount of oil which has flown into *T* will be indicated by the gage glass *G*. When sufficient oil is in *T*, shut *S* and *B* and open the water valve, and whatever pressure is exerted by the water will be impressed on the lower surface of the oil and tend to force the oil out through the valve *V*. By opening *V*, the oil will flow out through the main line and connections, as indicated at *O*.

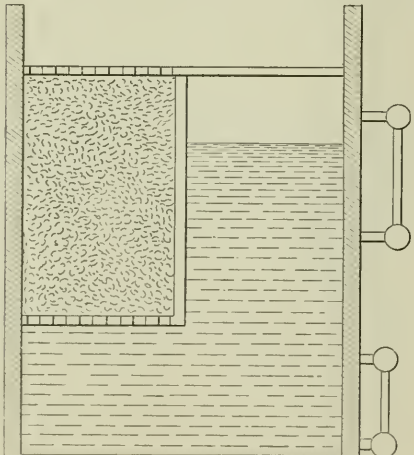

FIG. 5. DRY FILTER

To stop the system from feeding oil shut *V* and the water valve and allow the oil-return pump to run until all of the waste oil is pumped back into *F'*. After shutting down this oiling system it will not be necessary to disturb the setting of the valves located above the oil cups; therefore, on restarting the system adjustment of those valves will not be necessary. By doing this considerable time and labor are saved in starting up. Occasionally the tank *T* should be cleaned out. After allowing all of the oil to flow out of *T*, open the washing-out plug *P* and the valve *B* and allow all of the dirty water and sediment to flow off to the sewer; by playing a strong stream of water through *P* it will facilitate matters considerably.

In fitting up the system it is a good plan to have the oil pipes enter the top of the cups loosely and connected to one side of each cup, as shown in the drawings, as this permits of lifting out the pipes from the cups and of hand oiling, should anything occur to prevent the system from operating. Also, the oil cups may be cleaned or new glasses inserted without having to unscrew the piping.

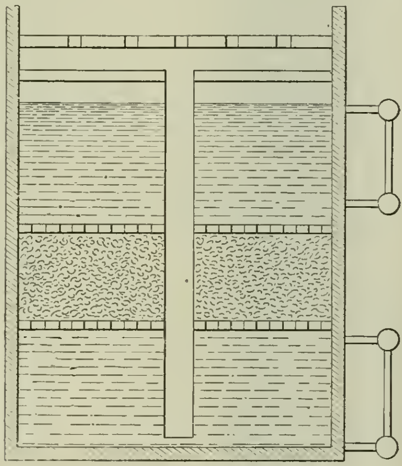

FIG. 6. WET FILTER

Protection of Underground Pipes

C. H. Staten spoke before the Modern Science Club, of Brooklyn, N. Y., Tuesday evening, December 22, on "Insulating and Protecting Underground Steam and Hot Water Pipes." He dwelt at length on the history of the development of central-station heating plants and traced the poor results and failures, which marked the earlier ventures in this direction, to lack of proper protection and insulation.

With a system designed in accord with the best practice of the present time, Mr. Staten said, heating could be done from central stations at a cost not exceeding 30 cents per square foot of radiating surface for seven months.

The Compression Refrigerating System

By F. E. Matthews

What are the general functions of a refrigerating system as a whole and of its different parts? Why does the back pressure rise when the machine is shut down? What is "frosting back"? Is it a waste?

The function of a refrigerating means, whether it be an absorption or a compression refrigerating machine, or simply a bunker full of ice, is to provide a heat-absorbing medium which, after it has absorbed its fill of heat from the products that it is desired to cool in the cold-storage rooms, or other places to be refrigerated (which for simplicity we will hereafter call coolers), may be removed from such coolers so that the heat absorbed may also be removed. After its removal from the "coolers" this medium may either be divested of its heat, after which it may be again returned to the coolers and allowed to absorb more heat, as in the case of ammonia or brine circulated through coolers, or it may be thrown away and a new supply introduced, as in the case of cooling by ice.

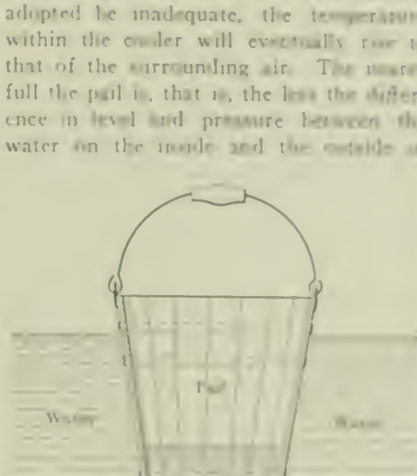
A pound of liquid ammonia in evaporating at 0 degree Fahrenheit has a heat-absorbing capacity of 555.5 British thermal units (B.t.u.) of heat, a B.t.u. being the amount of heat required to raise the temperature of a pound of water 1 degree Fahrenheit. Vapors of ammonia are easily liquefiable, so that in consideration of its high commercial value it becomes economy to use this medium over and over again.

A pound of ice in melting has a heat-absorbing capacity of 144 B.t.u. While the water from the melting ice might readily be frozen again by mechanical means and might accordingly be used over and over again, as is the case with ammonia, its low commercial value when coupled with the fact that it can often be obtained already in the naturally frozen state, to say nothing of such factors as contamination by products in the coolers and transportation to a place where it might be frozen, makes it eminently impracticable even to consider using this medium but once.

An apt though rather old illustration of the action of a refrigerating machine, or in fact any heat absorbing means, is that of the absorption of water by a sponge. The tendency of the sponge to absorb water after one charge has been squeezed out of it is not altogether unlike that of anhydrous ammonia and other liquefiable refrigerating media to absorb heat after the former charge has been squeezed out. The two media, water and heat, may both be considered passive, and simply acting under the influence of the sponge and the refrigerating medium.

A containing vessel, such as a more or less leaky pail, partially sunk in a body of water, as roughly indicated in the accompanying sketch, may be shown to be similar to a cold-storage compartment surrounded by an atmosphere higher in temperature than that within. Since the level of the water in the pail is lower than that on the outside, and since the pail is more or less leaky, a certain amount of water will leak into the pail from the outside. If none of the water is removed or if the process of removal proceeds less rapidly than the infiltration, the pail will eventually fill up to the level of the water on the outside.

Carrying out the comparison in the case of a cooler, the higher temperature on the outside tends to cause an infiltration of heat through the more or less leaky cooler walls. If no steps are taken to remove this heat or if the means adopted be inadequate, the temperature within the cooler will eventually rise to that of the surrounding air. The nearer full the pail is, that is, the less the difference in level and pressure between the water on the inside and the outside of



ILLUSTRATING A COLD-STORAGE PRINCIPLE

the pail, the less will be the water leakage. The warmer the air in the cooler, that is, the less the difference in temperature between the atmosphere on the inside and outside of the cooler the less will be the heat leakage. Furthermore, in the process of "bailing out," the lower the water level in the pail, making it necessary to lift it through a greater distance, the more work will be required. Similarly, the lower the temperature in the cooler the more energy must be expended to expel the heat on account of the increased range of temperature through which it must be raised.

In brief, a compression refrigerating machine consists of the necessary mechanical means of circulating a heat absorbing medium through the cooler and of removing from this medium the heat which it absorbs en route. The heat absorbed in the cooler passes from the atmosphere, products, etc., by virtue of the fact that the refrigerating medium is lower in temperature. This same heat must be similarly removed from the refrigerating medium by introducing a secondary cooling medium materially lower in temperature. Since there is no secondary cooling medium of a lower temperature available than the refrigerating medium, even at the temperature at which it returns from the cooler after having absorbed large quantities of heat, it becomes necessary to raise the temperature of the refrigerating medium enough so that it can be cooled. This is effected in the case of the absorption system by the direct application of heat in the "generator" and in the compression system by the performance of work in a suitable form of "compressor."

Carrying out the comparison of the sponge and the water in the pail, it is evident that the water after being absorbed by the sponge must be raised to a higher level before it can be made to flow away to the surrounding water at the higher level.

More specifically, a compression refrigerating system consists of a set of pipes, or other containing vessel, in the cooler in which the refrigerating medium absorbs heat at a low temperature from the products to be refrigerated and a second set of pipes, or other containing vessel, outside of the cooler in which the refrigerating medium gives up its heat to a secondary cooling medium, such as water or air at a comparatively high temperature, and a compressor for raising the temperature of the refrigerating medium sufficiently to enable it to give up its heat to the secondary cooling medium.

In the operation of such a system almost any gaseous working medium might be employed. In practice, however, the list is limited to only such gases as are capable of being liquefied under ordinary natural temperatures and not too high mechanically produced pressures. Judging from the relative number of commercial installations employing the different media one may assume that under the average conditions anhydrous ammonia comes more nearly to fulfilling all of the requirements of an ideal working medium than any other. This medium will be considered throughout the remainder of this article.

The pipes located in the cooler, through the walls of which the ammonia absorbs heat from the objects to be refrigerated are commonly called "expansion" coils and those located outside the cooler through the walls of which the ammonia gives up its heat, condenser coils. The ammonia, previously liquefied in the condenser under a pressure of from [illegible] to [illegible] pounds, according to the temperature of the cooling water, is conveyed from it to the "receiver," which consists of an approximately cylindrical containing vessel which acts as a storage tank in which the [illegible] is collected and stored until it passes, as required, into the expansion coils. The flow of this high-pressure liquid into the expansion coils is regulated by "expansion" valves, which are virtually nothing more than [illegible] mechanical devices for accurately varying the opening through which the liquid ammonia must pass on its way to the expansion coils. As stated, the word "expansion" has been erroneously applied to these coils and valves because of the idea, likewise erroneous, that the liquid ammonia vaporizes or "expands" immediately the pressure is relieved, as it passes the regulating valve and enters the cooling coils. As a matter of fact, before it is possible for a pound of ammonia to change from the liquid to the gaseous state it must be supplied with about 555.5 B.t.u. of heat.* If this amount of heat were absorbed at the expansion valve, which its immediate vaporization assumes, there would be no further heat-absorbing capacity in the ammonia, and its introduction into the "expansion" coils would be useless.

In the expansion coils the liquid ammonia, which has the peculiar property of boiling at a very low temperature, 28.5 degrees below Fahrenheit zero under atmospheric pressure, absorbs heat from the surrounding atmosphere, boils and vaporizes in much the same way as water, absorbs heat from the hot furnace gases, boils and vaporizes in the similarly constructed pipe coils of an ordinary water-tube boiler.

Having evaporated to a dry gas, the ammonia vapor leaves the expansion coils and enters a "return" header which conveys it back to the suction side of the compressor. This return line is usually fitted with a "scale trap" constructed quite similarly to some of the more simple types of steam separator. The function of this trap is to prevent any scale from the inside of the pipes, or other foreign substances, from entering and damaging the compressor.

It often happens that the expansion valves are not properly adjusted, or that the expansion coils are so arranged that, like poorly designed boilers, there is an abnormal entrainment and considerable liquid ammonia is carried back with the returning vapor. In this case the scale separator may act as a veritable separator and temporarily interrupt the passage of the entrained liquid ammonia to the machine. On account of the difficulty of returning any liquid so trapped to the expansion coils the scale traps are of little value as separators except as means of keeping occasional large volumes of liquid from returning to the compressor. Once having become filled with liquid ammonia they remain in this condition for some time. Since in order to evaporate, the ammonia must have heat, and since the temperature of the boiling ammonia corresponding to the back pressure usually carried in refrigerating and ice-making work is sufficiently low to produce ice on the outside of the traps, piping, etc., these parts soon become heavily insulated with ice which further materially reduces the amount of heat that can be absorbed, and the entrained liquid enters the compressor with considerable capacity for absorbing heat. If this amount is abnormal it may cause the compressor to pound for the same obvious reason that a steam engine pounds when it receives a quantity of entrained water in the steam. When quantities of liquid ammonia sufficient to cause the compressor to pound enter the compressor cylinder, it is usually evidenced by the abnormal cooling effect on the compressor walls, or more noticeably that of the piston rods which, through their contraction, as well as that of the packing and stuffing boxes, may even allow the ammonia to leak by the packing. The evaporation of this entrained liquid ammonia in the compressor cylinder, or that introduced directly into the cylinder through an expansion valve designed for that purpose, refrigerates the gas as well as the compressor parts and tends to prevent superheating of the gas during compression. The evaporation of the liquid ammonia remaining in the expansion coils when the compressor is shut down causes the rise in back pressure usually so noticeable a few hours after the plant has been shut down.

The condition of the ammonia vapor as regards saturation or supersaturation may best be arrived at through thermometers inserted in mercury wells in the return and discharge lines near the compressor. Tables of "properties of saturated ammonia" indicate at a glance the temperatures at which the vapors should return to the machine under different conditions of back pressure and assumed saturation.

If the last trace of the liquid ammonia is evaporated before the vapors reach the compressor, and the return pipes are uninsulated, there is likely to be considerable superheating, i.e., the temperature of the vapor entering the compressor is likely to be several degrees higher than that shown by the tables to correspond to the back pressure carried. This condition results in a considerable loss of efficiency and should not be allowed to continue.

While difference in opinion regarding the amount of unevaporated liquid the return ammonia gas should contain in order to give maximum efficiency has given rise to two distinct systems, viz., the "wet" and the "dry" compression, a discussion of the relative merits of the two systems would be too far-reaching to warrant its introduction here. The best general rule regarding the wet or dry operation of compressors is to follow the instructions of the respective builders as closely as possible.

In the absence of more accurate means, such as thermometers, for determining the temperature of the returning ammonia gas, the "frost line" has been forced into service to give at least some slight indication of such temperatures. The simple formation of frost on the outside of a pipe containing cold ammonia gas, or, in fact, any other cold medium, indicates nothing more nor less than that the heat from the outside atmosphere is absorbed with sufficient rapidity to reduce the temperature of the pipe and nearby air to at least 32 degrees Fahrenheit, under which condition atmospheric moisture is, first, precipitated, just as rain or dew is formed when moisture-ladened air becomes cooled by heat radiation to air at a lower temperature or contact with other colder objects and, second, is frozen, just as dew is frozen to form frost when its temperature is reduced to 32 degrees Fahrenheit.

Since the formation of frost on an ammonia pipe is influenced by the room temperature, it cannot be an ideal means of judging temperature. Where considerable entrained liquid ammonia is present to evaporate and absorb heat rapidly, the general appearance of the frost formed, or the way one's wet finger sticks to the pipe, may give some slight indication of the action taking place inside. Where low temperatures are carried the return gas may be so far below 32 degrees Fahrenheit that the same rise in temperature that would ordinarily completely change the appearance of the return line if it took place at a higher temperature would not affect the frosted line at all, as far as outward appearances are concerned.

It may be generally asserted that it costs an expenditure of energy to remove heat from any substance at any temperature to another substance at a higher temperature. If, then, a certain amount of the heat in the returning ammonia gas has its origin in the engine room, where its absorption is manifested by frost in the return line to the compressor, it is evident that the frosting of the line costs energy to drive the compressor and that this energy costs coal, labor and, finally, money. The return lines to compressors should be effectively insulated to reduce this loss. Nothing is more erroneous than the argument that because the returning gas has passed the rooms that it is sent out to cool, there will be no loss by heat absorption through exposed, uncovered cold pipes. The actual cost of producing a B.t.u. of refrigeration can be computed for any refrigerating plant by simply dividing the total operating cost of that plant by the number of B.t.u. of refrigeration produced. The useless expenditure

*In practice not all of the 555.5 B.t.u. of heat-absorbing capacity, or *negative* heat of a pound of anhydrous ammonia available at 0 degrees Fahrenheit can be utilized for useful cooling work. This on account of the cooling work which must first be expended on the ammonia itself in order to reduce its temperature from that of the condenser to that of the cooler. This may be illustrated by a similar process in which water is the medium in question.

The amount of heat that must be abstracted from one pound of water at 32 degrees Fahrenheit, in order to freeze it, is 144 B.t.u. On this basis a ton of ice would represent 288,000 B.t.u. of negative heat. In practice the expenditure of this amount of cooling will not freeze a ton of water because it must first be cooled from its natural temperature or, in crystal-ice systems, from the temperature of the distilling tank down to 32 degrees Fahrenheit. This involves a further expenditure of 1 B.t.u. pound per degree Fahrenheit cooled through.

of a single unit of refrigeration is just as prodigal as the throwing away of an equivalent amount of money. The fact that this and similar losses are allowed to continue in some of the largest refrigerating and ice-making plants in the country is poor excuse for their existence in others.

Catechism of Electricity

888. *How should the motor be wired in circuit?*

In accordance with the diagram of connections accompanying the machine, or if such a diagram is not furnished, in accordance with the general arrangement shown respectively in Figs. 276, 277 and 278 for shunt-, series- and compound-wound motors.

889. *For which direction of rotation is a motor usually arranged when leaving the factory?*

Unless otherwise specified, motors are usually tested and connected for a left-hand direction of rotation; that is, when facing the machine at the commutator end the top of the armature will turn toward the left. An arrow indicating the proper direction of rotation is generally painted on the machine at the commutator end.

890. *What preliminaries should be observed before starting up a motor for the first time?*

Slowly turn the armature over a few times by hand to make sure that it does not rub or bind, and is perfectly free to revolve. See that the machine throughout is free from dirt or foreign matter, and is properly lined up so that the belt runs in the middle of the pulley. Check up the connections of the motor and its starting rheostat with the wiring diagram for this particular case. Fill the bearings with high-grade dynamo oil until the oil gages show that the proper amount of oil has been introduced. Make sure that the

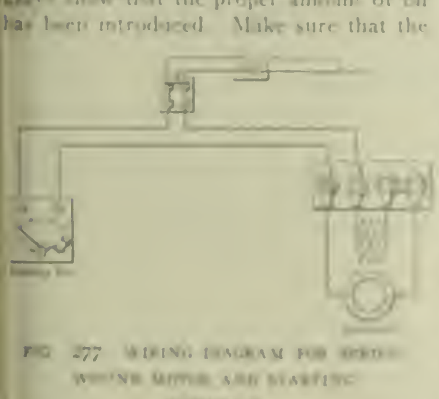


FIG. 277. WIRING DIAGRAM FOR SERIES-WOUND MOTOR AND STARTING RHEOSTAT

oil rings are properly carrying the oil over the bearing surfaces when the armature is turned.

The brushes should be given the proper pressure on the commutator, about 2 pounds per square inch of contact surface. The following table will be found useful in determining the approximate pressure of the brushes on the commutator for various sizes of brushes:

For brushes 1 inch or less wide, about 1 pound.
For brushes 1¼ inches wide, about [illegible] pounds.
For brushes 1½ inches wide, about 1½ pounds.
For brushes 1¾ inches wide, about [illegible] pounds.
For brushes 2 inches and over, [illegible] pounds.

891. *How should the pressure of the brushes on the commutator be determined?*

Use an ordinary spring-balance scale *b*, Fig. 278, placing the hook so as to raise the brush *e* perpendicularly to the commutator *a*, and then read on the scale the

FIG. 276. WIRING DIAGRAM FOR SHUNT-WOUND MOTOR AND STARTING RHEOSTAT

pull in pounds necessary just to lift the brush from the surface of the commutator. If the tension is too great, loosen the thumb screw *s* in the brush holder *c*, which will loosen the spring that presses the brush in position, and if it is too slight, tighten the thumb screw. It is necessary to have the pressure of all the brushes exactly the same.

892. *What directions should be followed in securing the proper position of the brushes on the commutator?*

Motors vary considerably in regard to the position in which their brushes must be placed for the best results. In bipolar motors or motors arranged for rotation in either direction, the position of the brushes should be midway between the pole pieces.

In multipolar machines, a punch mark is generally placed on the rocker arm and two punch marks on the bearing case. If the motor runs with a left-hand rotation, the punch mark on the rocker should be over the right-hand punch mark on the bearing case, and with a right-hand rotation over the left-hand punch mark. Reversible motors have only one punch mark on the bearing, the brushes being set centrally, and these motors should run equally well in either direction. A change in the direction of rotation of a motor from right-hand to left-hand rotation is effected by interchanging the main leads and shifting the rocker arm in clockwise direction until the punch mark on the rocker is over the right-hand punch mark on the bearing case.

893. *If there are no punch marks, how should the brushes be placed?*

The brushes should be placed midway between the centers of the pole faces, allowing for a certain lag previously explained to be necessary, which varies from ¼ inch to an inch or more, depending upon the size of the motor.

In bipolar machines there are always two studs or sets of brushes and these must be placed exactly 180 degrees apart. In multipolar machines there are usually as many sets of brushes as there are pole pieces. By a certain connection of the armature winding the number of sets of brushes may be reduced to two and these in a four-pole motor should be set 90 degrees apart, in a six-pole motor 60 degrees apart, in an eight-pole motor 45 degrees apart, in a ten-pole motor 36 degrees apart, and in a twelve-pole motor 30 degrees apart.

894. *How should the motor be started for the first time?*

Throw off the belt, close the circuit breaker, if there is one, and then close the main switch, having first made sure that the starting rheostat handle is in the "off" position; then start the motor by moving the rheostat handle to the first contact, hold it there a moment and slowly pass to each succeeding contact until all resistance is cut out. Give the motor time to speed up before passing from one contact to another.

Allow the motor to run without load for a time to make sure that it is in proper working order. If the machine operates at a speed higher than that on the nameplate or does not appear to be working properly, turn off the current by opening the main switch. Do not continue to run the motor without locating and remedying the trouble.

When the armature has attained full speed see that the oil rings revolve properly and that they supply the journals with oil, as otherwise the bearings will run hot. Feel all joints and connections. If any one is warmer than the others, the connection is imperfect and should be tightened.

Care should be taken that the shunt-field circuit of a motor is not opened.

FIG. 278. WIRING DIAGRAM FOR COMPOUND-WOUND MOTOR AND STARTING RHEOSTAT

If this should happen during the operation of the motor the armature will tend to run away, if lightly loaded, and burn up, if heavily loaded. If the shunt-field circuit is opened while carrying current and the motor is not operating, there is danger of the field coils being punctured. If it becomes necessary to break the field circuit it should be done slowly, allowing the arc formed to die out gradually.

Gas Engine Compression and Efficiency

A Simple Explanation of How and Why the Degree of Compression Affects the Theoretical Efficiency and the Operating Economy

BY PAUL C. PERCY

The statement that the efficiency of a gas or oil engine is increased by increasing the compression pressure of the engine is familiar to all readers who are interested in the subject. The explanation of the statement is probably not so familiar. Put concisely, it is that increasing the compression increases the temperature range of the cycle, and the thermal efficiency depends on the operating temperature range in any form of heat engine.

Just here it may be worth while to remind the reader that a gas engine, like other heat engines, yields several kinds of efficiency, namely, the theoretical cyclic efficiency, the thermodynamic efficiency, thermo-brake efficiency and the mechanical efficiency.

The theoretical cyclic efficiency is the proportion of the heat in the combustible mixture that is available for doing work as it passes through the cylinder. For example, if the charge contains 1000 heat units and 400 of these are discharged in the exhaust gases, the available heat is 1000 — 400 = 600 B.t.u. and the cyclic efficiency is

$$\frac{600}{1000} = 0.6,$$

or 60 per cent.

The thermodynamic efficiency is the proportion of the heat in the gas that is actually utilized in doing work. For example, if the charge contained 1000 heat units and the work per cycle done by the expanding gases on the piston were 233,400 foot-pounds, this would mean that

$$233,400 \div 778 = 300$$

heat units had been utilized in doing work, and the thermodynamic efficiency would be

$$\frac{300}{1000} = 0.3,$$

or 30 per cent. If it were possible to operate an engine without losing heat through the cylinder walls and piston, and if complete combustion of the gas were obtained, all of the heat in the gas except that discharged in the exhaust gases would be turned into work and the thermodynamic efficiency would be equal to the cyclic efficiency.

The thermo-brake efficiency is the proportion of heat that is turned into useful work outside the engine and the mechanical efficiency is the ratio of the useful work to the total work done on the piston. For example, if the charge contains 1000 heat units, if the work done on the piston per cycle is 233,400 foot-pounds and if the outside work done by the engine in driving machinery, shafting, etc., is 186,720 foot-pounds per cycle, the thermo-brake efficiency will be

$$\frac{186,729 \div 778}{1000} = 0.24$$

or 24 per cent. and the mechanical efficiency will be

$$\frac{186,720}{233,400} = 0.8,$$

or 80 per cent.

These efficiencies are clearly related to each other, and if one is increased or decreased it will affect one or more of the others. Increasing the cyclic efficiency will increase the thermodynamic efficiency within certain limits, which are different for different engines and different operating conditions. Increasing the thermodynamic efficiency will increase the brake efficiency provided it does not decrease the mechanical efficiency too much by enhancing the friction of the working parts. Increasing the mechanical efficiency will increase the brake efficiency provided the thermodynamic efficiency is not decreased correspondingly, and so on. Now it is the theoretical cyclic efficiency which is directly affected by the compression pressure, and increasing the compression would increase this efficiency indefinitely, as shown by the following analysis:

In the theoretical cycle, in which it is assumed that no heat is lost through the cylinder walls and piston, and that combustion is instantaneous and complete, the temperature rise due to combustion is equal to the heat units in one pound of the cylinder contents divided by the specific heat of the cylinder contents. Now, assume that the cylinder contents weigh one pound, that the admission temperature is T_a degrees, that the compression temperature is T_c degrees, that the explosion temperature is T_x degrees and that the temperature of the exhaust gases is T_e degrees, absolute. The rise of temperature due to combustion will be equal to the heat in the gas (H) divided by the specific heat (C_v) of the cylinder contents at constant volume, thus:

$$T_x - T_c = \frac{H}{C_v}.$$

Consequently, the total heat required to produce a given temperature rise $(T_x - T_c)$ will be equal to

$$H = C_v(T_x - T_c).$$

The heat in the exhaust gases is equal to the quantity that would have been required to raise their temperature from that of admission, T_a, to that at which they escape, T_e; this is equal to

$$h = C_v(T_e - T_a).$$

The theoretical cyclic efficiency is equal to

$$\frac{H-h}{H} \text{ or } 1 - \frac{h}{H},$$

and substituting the foregoing equivalents for H and h gives

$$1 - \frac{C_v(T_e - T_a)}{C_v(T_x - T_c)}$$

as the cyclic efficiency expressed in temperatures. The specific heat symbols cancel out, leaving

$$1 - \frac{T_e - T_a}{T_x - T_c} = \textit{cyclic efficiency}.$$

Since both compression and expansion are assumed to be adiabatic in the theoretical cycle, the ratio of explosion temperature to exhaust temperature is the same as the ratio of compression temperature to admission temperature, thus:

$$\frac{T_x}{T_e} = \frac{T_c}{T_a}.$$

Consequently,

$$\frac{T_e - T_a}{T_x - T_c} = \frac{T_a}{T_c},$$

and the formula for theoretical cyclic efficiency may be reduced to

$$1 - \frac{T_a}{T_c} = \textit{cyclic efficiency}.$$

The higher the compression pressure, the higher will be the compression temperature and the smaller will be the fraction

$$\frac{T_a}{T_c};$$

consequently, the higher will be the cyclic efficiency. Take, for example, two engines taking in equal quantities of gas per cycle and at the same temperature, say 700 degrees absolute. Suppose one compresses the cylinder contents from 14 pounds to 61 pounds absolute pressure per square inch; the temperature of compression will be 983 degrees absolute. Now suppose the temperature rise due to combustion were 1966 degrees; then the explosion temperature would be 1966 + 983 = 2949 degrees absolute. The *theoretical* exhaust temperature would bear the same relation to the explosion temperature that the compression temperature bears to the admission temperature; consequently the theoretical exhaust temperature would be

$$\frac{2949}{983} \times 700 = 2100$$

degrees absolute. The theoretical cyclic efficiency would be

$$1 - \frac{2100 - 700}{2949 - 983} = 0.1879,$$

or 18.79 per cent. The shorter formula gives the same result, thus:

$$1 - \frac{700}{983} = 0.1879.$$

Now suppose the other engine compressed the cylinder contents to 182 pounds absolute pressure per square inch. The compression temperature would be 1457 degrees absolute, and the theoretical cyclic efficiency would be

$$1 - \frac{700}{1457} = 0.48,$$

or 48 per cent, as compared with 18.79 per cent for the first engine.

Effect on Operating Efficiencies

It does not follow that increasing the compression will always increase the thermodynamic and thermo-brake efficiencies, however. It will do so up to a certain point, but beyond that point any further increase in compression will produce a decrease in operating fuel economy. The point at which this change occurs differs in different engines, and it is not usually the same for both indicated and brake efficiencies. During compression some heat is lost through the cylinder walls and piston, and the higher the compression the greater will be the heat loss. Moreover, higher compression means higher explosion temperature and that increases the heat loss through the walls during combustion and expansion. The loss of heat due to these several causes increases more rapidly than the thermodynamic or indicated efficiency increases; consequently, there is a point at which increasing the compression any further will cause more heat loss than the increase in cyclic efficiency will offset, and the net result will be a decrease in thermodynamic efficiency. Assume, for example, that an engine using natural gas and compressing to 130 pounds absolute shows a thermodynamic efficiency of 30 per cent. The heat taken in per indicated horsepower-hour will be 8483 B.t.u. Now suppose that increasing the compression to 140 pounds would increase the efficiency to 32 per cent if there were no additional heat losses, but that in fact the heat losses were increased 700 B.t.u. The net result would be that the engine would take in [illegible] B.t.u. per indicated horsepower-hour and the thermodynamic efficiency would be reduced from 30 to [illegible] per cent instead of being increased to 32 per cent.

Increasing the compression increases the pressures on the crankpin and main-shaft bearings and thereby increases the friction and decreases the mechanical efficiency, which tends to offset any increase in indicated efficiency. There are consequently two critical compression pressures, one beyond which the indicated or thermodynamic efficiency begins to decrease by reason of the preponderance of the increase in heat losses and one beyond which the brake efficiency begins to fall off by reason of greater loss due to added friction than gain in indicated efficiency. Usually the latter is lower than the former, though it is possible for the two to coincide.

Influence of Burnt Gases

There is another factor which undoubtedly affects the relation between compression and operating efficiency, although it does not come into the question of theoretical cyclic efficiency. That is the influence of the spent gases in the "clearance" upon the combustion of the fresh charge. It is quite customary to assume that after the expulsion stroke is completed the combustion space or "clearance" remains filled with burnt gases and that the succeeding suction stroke draws in a volume of fresh mixture equal, at the most, to the piston displacement. Except where special means are provided for scavenging, there is no reason to question the accuracy of this assumption. At any rate, it is doubtless true that these conditions are obtained in a large majority of four-stroke gas engines. In such cases, therefore, it is also true that increased compression tends to increased economy by reason of the smaller proportion of dead gases in the cylinder contents at the time of combustion. For example, if the compression ratio of an engine were three, that is, if the cylinder contents were compressed to one-third the volume which they occupied before compression began, the volume of the combustion space would be one-half as great as the volume swept out by the piston, consequently one-third of the cylinder contents would be dead gases and two-thirds fresh mixture. With a compression ratio of six, only one-sixth of the cylinder contents would be dead gases. Consequently, the rise of temperature in the latter case would be one and a quarter times the rise of temperature in the former case, and the area of the theoretical indicator diagram would, therefore, be considerably larger, although the quantity of fuel used would be the same in both cases. Assume, for instance, that the piston displacement in each case is such as to take in a cubic foot of fresh mixture, containing 100 B.t.u.; then the weight is 0.08 pound and the specific heat at constant volume is 0.25. With the compression ratio of three, the total weight of the cylinder contents, including the gases in the combustion space, would be 0.12 pound. The theoretical rise of temperature due to combustion, therefore, would be

$$\frac{100}{0.12 \times 0.25} = 3333$$

degrees Fahrenheit.

With the compression ratio of six, the total weight in the cylinder would be 0.096 pound, and the heat units the same as before. The theoretical rise of temperature, therefore, would be

$$\frac{100}{0.096 \times 0.25} = 4167$$

degrees. Assuming equal combustion efficiency for the two cases, and putting it at 30 per cent, the actual rise of temperature would be [illegible] degrees with low compression and [illegible] with high compression.

With the lower compression ratio the compression temperature would be about [illegible] degrees absolute and the pressure about [illegible] pounds. With the higher ratio, the compression temperature would be about [illegible] degrees and the pressure about [illegible] pounds. Since the relation between compression and explosion pressures is the same as that between compression and explosion temperatures, the following temperatures and pressures would be obtained:

Compression ratio	[illegible]	[illegible]
Compression pressure	[illegible]	[illegible]
Compression temperature	[illegible]	[illegible]
Explosion temperature	[illegible]	[illegible]
Explosion pressure	[illegible]	[illegible]
Release temperature	[illegible]	[illegible]
Release pressure	[illegible]	[illegible]
Mean effective pressure	[illegible]	[illegible]

The figures for temperatures and pressures are based on an initial temperature of 700 degrees absolute, initial pressure of [illegible] pounds absolute, and on [illegible] as the exponent of the compression and expansion curves. In practice, the engine with the higher compression would show better combustion efficiency because of the more intimate commingling of the molecules of gas and air and the lesser radiating surface of the combustion space, although the latter might be neutralized by the greater average temperature during combustion. However, the figures [illegible] clearly and roughly the general effect of high compression upon fuel economy. They also indicate the effect of temperature range during expansion, on which the theoretical cyclic efficiency is based; the figures would not agree exactly with those relating to cyclic efficiency because in this case the influence of the spent gases upon the explosion temperature and pressure is taken into consideration.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 *we printed and circulated* 1,836,000 *copies of* POWER.

Our circulation for December, 1908, *was (weekly and monthly)* 191,500.

January 5............. 46,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

Unreasonable Specifications

It is all right, of course, for the purchaser of machinery to make rigid specifications covering the performance and durability of that machinery. It by no means follows, however, that it is fair for the buyer to specify details of design which affect the performance and durability of the machine unless he is willing to shoulder the entire responsibility. If we expected to buy a gas engine, steam engine or any other power-plant equipment, we should be quite content to dictate the maximum continuous ability under stated conditions, the economy at stated loads, the limits of speed variation and the degree of builder's responsibility for breakages or failures within a reasonable period of time. We certainly should not expect or desire to dictate the method of regulation to be employed on a gas engine, for example, the material of which the cylinders should be made, or any other such vital features, and then expect any reputable builder to assume the responsibility for the results. And if we were building gas engines we should try to content ourselves with what orders we could get from people who are willing to accept satisfactory results without trying to dictate the methods of obtaining them.

Necessity for Good Work on Suction Piping

In a condensing system the large volume of cooling water used necessitates the use of large and, frequently, long suction pipes, which are almost always placed underground. Owing to the fact that flanged cast-iron pipe, or wrought-iron pipe with threaded or flanged ends, is in large sizes more expensive than cast-iron pipe with bell-and-spigot ends, and that the expense of laying is much less in the case of the bell-and-spigot pipe, this form is most frequently chosen.

To secure tight joints in this kind of pipe requires the conscientious exercise of rare skill. Lead joints, so-called, under pressure are easily inspected and leaks readily detected, but when under "suction" inspection is difficult and uncertain. Moisture to the slightest extent on the outside of a joint is evidence of leakage and may be attended to; but the leakage of air to the inside of the pipe is not so readily seen and may be quite large before it is suspected. When suspicion is confirmed it is still difficult, in some cases nearly impossible, to locate the leak. This is particularly the case when leaks are numerous and small. Where surface condensers are used, air-adulterated circulating water causes no serious trouble or impairment of condenser efficiency. It means only a slightly higher rate of speed for the circulating pump. But with the jet and barometric systems air leakage into the injection water means a reduction in vacuum that cannot be met by accelerated pump action or wider opening of the injection valve, for a vacuum can be vitiated by a surplus of water as well as by air.

All natural water carries in solution more or less air; an amount at times equal to five per cent. of its volume. This dissolved air is at once released under the influence of the vacuum in the condenser, and when to this is added the volume of free air which comes along with the cooling water where a leaky suction obtains, the difference between the vacuum due to the temperature and the actual vacuum is marked. It frequently happens that in a jet or a barometric condenser, where a vacuum of 26½ inches is expected, only 23 or 24 inches are realized, and as an increase of cooling water does not help matters, the condenser is charged with being inefficient or too small for the work; while, as a matter of fact, the real cause of failure is the excessive amount of air which leaks into the system through poorly made joints.

Where dry-vacuum pumps are installed with barometric condensers, a high vacuum is maintained by the extra work done by the air pump, and the real effect of the surplus air entering through the joints is felt only in the extra work put on the air pump, which falls short of its calculated efficiency.

Too much care cannot be exercised in the making of joints in the pipe supplying jet or barometric condensers with water, and no grade of skill in pipe laying, particularly in the making of the joints, whether screwed, flanged or bell-and-spigot, is too high to be employed.

Effect of Superheated Steam on Valves and Fittings

Steam-piping systems, which may be termed the arteries of the power plant, in the last twenty years have received practically as much attention as any part of the power-generating installation. The adoption of the standard thread and the manufacturers' standard for flanges, the almost universal acceptance of a fixed set of dimensions for fittings and valves for 100-pound pressures, and the use of standard pipe up to the 12-inch size, with bent pipe for flexibility, have made low-pressure piping an easy problem susceptible of a very satisfactory solution. With the "Van Stone," or rolled lap, and welded flanges, the 200-pound standard valves and fittings and the corrugated gaskets, both copper and steel, the high-pressure piping problem is practically solved.

Now a new Richmond has entered the field and with the increasing use of superheated steam the problem has had to be taken up anew, this time not with the idea of heavier, stronger and better work, but with the necessity of finding a material better suited to the changed conditions of pressure and temperature.

The standard valve and fitting material, cast iron, has suffered in many cases a marked and continuous deterioration under the action of superheated steam. We have already illustrated this action in the columns of POWER and the reports of failures of valves and fittings are still coming in. Numerous explanations of this action have been offered, but are not satisfying.

To obviate this trouble manufacturers are offering valves and fittings of various qualities of cast steel which, up to the present writing, have presented no serious failures. These steel fittings have been in service approximately three years, and while it cannot be maintained that the problem is solved, at least a very satisfactory result has been obtained. At the outset the cost of this material was very high, but the increasing demand has led more manufacturers to embark in the steel-casting business and it will be only a short time before steel valves and fittings may be obtained at reasonable advance above the price of the cheaper material.

It must be added, however, that a number of manufacturers are endeavoring to discover the cause of the deterioration of cast iron by superheated steam, so far without success.

Through Bracing

A large class of engineers, who have made a study of steam boiler construction, and particularly those who have been brought up under marine-boiler influence, are predisposed to advocate the through form of bracing wherever this type can be put in. It appears that the chief advantage of this form lies in the fact that the strain produced by the pressure on the supported surface causes a direct tensile stress in the brace, while in the crowfoot form the angularity of the brace detracts from its effective holding power. It must be admitted that when considered as an abstract mechanical problem the above statement is correct, but it is doubtful if this is true under many conditions met in boiler practice. That this supposed increased value has considerable weight is evidenced in the new Massachusetts rules which allow twelve and five-tenths per cent. stress on the through form of brace above that allowed on the crowfoot form when both are of weldless-steel construction and over one and one-quarter inches in diameter, this increased allowance being reduced to six and six-tenths per cent. when the braces are one and one-quarter inches in diameter or less.

Notwithstanding the established prestige of the through form of bracing, it would appear that there are often reasons why the solid crowfoot form could be substituted for it to advantage. First, in the matter of effectiveness, through braces are often subjected to strains far in excess of those due to direct pressure loads. This is particularly true where braces are used in the steam space and where they are very long and of small diameter. In such cases the braces are often subject to serious vibration due to synchronism between the period of the brace and that of the varying pressure on the boiler heads and to the impingement of water thrown up by the liberation of steam. That the stresses caused by this vibration are severe is indicated by the fact that they are often found to be stretched after considerable use and sometimes broken near the point of connection to the heads.

When through braces are pinned to one head it is often found that the connections have been strained to such an extent that the brace is too loose to be effective. It is not practicable to space through braces closely enough together properly to distribute the load, and it is therefore necessary to stiffen the heads with angles, or channels, which add to the difficulty of making a tight connection at the brace ends. Through bracing interferes with the proper cleaning of the interior surfaces, which in most cases is a serious defect.

On account of the inadvisability of riveting the blade of a crowfoot brace to the interior of the shell immediately above the fire, in return-tubular boilers the through brace below the tubes is practically indispensable. It appears that if the assumed superior strength of the through brace is not a reality, and other considerations render the crowfoot form more advisable, it should not be discriminated against.

Clean Feed Water

Of all requirements for efficient operation in the boiler room, clean water is by no means the least. Much attention is given in the modern plant to the selection of coal adapted to the particular design of grate in use and to the specific conditions of draft existing. The coal question is, of course, important and is worthy of all the consideration it receives; still there are other factors equally important and demanding the same careful attention to detail. One of these factors is the removal of sand, leaves and other débris from the suction water of a plant. The importance of such a step is generally recognized, but is not always given careful attention. Inoperative valves, deterioration in packing and bushings, worn cylinders and boilers overloaded with sludge tell the tale and bring home to the engineer the results of such neglect in a way not to be forgotten.

Oftentimes but little provision is made of removing suspended matter from river or pond water, when water is to be used in the condenser, and even when used for boiler feed nothing is done in the way of purification until the water reaches the boiler room. It is always a good plan to strain the water at the suction inlet and, when the size of the plant will warrant the expenditure, a filter bed of sand and gravel is preferable. Screens are usually cheaper but, if properly installed, should prove more or less effective. They should be constructed and arranged so that they may be easily raised for cleaning. In raising a screen for this purpose a certain amount of debris will drop off and pass on to the next screen, so that it is better to have at least three screens in action, or even four would not be extravagant, but would allow the operator the privilege of cleaning or repairing a screen at his leisure.

Ordinarily screens are much too small for the service demanded of them. It does not take long to choke up the mesh and almost entirely shut off the supply of water. The finer the screen the sooner will this condition be reached, therefore the more need for a screen of large area. In a certain plant a screen of 1-inch mesh and 1/4-inch wire was used, and with a ratio of suction area to screen area of 1 to 13, or 1 to 7, when compared to the openings in the screen, fairly satisfactory results were obtained. Better results would have been secured with a larger screen, and at that the ratios given are considerably larger than found in common practice. After passing through the screens the water should flow to a well or basin of sufficient area to allow the small particles of dirt to settle, and in addition a screen of fine mesh over each suction pipe is advisable.

On first sight such precautions in protecting the suction inlet might appear unnecessary, but it is perfectly apparent that whatever purification is effected externally will not be necessary within the plant. Smaller expenditures for purifying apparatus in the boiler room, deterioration at a less rapid rate and the saving of considerable trouble and annoyance in the operation of the plant will result.

The management of a power station recently experienced considerable trouble from the breaking of boiler-tube cap bolts on the water-tube boilers. The bolts looked all right, but every time a boiler was cooled down and brought up to steam again a number of the bolts would break off short. The trouble became so serious that several bolts were sent to Arthur D. Little of Boston, an expert chemist, for analysis. He discovered that the bolts were made of overheated steel instead of the best quality of wrought iron, for which the company had paid and supposed it was obtaining.

The Lazier Vertical Gas Engine

The accompanying engravings illustrate the latest type of vertical gas engine built by the Lazier Gas Engine Company, of Buffalo, N. Y. The engine works on the four-stroke cycle and is of the single-acting two-cylinder type, as indicated in Fig. 1, which shows an engine built for belt driving. Both of the valves work in cages set into the cylinder head, as indicated in Fig. 2, which is a vertical section of one side of the engine with the valve-actuating mechanism omitted. The valves are operated by short rocker arms and the usual cam shaft; but the latter is located along the tops of the cylinders instead of lower down on the frame, which is the more common custom. This arrangement, which is illustrated on a larger scale in Fig. 3, eliminates long push rods with the attendant disadvantages of that construction. The cam shaft is driven through spiral gears by the vertical governor shaft, the location of which is shown in Fig. 1. From the ends of the cam shaft the igniters are actuated by means of eccentrics and short push rods.

The cam shaft carries in addition to the regular operating cams a set of compression-relief cams which, when shifted into the position for starting the engine, hold the exhaust valves open during a part of the suction stroke and thereby reduce the compression; after the engine has "picked up," the compression-relief cams are thrown out of action and the engine operates with normal compression. The handle for shifting the relief cams into and out of action is shown in Fig. 3 near the left-hand end of the trough in which the cam shaft is located.

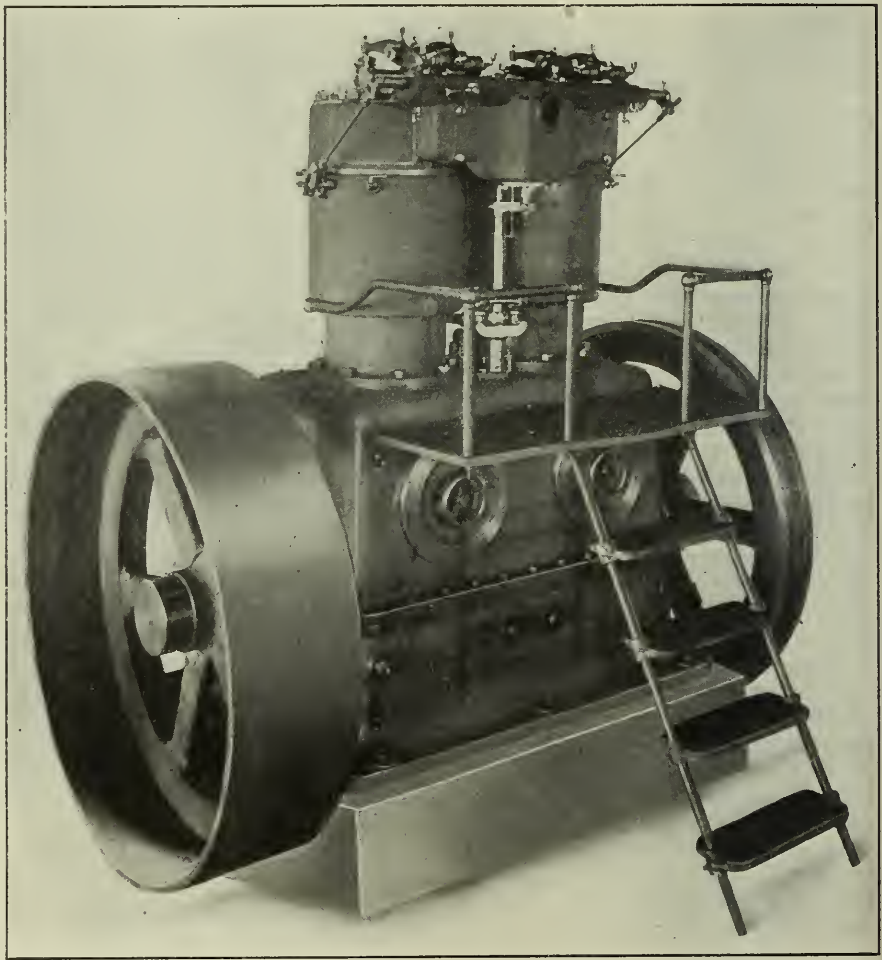

FIG. 1. LAZIER GAS ENGINE

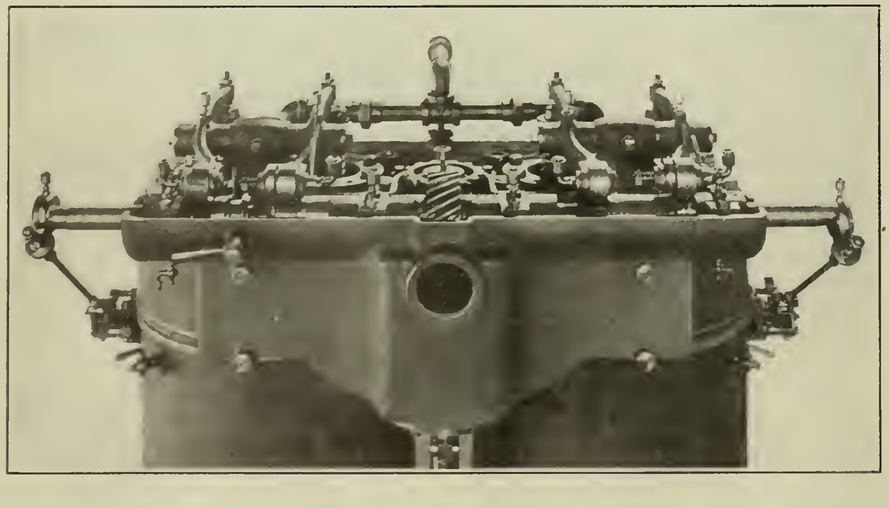

FIG. 3. LAZIER CAM SHAFT AND VALVE GEAR

The igniters are of the make-and-break variety; the construction of the operating mechanism is shown by Fig. 4. The tripping finger or trigger is pivoted near the end of the rocker arm and its upper end is provided with a 45-degree extension which engages with a tripping roller immediately above it and is thereby pressed over to the right until the lifting block is carried beyond the end of the actuating lever; then the spring snaps the lever and the movable electrode back to the idle position, separating the electrodes and making the spark between their contact points. The short finger with a right-angle lug at its end and located immediately below the actuating lever is mounted on the stem of the movable electrode; this finger and the actuating lever are acted on by a single spring which tends to draw their ends together. When the lever is lifted by the trigger, the spring forces the electrode finger up with it until the movable electrode comes in contact with the stationary one and its motion is stopped; when the lifting block is pulled out from under the actuating lever by the tripping roller, the spring snaps the actuating lever downward against the electrode finger, giving a quick-break effect at the electrode contacts.

through the ports into the intake manifold, being agitated by passing through the narrow openings and the mixture thereby improved. The circular grid valve is connected rigidly to the linkage controlled by the governor, and the stem of the disk valve is adjustable up and down in the hub or sleeve of the grid valve. By this means the relative positions of the two valves, and thereby the proportion of gas to air in the mixture, is variable to suit the fuel being used.

The use of the disk valve further provides automatic means for varying the quality of the mixture as the load varies.

shops. It may be pointed out, however, that the cranks, which are located in the same plane, are counterbalanced by weights attached to the backs of the cheeks, thus eliminating the tendency to lateral vibration which exists when counterbalancing weights are used in the flywheel. The vertical countershaft, on which the governor is mounted, is driven through spiral gears, as shown in Fig. 4. Lubrication of the internal parts is effected by the splash method. The rocker arms are lubricated by small grease cups and the cam shaft revolves in an oil trough, which lubricates the cams and gears, but the shaft bear-

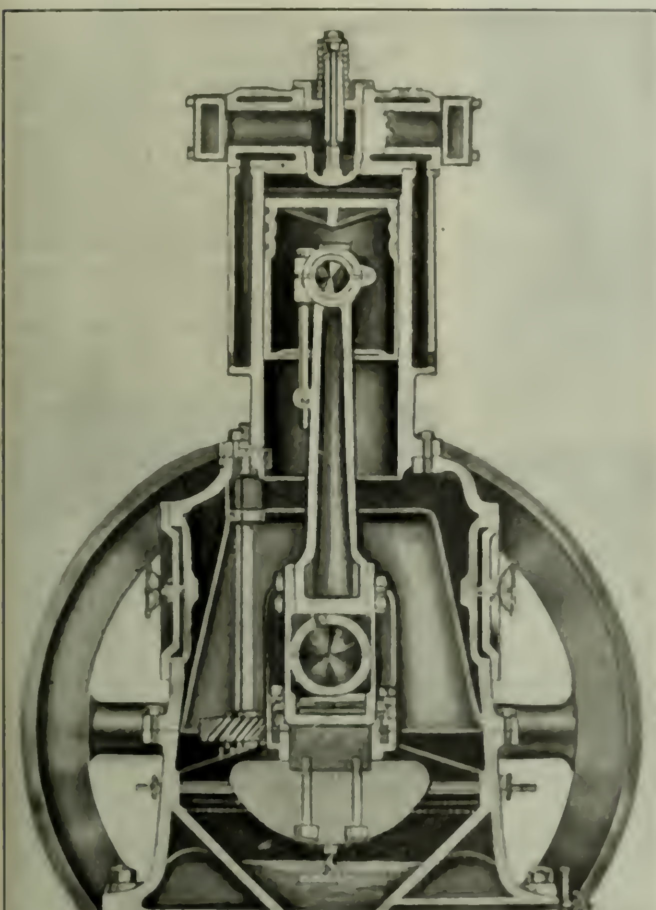

FIG. 2. SECTIONAL ELEVATION OF ONE CYLINDER AND CORRESPONDING PARTS

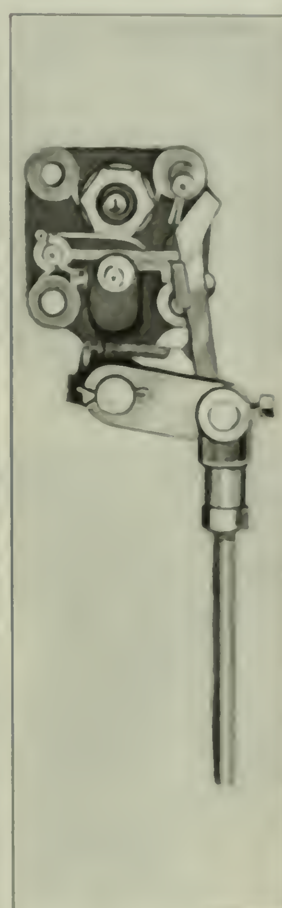

FIG. 3. [illegible]

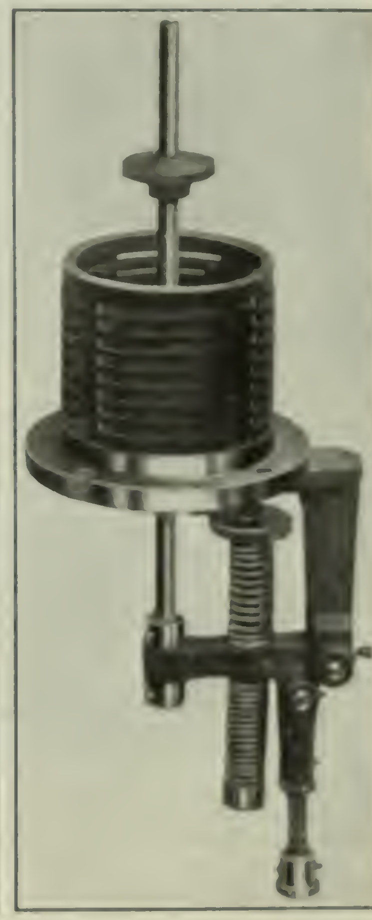

FIG. 5. [illegible] AND SPEED-REGULATING CAGE

The speed is regulated by means of a combination throttling and mixing valve controlled by the governor; this is shown in Fig. 5. The circular cage with ports through its wall is stationary and located in a chamber opening into the intake manifold. The air enters this cage freely at the top and gas enters it through a port controlled by the disk valve shown midway of the upper valve stem. Mounted on a sleeve on the valve stem is a circular grid valve inside the cage, and its position is varied vertically by the governor to cover more or less of the port openings in the wall of the cage. The air and gas are mixed inside the valve and pass

With full load the ports in the wall of the mixing-valve cage will be wide open and the gas port will be opened by the maximum amount proper for the fuel being used. When the load decreases the ports in the mixing-valve cage are partly closed by the governor and the disk valve also partially closes the gas port, thereby impoverishing the mixture slightly and keeping the compression higher than it would be if regulation were effected solely by throttling the mixture.

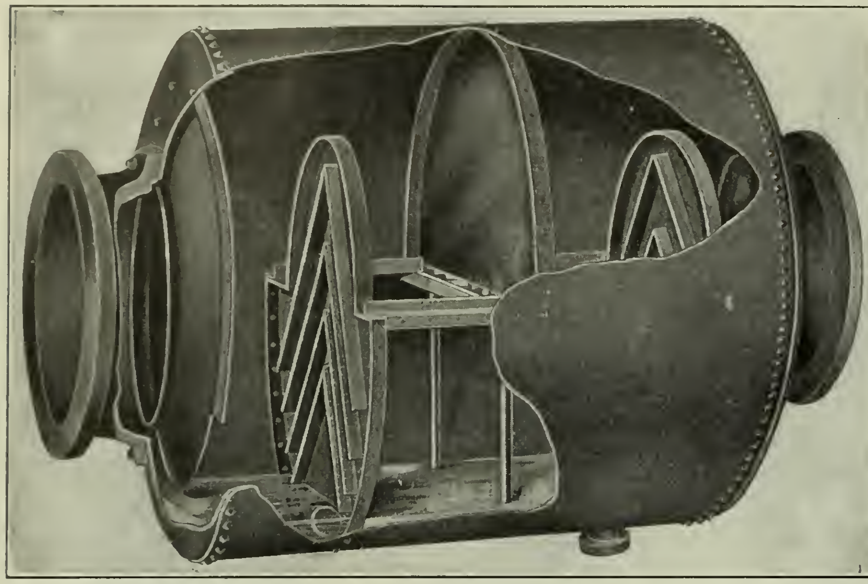
Fig. 2 shows the mechanical construction of the cylinders, pistons, connecting rods and crank case so clearly as to render unnecessary a detailed description of

ings are provided with individual cups as shown in Fig. 3. The crank shaft is a one-piece forging of open-hearth steel with pins somewhat larger in diameter than the main journals. The crank case is split horizontally in line with the center of the crank shaft, to facilitate the removal of the latter if it should ever become necessary. The flywheel is of the split-hub type, but not divided at the rim.

These engines are built in sizes ranging from [illegible] horsepower using natural gas, and from [illegible] horsepower using producer gas. [illegible]

Hoppes Horizontal Oil Eliminator

The Hoppes eliminator is especially designed for use in exhaust pipes of large size, for either vacuum or high-pressure service. The shell of the machine is made of flange steel, the heads and interior construction being of the same material, but the flanges for the pipe connections are of cast iron. The exhaust enters at the left-hand side and passes out at the right. As the oil and water for the most part follow the surface of the pipe, the inlet nozzle is made taper, and an intercepting plate, as shown in the illustration, is used to deflect the entrainment from a straight course into the eliminator, and direct it to the bottom of the shell.



HOPPES HORIZONTAL OIL ELIMINATOR

After the steam enters the shell, it strikes a baffle plate, the face of which is provided with a number of angle-iron strips which catch and hold the oil or water and carry it to the bottom of the shell. The exhaust steam, after passing over this baffle plate, is turned downward by another plate across the upper half of the shell, this plate being provided with an intercepting trough at its lower edge, which is kept partly filled with water, the excess water and oil being carried to the bottom by the drain pipes shown.

After passing the second baffle plate, the steam is prevented from flowing directly out of the outlet by another plate similar to the first one, and the oil and water are prevented from following the surface and escaping through the outlet by a short inwardly projecting nozzle. A small amount of water is always held in the bottom of the shell, as it has been found that this aids in catching and retaining the oil. The intercepting troughs partly filled with water stop the oil from creeping by.

This eliminator is manufactured by the Hoppes Manufacturing Company, Springfield, O.

Westinghouse Special Circuit Breaker

The accompanying engraving illustrates a special application of the standard Type CC circuit-breaker of the Westinghouse Electric and Manufacturing Company. This arrangement was devised in order to meet the requirement for a double-pole circuit-breaker which could be opened either by hand or by a magnet controlled from a distance, and which would also open automatically in the event of an increase in current beyond the maximum allowed in the circuit; the construction had to be also such that when the circuit-breaker was opened from a distance, it could be held open from that point regardless of efforts to close it by means of the resetting handle. The circuit-breaker was to protect a large motor, and the remote-control switch to open it and hold it open was located at the machine driven by the motor, under the control of the machine operator.

The circuit-breaker consists of two single-pole mechanisms, each having an automatic overload tripping coil, a handle located between the two mechanisms and arranged to close and open the two circuit-breakers, and a solenoid (shown beneath the handle) for opening the circuit-breakers in response to the closing of the switch at the machine. The mechanism in the middle is exactly the same as each of the tripping mechanisms of the circuit-breakers, and when it is tripped, by either the solenoid or the handle, it trips both of the circuit mechanisms; similarly, when

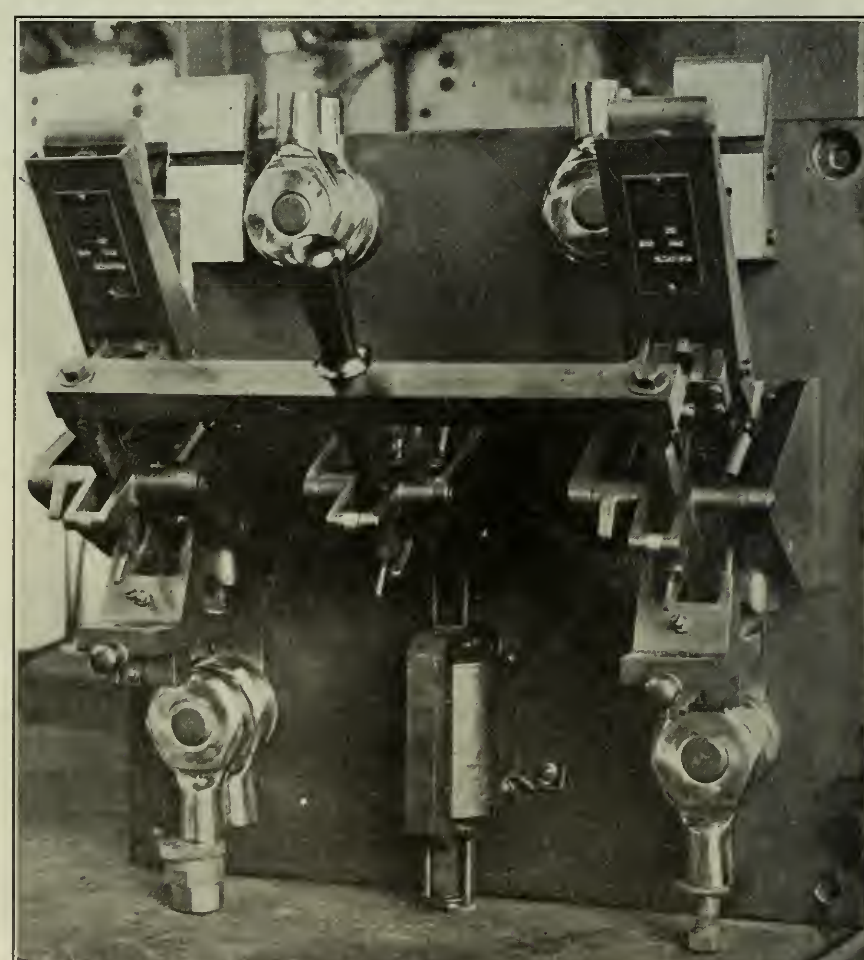


FIG. 1. SPECIAL APPLICATION OF THE WESTINGHOUSE TYPE CC CIRCUIT-BREAKER

either of the two circuit-breaker coils trips its own mechanism, that trips the other circuit latch and the middle latch. When the mechanisms are tripped by the

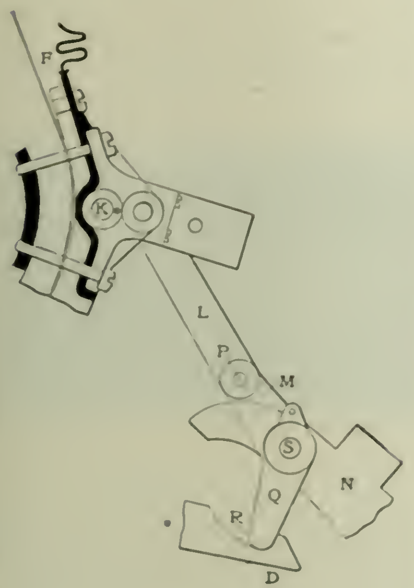

FIG. 2

FIG. 3

remote-control solenoid, the handle is caught by a latch which holds it in the open position as long as the solenoid remains excited. When the remote-control switch is open, the latch releases the handle, which may then be operated in the usual way.

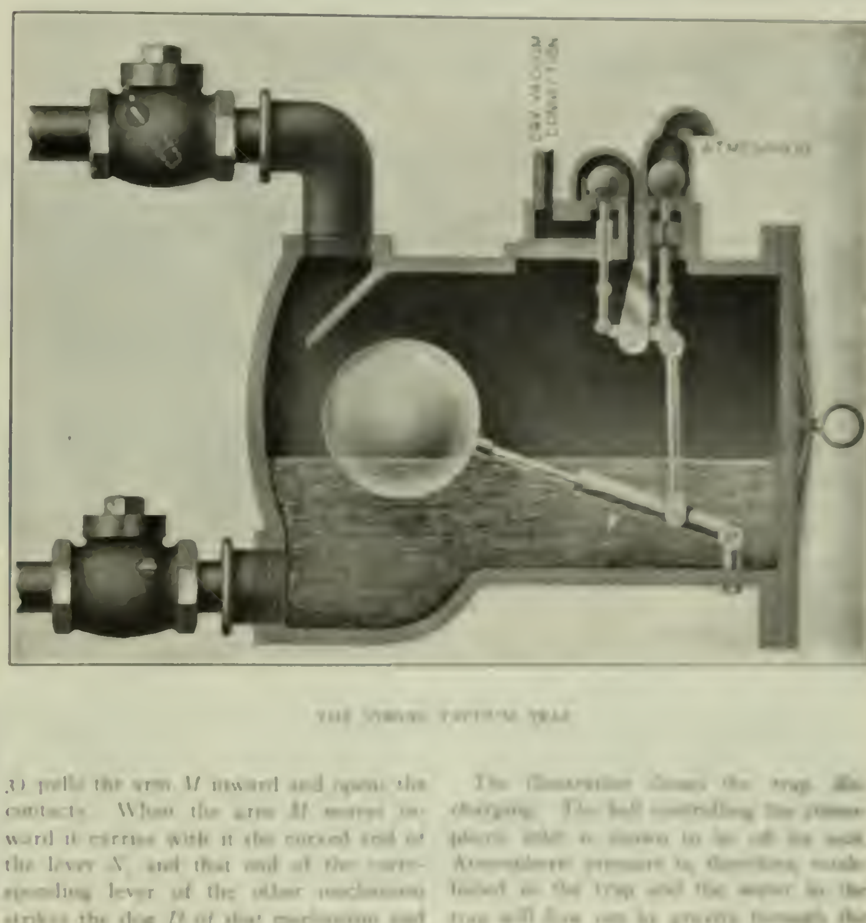
The arrangement of one of the circuit-breaker mechanisms is shown by Figs. 2 and 3. The lever N is one of the three which are bolted to the handle bar. It is mounted freely on the spindle S, on which the twin bell-crank M Q is also swiveled. The end M of the crank is attached by a pin P to the end of the link L which opens and closes the contacts. The end Q of the bell-crank carries a roller R which engages with a latch or dog D, the end of which is drawn upward by a spring and may be thrown downward by the trip (not shown). Figs. 2 and 3 show the mechanism in its closed position. If the overload coil, through its trip, throws the dog D down, releasing the bell-crank arm Q, a pair of heavy springs (see Fig. 3) pulls the arm M inward and opens the contacts. When the arm M moves inward it carries with it the curved end of the lever N, and that end of the corresponding lever of the other mechanism strikes the dog D of that mechanism and throws the contacts open. Raising the handle as shown in Fig. 1 moves both of the levers N and trips both dogs D simultaneously; the solenoid, when energized, raises the handle, with exactly the same result, of course.

When the circuit-breakers are open the curved end of the lever N on each one is down (the handle being up). When the handle is thrown down, the curved end presses the fulcrum R of each breaker forward, pushing up each link L and closing the contacts.

The Strong Vacuum Trap

The Strong vacuum trap consists of a large circular body, 18 inches outside diameter and about 30 inches long, with an inlet and outlet of any size desired from 1½ inches down. A ball float operates a lever which, in turn, operates two ground brass balls, one controlling the atmospheric pressure and the other controlling the vacuum pressure.

The valve seats are screwed into the valve chamber and are made of Government bronze. The valves are readily accessible as shown by the accompanying sectional illustration of the trap. It is not likely that dirt will get between the ball and the ball seat, as they are several inches above the water line and almost the length of the trap away from the inlet.



THE STRONG VACUUM TRAP

The illustration shows the trap discharging. The ball controlling the atmospheric inlet is shown to be off its seat. Atmospheric pressure is, therefore, established in the trap and the water in the trap will flow out by gravity through the swing check valve.

The valve rod operating the vacuum ball is shown to be in contact with the ball. The atmospheric conditions in the trap is transmitted through the inlet port into the cap covering the vacuum ball. The vacuum ball is, therefore, held on its seat by a pressure equal to the difference in pressure between the atmospheric and absolute vacuum it being created, multiplied by the area of the ball seat; this pressure with a 26-inch vacuum is [illegible] pounds.

As the water flows out of the trap, the tendency of the ball float is to drop with the water line. It cannot do so, however, because the vacuum rod is in contact with the vacuum ball and cannot lift it, as it is held on its seat by the pressure mentioned. The water continues to flow out of the trap, dropping away from the ball float until the weight of the ball float and its leverage are sufficient to lift the vacuum ball. When this occurs the ball float drops to the new water line. The vacuum ball is lifted off its seat about ½ inch and the rod operating the atmospheric ball drops the same distance, permitting the atmospheric ball to seat.

The trap is thus closed to the atmosphere and open to the vacuum through the dry-vacuum pipe. In three or four seconds the same vacuum will be established in the trap as is maintained in the vacuum system being drained. Water will then drop by gravity from the system into the trap.

The ball float will rise with the water line until the vacuum ball is about ⅛ of an inch off its seat, and the rod operating the atmospheric ball comes in contact with that ball. The same conditions now exist with the atmospheric ball as existed with the vacuum ball. The atmosphere on one side of the ball and the vacuum on the under side present a total pressure of 20 pounds holding this ball on the seat.

The ball float cannot lift the atmospheric valve under these conditions. The vacuum valve thus remains open and the water continues to flow into the trap, flooding the ball float, which cannot rise with the rising water line. When the ball float is flooded to such extent that its increased buoyancy and its leverage are greater than the pressure holding the ball valve on the seat, it will then raise the ball. The atmospheric ball is thus raised about ½ inch from its seat and permits the vacuum ball to drop to its seat.

The instant the ball is lifted from its seat the pressure of 20 pounds disappears, as the ball is then in equilibrium, the only pressure left being the weight of the ball, about ¾ of a pound. A variation of 6 inches in the water line is thus obtained, giving a capacity of 8 gallons per discharge. Three discharges per minute are possible, giving a capacity of 24 gallons per minute. This trap is manufactured by the Strong, Carlisle & Hammond Company, 336 to 344 Frankfort avenue, S. W., Cleveland, Ohio.

"Roto" Tube Cleaner

Following is a description of a new air- or steam-driven tube cleaner, the general construction of which is shown in Fig. 1, in position in a straight 4-inch water tube containing a heavy deposit of hard scale. The power is developed in a 2-inch cylinder 1½ inches long, containing a slotted piston and a single sliding blade. The cylinder bore is formed in the shape of a heart, the edges of the sliding blade exactly fitting it in every position during the revolution of the eccentric piston.

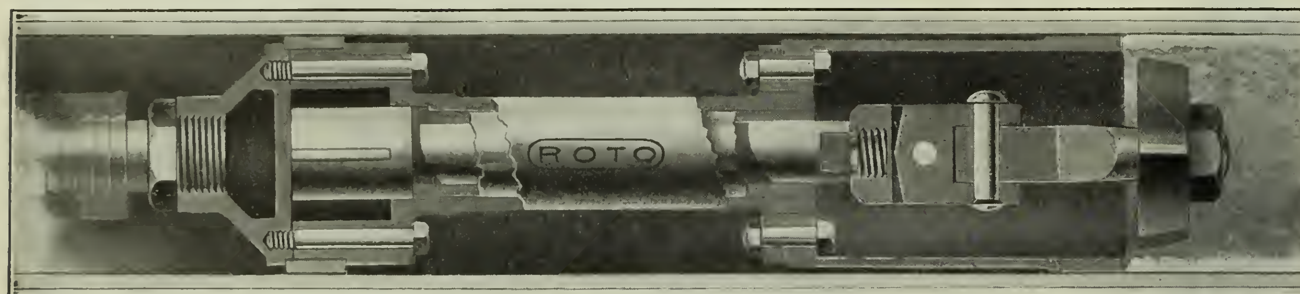


FIG. 1. SHOWING GENERAL CONSTRUCTION OF "ROTO" TUBE CLEANER

The piston shoulder is floated on a thin film of filtered oil, saturated with air or steam. Oil put in at the ball valve soaks into lampwicking in the oil receiver, and a very small jet of compressed air or steam admitted on top of the lampwick passes through it and conducts the oil under the piston shoulder, which it lifts a very little against the thrust of the air pressure and the weight of the tools and escapes in a thin film, thus forming practically a frictionless thrust bearing or step.

The single blade balances itself and admits of large eccentricity and piston displacement, being designed to allow the motor to run perfectly cool at very high speed. The motor is self-starting in all positions and has no spring or air pressure to force the blade against the cylinder walls.

This cleaner uses a hardened-steel sizing shield, carried by the motor and extending to a point close behind the cleaning tool which is thereby held in position to strike and remove the scale, and automatically to move on through the tube. With the sizing shield close behind the tool there is little likelihood that the operator will leave the cleaner in one position long enough possibly to damage the tube. It is not necessary to reduce its external diameter to pass through some one bad tube in the boiler, and so sacrifice thoroughness in cleaning the other tubes, as extra sizing shields are supplied, and these are quickly exchanged to fit the tubes being cleaned.

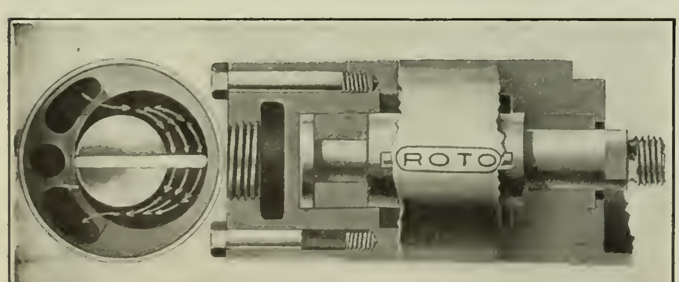

FIG. 2. DOUBLE-BEARING CLEANER

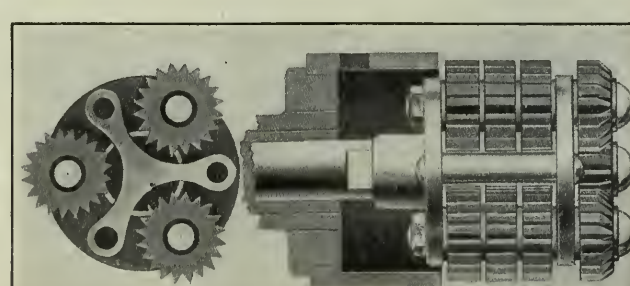

FIG. 3. MULTIPLE-EFFECT POLISHING HEAD

Where scale is very heavy, it may be first roughed out with a small sizing shield following a suitable tool, then with a larger shield. The tubes may be finished and polished by the same cleaner equipped with a larger shield and a finishing or polishing head suitable to the purpose. In short, the new cleaner with assorted shields is equivalent to several cleaners of different sizes. The cleaning should be done with the largest shield that will pass through the tubes when cleaned, so as to remove all the scale without cutting, grinding or bruising the already cleaned tube surfaces.

The cutters are formed of tempered high-speed tool steel. Where very heavy scale is encountered, a sharp pointed drill nut is substituted for the hexagon nut shown in Fig. 1. Several types of head, suitable for all purposes and including drill heads, cone-cutter heads and arm heads, are furnished.

Fig. 2 shows a view of a double-bearing cleaner made in small size for locomotive tubes, etc., the cross-sectional view showing the general construction of the air-driven motor. Fig. 3 shows two views of the "Roto" multiple-effect polishing head.

This apparatus is manufactured by the Roto Company, 62 Market street, Hartford, Conn.

The "Erieco" Engine Valve

The valve herewith described is especially adapted to single-cylinder high-speed engines of the automatic cutoff type, and has been used for the past three years in the "Erieco" engine, built by the Erie Manufacturing and Supply Company, Erie, Penn.

It is a balanced valve of the flat slide type, riding in a pressure plate. It is claimed that it takes up its own wear, and remains steam tight at all ranges of steam pressure. It is made in two pieces, having interlocking projections its entire width. The interlocking projections, having surfaces in opposite directions, are said to be held in steam-tight contact, owing to the difference in the exposed areas of the end of each half of the valve. By referring to Figs. 2 and 3 it will be seen that there are three projections at each end of both parts of the valve, forming five sides. Three of the sides at each end are surfaced to a steam-tight contact; to accomplish this the other two surfaces must spread.

As the valve wears it is held in contact with the pressure plate and seat, owing to the steam being admitted between the two halves of the valve. Steam is admitted between the halves of the valve through its ports, the location of which is such that the proper pressure is said to be maintained at all positions of the valve. The same principle of different areas is applied to the top and bottom of the valve.

It is claimed that the valve is kept steam-tight by the pressure under which it is operating, whether boiler pressure, compression, decreasing pressure due to expansion, atmospheric, or back pressure, and that this valve does away with the expense of frequent scraping by the engineer to keep it tight, and the trouble of shutdowns occasioned by that work. This valve is used on all "Erieco" engines.

The Orvis Furnace

In the accompanying illustrations is shown the Orvis furnace, which was designed by [illegible] Orvis, of the Orvis Economy Furnace Company, 27 Park row, New York City. The furnace consists of two principal features, an arrangement of air piping and one steam jet to produce an induced draft, and an independent arrangement of piping to circulate the water in the boiler. The latter arrangement is said to stop the formation of scale, and after the system has been installed for a short time cause the old scale to drop off. The illustrations show the furnace adapted to an ordinary tubular boiler.

Differing from usual practice, the blowing device has been placed near the bridgewall instead of at the front of the furnace, or underneath the grate, and the air blast in passing through the contracted space or throat between the top of the bridgewall and the shell, induces a draft and brings the mixture of air and steam in contact with all the gases from the fire. The draft arrangement consists of the pipes *A* and *B*, the former being an air pipe as far down as the elbow, and the latter a small steam pipe, ending in a small jet introduced at the elbow of the air pipe. A small jet of steam issuing from the steam pipe causes a vacuum in the larger pipe, and in drawing the air from the boiler room through the hood *C*, fills the horizontal length of pipe with a mixture of air and steam. This mixture escapes with considerable velocity through a number of blasts in thin sheets toward the rear of the boiler, and in passing through the contracted area indicated in the drawing, increases the draft and consequently the evaporation and horsepower of the boiler.

With the device designed by Mr. Orvis embodying the vacuum principle the amount of steam required is very small, and some idea of the quantity will be obtained when it is stated that a 1-inch pipe will supply sufficient steam to operate thirty-two 100-horsepower boilers.

From a test recently made by Albert A. Cary, at a prominent plant in Newark, N. J., equipped with the Orvis system, it was reported that the blower could increase the steaming capacity of the boiler about 25 per cent., so that a considerable gain would be effected in the horsepower developed and the amount of steam produced per hour, which in a plant with a number of boilers would mean that the capacity could be increased sufficiently to avoid the installation of a new boiler.

Another claim for the device is that it will prevent smoke. From the construction shown in the illustration, it is apparent that the gases formed from combustion must pass rapidly in a thin sheet under the straight arch or baffle wall over a bed of incandescent fuel, which consumes the larger part of the smoke. The gases must then pass upwardly through a narrow passage and above the bridgewall, where they come in contact with a mixture of superheated steam and heated air in the proper proportions, causing the remaining particles of carbon to ignite and burn and in this way prevent any smoke from reaching the stack. The device then has apparently four advantages: To increase the draft, evaporate more water, remove scale and consume the smoke. It should, therefore, be of use in an overloaded boiler room, or where enough draft is not available.

The other feature of special prominence was the circulating tubes shown at *D* in the illustrations. Water is taken from the rear of the boiler, as shown, and caused to flow across the furnace in 4-inch charcoal-iron tubes, which are expanded into suitable headers bricked into the side walls, and from here it is returned into the front end of the boiler. The two connections to the boiler are on the same level, are below the water line and still far enough from the bottom to avoid the sludge and whatever impurities may have settled to this location. To produce the circulation, the tubes across the furnace are tilted slightly, so that the heated water will have a tendency to flow in one direction, and that toward the front of the boiler. By this means a rapid circulation is set up in the boiler and scale formation is prevented.

Inquiries

Questions are not answered unless they are of general interest and are accompanied by the name and address of the inquirer.

What Is Meant by Centennial Rating

Will you please explain what is meant by a boiler horsepower centennial rating?

C. D.

The centennial rule, so called, declared a boiler horsepower to be the evaporation of 30 pounds of water at 100 degrees temperature into steam at 70 pounds pressure in one hour. It is a measure of the rate of work and is equivalent to the evaporation of $34\frac{1}{2}$ pounds of water from a temperature of 212 degrees into steam at atmospheric pressure.

Comparative Heating Value of Wood

What is the heating value of wood as compared with good soft coal?

D. B.

Two and one-quarter pounds of dry wood contains about the same number of heat units as a pound of average bituminous coal. It is necessary that the wood be thoroughly dry. It seems to make little difference what kind of wood is used, as, pound for pound, poplar is as good as hickory or oak. Some experiments have shown the heat value of perfectly dry wood to be 0.4 that of carbon.

Concrete for Engine Foundation

I wish to build an engine foundation of concrete. What proportions of cement, sand and broken stone shall I use?

C. D. M.

One part, by measure, of good hydraulic cement to three parts of coarse, sharp sand and six parts of clean, broken stone that will pass through a screen of $1\frac{1}{2}$-inch mesh. Spread a batch of stone about 6 inches thick on a floor of plank and wet thoroughly. Mix a stiff mortar with the sand and cement and spread it evenly over the stone. Then, with shovels, turn until thoroughly mixed, wheel or carry it to the form and tamp, particularly around the outside next to the form, to prevent the formation of holes. If it is necessary to let the work stand unfinished over night, the top should be left as rough as possible and well wet before putting on fresh material.

Vacuum in Condensers

In my plant I have a jet condenser which until recently would show only 24 inches vacuum. Another engine was bought with a surface condenser, and the suction pipe which supplied the jet condenser was extended to furnish water for the other. When both condensers are running I get 27 inches vacuum in the jet condenser, but when it is running alone I get only 24 inches. Can you explain this?

F. C. A.

The suction pipe leading to the condensers leaks. When the jet condenser is running alone all the air which is drawn in through the leaks goes to the condensing chamber and expanding there reduces the vacuum. When the surface condenser is running the air is carried past the outlet to the first condenser which gets "solid" water, and a vacuum, due to the temperature of the condenser, is obtained. In order to get good results with a jet condenser it is necessary that the suction pipe be absolutely air-tight. Any air entering the condenser with the injection water produces the same results that come from air leaking through stuffing boxes or exhaust pipe joints. It expands in the condenser and reduces the vacuum.

Flywheel Energy

Is the energy stored in a flywheel during one portion of the revolution given back again without any loss during the rest of the revolution, assuming constant speed and eliminating friction?

G. F. D.

The energy given to the flywheel in the earlier portion of the stroke is delivered to the shaft during the later portion of the stroke when the mean pressure is lower, and this without any other loss than that of friction. You cannot assume the constant speed because the ability of the flywheel to receive and to give back energy lies in an allowable speed variation. The wheel is speeded up under the high initial pressure and slows down as it gives up the energy thus required later in the stroke. The energy necessary to get up a given velocity is

$$E = \frac{W V^2}{64.32},$$

from which it is easy to figure the amount of energy which a flywheel of a given weight with a given variation in velocity will distribute.

Cause of Pound in Ammonia Compressor

What causes an ammonia compressor to pound when it is started up after having been shut down for a few days?

E. W.

We are inclined to think that a pound in the compressor cylinder occurring under such conditions would be due to entrained liquid returning to the compressor with the return gas. If the piston rods are found to get very cold, the discharge pipe being unusually cool and the stuffing box shows a tendency to leak, this is undoubtedly the correct explanation. This liquid may either leak by the expansion valves into the cooler while the machine is shut down, or it may have been pocketed somewhere while the machine was in operation, in which latter case the low temperature of the insulation or possibly ice surrounding the part of the piping forming the pocket might have allowed it to collect faster than it could evaporate.

When the machine is shut down a portion of this residual ammonia will evaporate and increase the pressure on the condenser sufficiently to prevent its evaporation even at a higher temperature of the surrounding insulation, or after the ice has melted off, as the case may be. When the machine is again put in operation and the back pressure is quickly reduced, the comparatively high temperature liquid will begin to boil rapidly, and, as in the case of a boiler that is being "crowded," a certain amount of liquid is bound to pass off with the vapor. If parts of the piping can be found that frost or become abnormally cold, it will give support to this theory.

While it is a far less probable explanation, the contraction of parts of certain types of ammonia piston will sometimes allow of sufficient motion to produce a sound. This is usually where the pressure of the compressed gas is allowed to enter the piston and distend a "bull ring."

It is barely possible that the crank-end clearance is so small that the contraction of the piston rod allows the piston to strike the back head until the rod gets warmed up. This can be proved by taking the clearance and by inserting a piece of solder wire behind the piston just before the crank passes the back center.

A Deserving Cause

We are advised that a fund is being raised in England by subscription to provide for the invalid wife and young children of the late H. H. Thwaite, who in 1894 conceived and proved that blast-furnace gas can be used in gas engines. He was no business man and he got nothing out of it. He spent all his own fortune on it and died, a broken-hearted man, in the spring of 1908.

The widow set to work at once to provide for her two young children, but was attacked with a recurrence of a sickness for which she underwent an operation three years ago. Her case is now believed to be hopeless.

Friends of Mr. Thwaite got Andrew Carnegie interested to the extent that he has agreed to subscribe £100 ($500), provided a like sum be obtained from others.

The committee in charge of raising this fund consists of the following: H. A. [illegible] and T. E. [illegible], of *The Electrical Review*, London; Professor Arnold, of Sheffield; R. K. Gray, of the India-rubber and Telegraph Construction Company, Silvertown, London; W. M. Mordey, president of the Institution of Electrical Engineers, London; Harold Jones, *Iron and Coal Trades Review*, London; Sir William H. Preece, 8 Queen Anne's Gate, S. W., London.

The secretary of the committee, to whom contributions may be sent, is W. H. Booth, 3 Queen Anne's Gate, Westminster, London. Mr. Booth is well known to Power readers.

Obituary

Kenton Chickering, vice-president of the Oil Well Supply Company, of Pittsburg, died at Oil City, Penn., December 8. He was vice-president of the company from its formation, prior to which he was for thirty-nine years connected with Eaton & Cole and the Eaton, Cole & Burnham Company.

The first annual dinner of the superintendents and foremen of the Kinkora Works of the John A. Roebling's Sons' plant was celebrated at Roebling, N. J., on the evening of Wednesday, December 23. Assembled at the tables, where an appetizing dinner was served, were nearly fifty gentlemen bent on having a good time, and they had it. Appropriate favors were distributed. T. A. Major was the toastmaster. It is the intention to repeat this social occasion each year.

The annual smoker of Brooklyn Association No. 8, N. A. S. E., was held at its meeting rooms, 315 Washington street, Brooklyn, on Saturady evening, December 19. An enjoyable entertainment was furnished by the "bunch," assisted by Henry Elder, Carl Cronlin and Charles C. Drant. During the evening addresses were made by James Westberg, R. O. Smith, Thomas Cole and Timothy Healey. Frank Martin made a genial toastmaster. Refreshments of all kinds were constantly on tap.

Business Items

A handsome wall calendar for 1909, printed to represent burnt leather, is being distributed by the Wilpaco Packing Company, 109 Liberty street, New York.

The York Manufacturing Company, York, Penn., manufacturer of ice-making and refrigerating machinery, has closed 28 recent orders aggregating 1377 tons of refrigeration.

C. P. Bassett, of Charlotte, Mich., maker of the McNaughton sectional grates, has received a letter from W. P. Engel, president of the Peoples Gas and Electric Company, Defiance, Ohio, in which he says: "I acknowledge the com. Your boiler grates are far superior to any grate I have used. We have been using two full sets, under two 350-horsepower Heine boilers for two years and three months. The repairs have cost but $1.80 for the sectional grates. There has not been a warp or a sag in the bars, and the increase in draft is fully 25 per cent. We consider that we are saving 40 per cent. in repairs and 20 per cent. in fuel."

The Foos Gas Engine Company, Springfield, Ohio, is furnishing a producer-gas plant complete to the Standard Optical Company, for its new lens-grinding department, at Geneva, N. Y. The engine will be a 100-horsepower three-cylinder Foos vertical from which power will be transmitted by rope drive. The producer will use Pennsylvania anthracite and is so arranged that a portion of the gas will be drawn off and used for annealing furnaces. The plant will be very complete and will contribute materially to the economical operation of the factory. The Foos factory at Springfield has been working overtime for several months in the endeavor to keep up with orders.

The Buckeye Boiler Skimmer Company, South End, Toledo, Ohio, manufacturer of the Buckeye boiler skimmer for removing impurities from the water in boilers, has received a letter from Kelsey & Freeman, of Toledo, Ohio, in which they say: "We have had your automatic skimmers in use now about six months and have given them a pretty thorough test. We formerly cleaned one boiler each week and even at that had difficulty in pulling load on account of foaming. Now the old scale is dropping off and the water in boilers is considerably more free from settlement, thus requiring less attention and giving much better results. Your skimmers have done already what you guaranteed them to do and are worth their cost to us twice over since we installed them. To anyone using water as bad as Maumee river water we cannot recommend them too highly."

New Equipment

A new power plant is being erected for the Oconee River Mills, Milledgeville, Ga.

The Shelby (N. C.) Cotton Mill is building an addition. Electric power will be used.

The city of Clearwater, Fla., has voted to issue $25,000 bonds for water works.

The Beeville (Texas) Water and Light Company will rebuild water and light plant.

Wm. E. Everheart, Maryville, Mo., will establish an ice and cold-storage plant to cost $25,000.

Independent Ice Company, Nashville, Tenn., will erect a new factory building, boiler and engine rooms.

Morris & Co., Chicago, Ill., has had plans prepared for a cold-storage plant, which will cost over $700.000.

The Atlanta (Ga.) Power Company, recently organized, proposes to establish electric-power plant.

The Bellefonte (Penn.) Electric Company is having plans prepared for dam, concrete power house, etc.

The city of Hooker, Okla., voted $20,000 bonds for construction of electric-light plant and water works.

Help Wanted

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

AN ENGINEER in each town to sell the best rocking grate for steam boilers. Write Martin Grate Co., 281 Dearborn St., Chicago.

WANTED—Thoroughly competent steam specialty salesman; one that can sell high-grade goods. Address "M. M. Co.," POWER.

AGENTS to sell one of the best known and widely advertised shaking grates on the market. Exclusive territory granted to anyone who can make good. Liberal commission. Perfection Grate Co., Box 1081, Springfield, Mass.

Situations Wanted

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

YOUNG MECHANICAL ENGINEER, three years' experience as salesman, would like to connect with engineering house or contracting engineers. Box 82, POWER.

SALESMAN—Mechanical engineer, college graduate, 28 years old, five years' experience with large steel plant, desires salaried position as salesman handling power specialties. Preferably Pittsburg or Cleveland district. Address "F. J.," POWER.

CHIEF ENGINEER, 17 years' experience on engines, dynamos, plumbing, wiring, sewage disposal, telephones, etc. Am at present in good position, having effected saving of about 1000 tons per year. Best references; change of locality desired. Address "H." Box 80, POWER.

ENGAGEMENT DESIRED to install small, or medium-sized steam, electric or hydro-electric plant, or as chief engineer mining company in South or West preferred. Am graduate electrical engineer, experienced in mining and milling work. Can give references. At liberty February 1. Box 81, POWER.

POSITION WANTED as chief engineer; experienced with all kinds of engines, steam turbines, a.c. and d.c. generators, motors and switchboards, boilers and pumps. I can get results and furnish the references; have been seventeen years in the mechanical and engineering business. Box 9, POWER.

POSITION WANTED by a thoroughly competent and practical engineer. Long experience in erecting, installing and operating steam, water and electric power plants; capable of taking full charge of any plant. Am now holding good position under first class Massachusetts license, but desire a change. Best of references on application. Box 77, POWER.

Miscellaneous

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

DRAFTSMEN—Put in a requisition for my parallel device, $2.50. F. G. Hobart, Beloit, Wis.

WANTED—Left hand, second hand Corliss engine in first class condition to develop 100 to 150 horsepower. Box 79, POWER.

IF YOU DESIRE to learn the latest improvements in steam boilers, correspond with the Detroit Water Tube Boiler Co., Detroit.

WOULD BUY ARTICLE in machine line to manufacture. If you have inventions, write, giving full descriptions. If patented give numbers. Box 78, POWER.

ENGINES AND BOILERS, ¼ to 2 h.p., engine castings in sets. Models and general machine work. Sipp Electric and Machine Co., Paterson, N. J. Catalog 4c.

PATENTS—H. W. T. Jenner, patent attorney and mechanical expert, 608 F St., Washington, D. C. I make an investigation and report if patent can be had, and exact cost.

PATENTS secured promptly in the United States and foreign countries. Pamphlet of instructions sent free upon request. C. L. Parker, Ex-examiner, U. S. Patent Office, McGill Bldg., Washington, D. C.

ENGINEERS AND FIREMEN—Send 10 cents in stamps for a 40-page pamphlet containing a list of questions asked by an examining board of engineers. Stromberg Publishing Co., 2703 Cass Avenue, St. Louis, Mo.

THE ANNUAL MEETING of the stockholders of the Hill Publishing Company, for the election of directors for the ensuing year and for the transaction of such other business as may properly come before the meeting, will be held at the office of the company, in the Hallenbeck Building, 497-505 Pearl St., Borough of Manhattan, New York City, N. Y., on Tuesday, January 26, 1909, at 12 o'clock noon. Dated, New York City, December 9, 1908. Robert McKean, Secretary.

For Sale

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

150 HORSE-POWER tandem compound Corliss engine, in good order; 16-ft. wheel; 24-in. face. F. W. Iredell, 11 Broadway, New York.

CHANCE TO GET A TRACK SCALE CHEAP. Fairbanks, Morse & Co., No. 4369, T. R. B. scale with dead rail, style 12, never been used. Morgan & Wright, Detroit.

FOR SALE—20x48 Wheelock engine and two 72″x18′ high pressure tubular boilers in good condition cheap. Address "Engineer," Box 2, Station A, Cincinnati, Ohio.

PLANIMETERS FOR SALE—Get the mean pressure of any diagram with the simplest and best planimeter in a minute's time. Send $1 to Peter Eyermann, Consulting Engineer, Du Bois, Pa., for the planimeter and instructions.

FOR SALE—20″x42″ improved Greene engine. Wheel 32″x14′. Used seven years. Also 24″x48″ improved Greene engine. Wheel 42″x16′. Used eight years. Both engines in first class shape. Can be seen running. The Capewell Horse Nail Co., Hartford, Conn.

New Power Plant of Carnegie Institute

Designed for Appearances as well as Efficiencies, with Extensive Heating and Ventilating Systems and Unusual Metering Facilities

BY THOMAS WILSON

In looking over Pittsburg, strangers never fail to visit the far-famed Carnegie Institute. This is an immense structure occupying a ground plan of about 440x660 feet, with a total floor space of over 15 acres and representing an expenditure of $6,000,000. The building is located in Schenley park in the midst of the residential district of Pittsburg and originally consisted of the Carnegie Library building and Music Hall. In 1900 a large sum of money donated by Andrew Carnegie made it possible to make extended additions to the library and educational institute and to add museums, art galleries and a large hall of architecture and sculpture. Architecturally the building has been given every attention. It is of stone construction with an imposing exterior, and within the design and decoration are highly artistic. For the greater part it is three stories in hight, the bookstack section alone having eleven floors, and is well lighted from an unusual number of large windows. Alden & Harlow, of Pittsburg, were the architects, and Charles R. Cunningham is superintendent of the building.

With the large extensions to the institute it was necessary greatly to increase the capacity of the mechanical plant, and for reasons of economy and convenience of operation it was decided to install a plant entirely new and of sufficient capacity to serve the entire building. Every effort was made to secure the best equipment on the market, to give it the best arrangement possible from an artistic as well as an economical standpoint, and above all to make the plant as attractive as any department in the building. From the photographic illustrations it is apparent that the efforts of Mr. Cunningham were not in vain.

FIG. 1. THE BOILER INSTALLATION

A building of such immense proportions required a large plant, involving the generation of electric current for light and power, heating and ventilation, refrigeration, elevator service, vacuum cleaning and the compression of air. Machinery for these various services was located in the basement of the Institute, but to have a boiler room with its dirt and smoke in such close proximity to the main (very) and important exhibits in the building, was not looked upon with favor. Fortunately a deep ravine nearby offered a favorable site, and when erected but very little of the boiler plant was visible from the institute. Furthermore, one of the conditions was to design a plant which would not produce smoke, and the difficulty of connecting the two departments of the plant with steam and water piping was rendered unobjectionable by cutting a tunnel 500 feet long through solid rock to the central portion of the basement. In all 2400 horsepower of boilers have been installed and in generating equipment 2200 horsepower for supplying with current 30,000 incandescent lamps and over 500 horsepower in motors. The exhaust from these units must heat nearly 14,000,000 cubic feet of interior volume, and a large amount of live steam is required for the various pumps, ammonia compressor and other machines.

Boiler House

Part way up the ravine and about 60 feet below the grade of the institute, a level plot was blasted out of the solid rock to afford a site for the boiler house, which is a brick and steel structure 65x150 feet in plan and 58 feet from the floor to the eaves, bounded by a concrete floor and roof. The entire upper portion is given over to continuous coal bunkers of concrete, holding 8000 tons of coal, and an ash pocket with a capacity of 1000 tons. The tunnel, which is 7½ feet wide by 12 feet high, is 32 feet above the boiler-house floor, and is connected by a stairway with an extensive system of iron grating giving access to the top of the boilers and piping. From this grating stairways lead to the boiler-room floor and to the coal bunkers above. The stack is on the institute side, rising 195 feet above the boiler-room floor. It was built of radial brick by the Alphons Custodis Chimney Construction Company and has an interior diameter at the base of 9 feet.

Eight 300-horsepower Babcock & Wilcox water-tube boilers are installed and are set in four batteries of two each. The settings are spaced 6 feet apart and have been placed to allow a firing floor of 24 feet in front and a distance of 11 feet from the rear of the settings to the wall. The boilers are of the standard heavy-pressure type with two steam drums 42 inches in diameter and 23 feet long, a 12-inch cast-iron mud drum and 144 four-inch tubes 18 feet in length. The tops of the steam drums are covered with 2-inch magnesia blocks which are supported on a wire netting to allow a 2-inch air space between them and the boiler. Each boiler contains 3051 square feet of heating surface, carries a working pressure of 150 pounds and is equipped with an 8-inch delivery nozzle, two 4-inch nickel-seated safety valves set for 160 pounds and a Williams feed-water regulator and gage column.

A grate area of 52 square feet in a Greene chain-grate stoker is provided in each boiler. A water back which can be run close to the fuel bed or raised to allow clinkers to pass is in place at the rear, and with an arch a little longer than usual almost perfect combustion is obtained. Only on rare occasions is smoke visible from the top of the stack and then only a light haze, due to starting up one of the boilers or a similar reason. The stokers are eccentric-driven from a shaft beneath the floor, and this in turn is belted to two Westinghouse Junior 7-horsepower engines, one being held as a reserve. At the rear of the boilers a breeching, 37x60 inches, carries the gases toward the stack, discharging into a rectangular flue at the center 7 feet wide by 10½ feet high, the breeching increasing in size to meet these dimensions as it proceeds toward the stack. The boiler connections are 37x49 inches, and each is fitted with a balanced damper. In the flue or main connection to the stack is a set of double vertical dampers. These are mounted on ball step bearings below the casing, and are controlled by a Kieley "Climax" damper regulator.

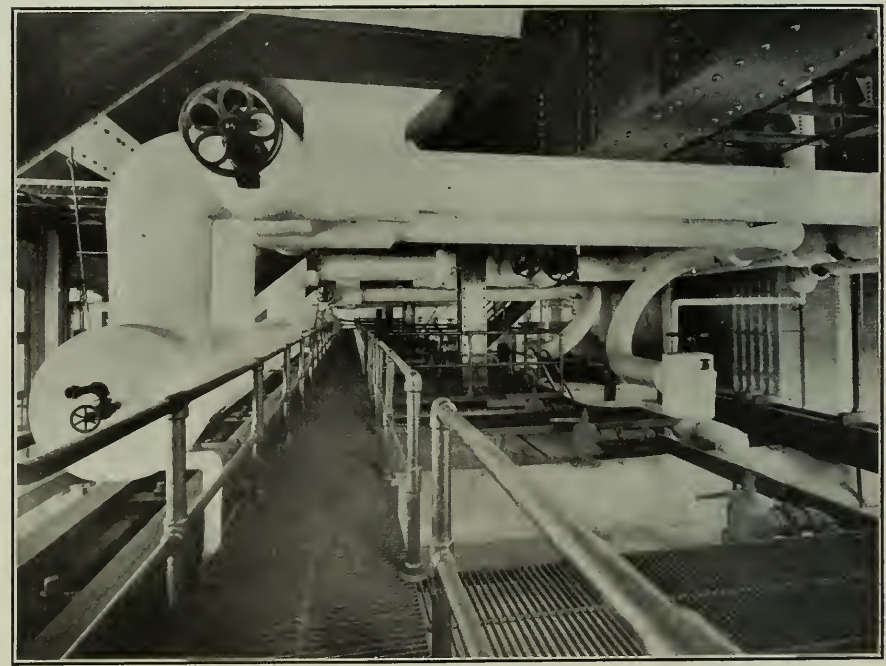

FIG. 2. PIPING AND WALKWAYS ABOVE THE BOILERS

Coal and Ash Handling

As previously stated coal is stored in bunkers of 8000 tons capacity. These are four in number and extend the entire width of the building with a 40-degree slope toward the center. Concrete walls on 30-foot centers divide the bunkers, and at the end an ash pocket of the same width and 15 feet long is located directly over the spur track carrying the coal into the boiler house. From each bunker there are two delivery spouts, one to each boiler, terminating in cutoff gates directly above a runway carrying two weighing hoppers, each of 1000 pounds capacity. These are mounted on four-wheel trucks which can be moved to any one of the eight boilers by a gear operated from the floor and the contents weighed before entering the stoker. The weighing-lever mechanisms, of Howe make, are suspended to within a convenient distance from the floor and are inclosed in "banjo" covers. Usually the scales are set at 700 pounds and coal is allowed to run into the weighing hopper until this weight is lifted. In this way the coal never overflows the hopper and a convenient amount is obtained to fill the stoker hopper.

In the ravine a spur from the Baltimore & Ohio Railroad delivers the coal to the plant, the track extending into the building and allowing the coal to be dumped directly from hopper-bottom cars into a receiving hopper below, which holds an entire carload.

Before being dumped the coal is weighed, a section of track 42 feet in length and the scale beams being suspended from steelwork above. Slack is the fuel usually burned, and in this case it is taken directly from the hopper by a McCaslin conveyer of the overlapping gravity-bucket type, which encircles the entire boiler room, running directly under the ashpits and up into a monitor above the coal bunkers, where a trip set at the desired location empties the buckets as they pass. The conveyer is driven by a 20-horsepower General Electric inclosed motor, which is located at one end of the monitor. The starting box is placed near the motor, so that it is necessary to start the machine at this point, as it is always well to look things over before setting the conveyer in operation. There is a second switch, however, in the basement near the crusher controlling the motor circuit, and this may be opened at any time to stop the conveyer. If the coal is of lump size it is first passed through a McCaslin single-roll crusher, driven by a 30-horsepower General Electric inclosed motor. This machine, by means of gearing and a winch is also called into service to pull the cars from the spur into the boiler house.

From the chain grates ashes drop into steel-plate hoppers immediately below and thence through undercut gates into the buckets to be conveyed to the ash bunker above. As this is directly over the track the ashes are run into the empty cars and from these dumped through the trestlework into the ravine. It is the intention in the near future to give the ashes free passage to the ravine by means of a spout connection to the bunker, as in storing the ashes to any depth they have merged into a solid mass, causing much difficulty in their removal. With the spout arrangement there would be no need for storage, and as the demand for ash filling is great, there would be no accumulation in the ravine. With the present arrangement it is an easy matter to weigh the ashes on the car scales.

Path of the Feed Water

Most of the water for boiler feeding comes from the returns of the heating system and whatever is lacking is made up from the city mains. The condensation is collected in two Webster "Star" vacuum open feed-water heaters of 1000 horsepower capacity each. From these the water is conveyed in an 8-inch line through the tunnel to the boiler house, dropping vertically to the basement and first connecting to a Wainwright surface condenser, with bypass connections, and thence to a special air chamber and continuing to the pumps through 6-inch branches.

Steam from the pumps in the boiler house and the stoker engines is passed through the Wainwright condenser and utilized to increase the temperature of the feed water. The condenser is 4 feet in length, 18 inches in diameter and contains thirty-six 1½-inch corrugated-copper tubes 36 inches long. It is built to withstand a working pressure of 125 pounds. The air chamber is a 12-inch pipe, 10 feet high, in which the water enters at the bottom and is taken off 3½ feet above. The top is capped with a blank flange, and the 6½ feet above the outlet is the air chamber.

The two pumps are of the Wilson-Snyder outside-packed plunger pattern, 8x12x8x18 inches, and both suction and discharges are cross-connected, so that the pumps may be readily interchanged. From the pumps the water next passes to a Cumming reheater and purifier and then to a Cumming filter and thence through a Worthington meter to be measured. There are two sets of Cumming filter and reheater, each of 1200 horsepower capacity, and by the use of live steam at boiler pressure the outfits are capable of raising the feed water to 310 degrees Fahrenheit, at the same time removing most of the scale-forming ingredients contained in the water. The reheaters are steel tanks 42 inches in diameter, 12 feet long and containing 800 feet of 1¼-inch copper tubing, while the filters are 15 inches in diameter by 8½ feet high. The reheaters were built to withstand a pressure of 160 pounds, but at the present writing are out of commission on account of leaks and grave doubts are expressed by the management as to the advisability of using live steam to secure that additional 100 degrees in the feed water. Consequently the reheaters are bypassed and the water turned to the boilers through a common 5-inch copper main running under the boiler room floor. From the main a 3-inch brass pipe carries the water to each boiler, passing on its way up through a graduating valve and a combination check and stop valve at the boiler connection.

Two blowoff connections are made to each boiler, each 2½ inches in diameter and connecting at opposite ends of the mud drum. All the connections lead into a common 4-inch main leading to a receiving tank 4 feet in diameter by 12 feet long at the rear of the basement. This tank receives the dirty drain as well as the boiler waste, and is provided with [illegible]

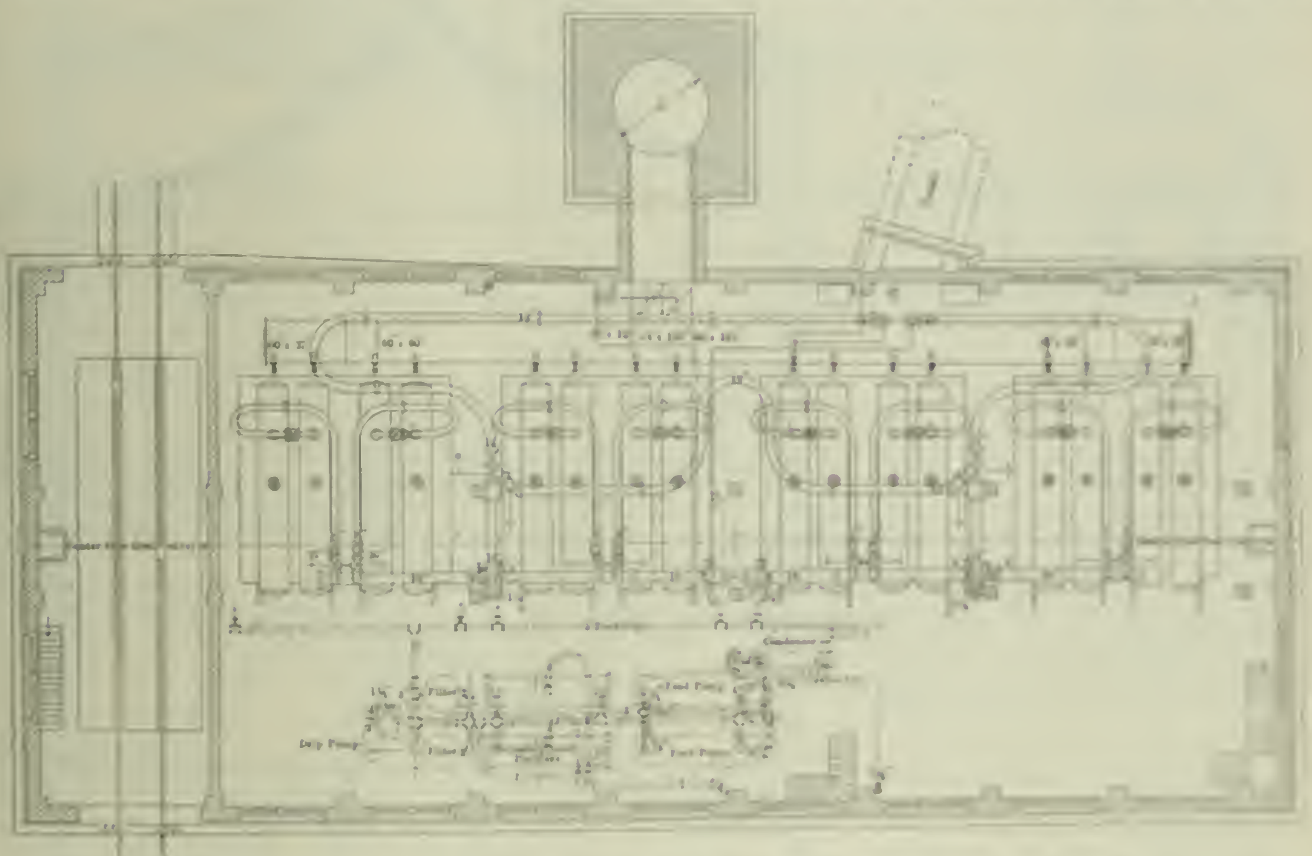

FIG. 3. PLAN OF STEAM PIPING IN BOILER HOUSE AND FEED-WATER APPARATUS OF BASEMENT

feet of 2-inch brass piping to cool the water before discharging it to the sewer. The overflow to the sewer is at a point 8 inches from the top of the tank, which is always nearly full of water and will tend to cool additional water as it is received. A 4-inch connection leading to an exhaust head above the roof allows the steam and vapor to escape.

Boiler Piping

Owing to the size of the plant and the distance between the boiler and engine rooms, an elaborate system of piping has been arranged to carry the steam from one department to the other. The arrangement of this piping is shown in the plan views, Figs. 3 and 7. Primarily the system consists of a large main header in the boiler room, which is connected to a large distributing header in the engine-room basement by two 12-inch mains running through the tunnel and measuring nearly 600 feet in length. The main header in the boiler room is 16 inches in diameter, 93 feet long, and near the front edge of the boilers is carried on roller supports. Leaders 8 inches in diameter connect the boilers to the header, and to provide for expansion these are turned in long radius bends, as shown in Fig. 3. Each leader is provided with a Chapman nonreturn stop and check valve. At the center the main header is sectionalized by a stop valve, and to each half are connected four boilers and one of the 12-inch delivery lines. The supply lines are cross-connected, so that either set of four boilers may supply either line, and at the center of this connection expansion is provided for by the U-bend shown in the drawing.

Each of the supply lines is equipped with motor-operated valves, and these may be controlled from five different places on the engine-room side of the tunnel. Three of these points are in the engine room, one in the engineer's office and one in the pump room. At each control point is a panel carrying three push buttons and three colored miniature lamps; one button starts the motor to open the valve, another button stops the motor, and a third button starts the motor in the opposite direction to close the valve. A red light in connection with the first button shows the valve opening, a white light shows that the motor is running, and the blue light shows the valve closed. After a few trials it is an easy matter to tell the approximate position of the valve, and the control panels are often tried out to show that they are in working order. There is also provision to close the valves by hand in the boiler room. With this arrangement the valves may be readily closed at either end and much trouble averted if a supply line should accidentally burst in the tunnel. The Chapman Valve Manufacturing Company designed this equipment.

The auxiliary header shown in Fig. 4 is 6 inches in diameter and was designed to supply all steam required in the boiler house. It has connections to the

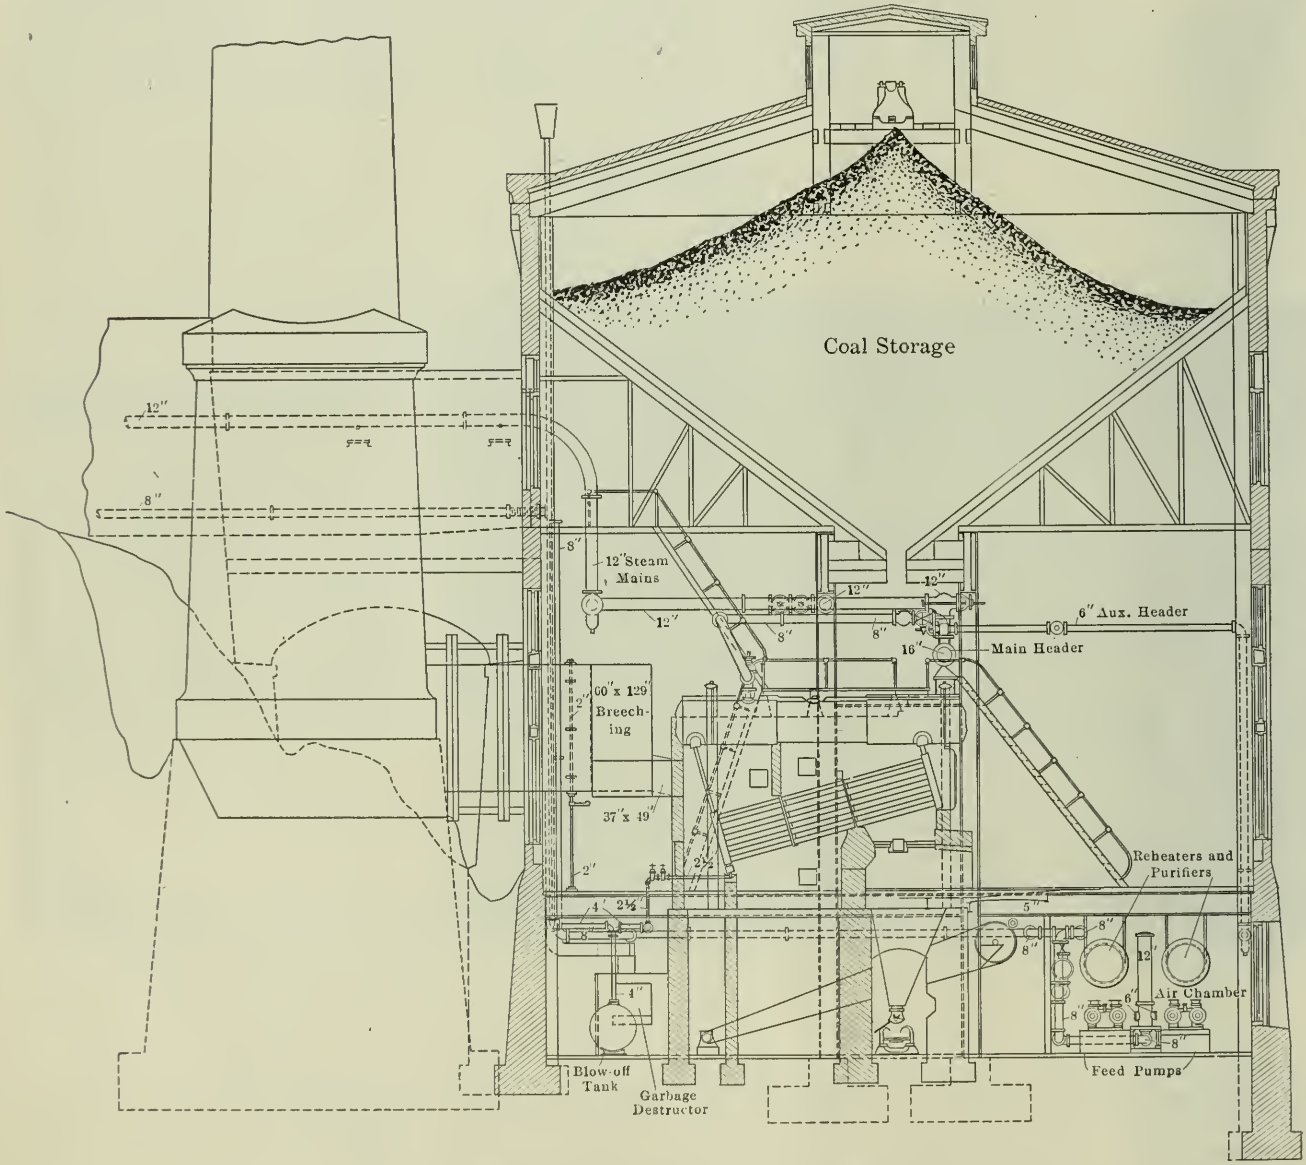

FIG. 4. TRANSVERSE SECTION THROUGH BOILER HOUSE

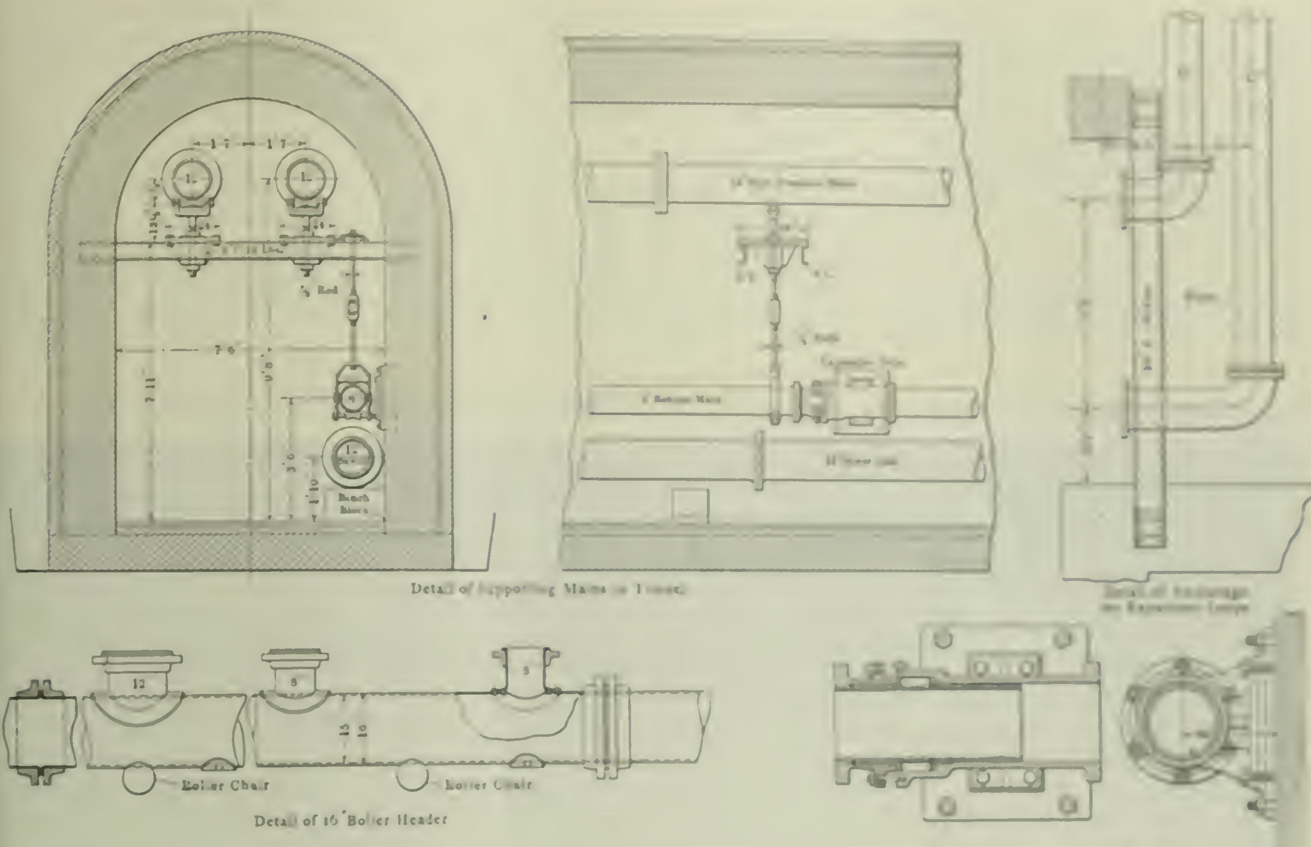

Detail of Supporting Mains in Tunnel

Detail of Anchorage on Expansion Loops

Detail of Expansion Joint

FIG. 5. DETAILS OF BOILER HEADER AND PIPING IN TUNNEL

main header on either side of the sectionalizing valve, and extends from the front of the boilers to the wall, where it drops to the basement to supply the auxiliary equipment.

The 12-inch supply lines are connected to the top of the main header and from angle valves run horizontally to the rear with long, sweeping bends and return to points in line with the tunnel. Here drip pockets are provided and the mains rise vertically 15½ feet to enter the tunnel, and at the entrance are bent on a 6-foot radius. In the tunnel their arrangement and method of support is shown in Fig. 5. The two supply mains occupy the arch of the tunnel and at points 12 feet apart are supported by 6-inch channels running transversely across the tunnel and imbedded in the masonry. The channels are 24 inches apart and between carry a block supporting an 8-inch roller conforming to the shape of the pipe. This roller is carried in trunnions on the upper ends of screw rods which pass vertically through the block and are adjusted by nuts above and below. At a bend in the tunnel near the center point the mains are rigidly anchored to the tunnel wall, so that expansion may occur in either direction. Toward the engine room expansion is provided for by U-loops extending horizontally and at right angles for a distance of 20 feet, and as the mains are rigidly anchored in the engine-room basement by means of a 10-inch channel attached to the steel work of the building, all expansion or contraction must be taken up by the U-loops.

Ample provision has been made for draining the mains. There is a drip leg at the bottom of the vertical rising from the boiler room to the tunnel, another at the center of the tunnel, and a third at the expansion loop near the engine room. The first two drips mentioned and those in connection with the main header in the boiler room are taken by a Wilson-Snyder 7½x4½x6-inch duplex drip pump and discharged to the suction side of the boiler feed pumps. The condensation from the expansion loops enters the engine room system of drips.

In the tunnel there are two other mains, one an 8-inch return from the Webster heaters and the other a 10-inch sewer line. The former is hung from the supply main channels by means of a rod provided with a turnbuckle, so that its elevation may be readily varied, while the sewer line is carried on bench blocks upheld by the tunnel floor.

It may be of interest to note that the tunnel is 9½ feet wide, 12 feet high to the

For 1½ Pipe

FIG. 6. DRIP-LEG TEES USED IN STEAM PIPING

crown of the arch, and from the engine room to the boiler-house wall has a total length of 410 feet. About 60 feet from the boiler house the tunnel emerges from the side of the ravine, and for the remainder of the distance is carried above ground resting on a heavy concrete arch where the sloping bank of the ravine necessitates.

Engine Room

In this department every effort has been made to secure a sightly appearance. At one end is a gallery floor 11 feet wide and 13 feet above the engine-room floor. Looking from this gallery nothing but the generating units and switchboard are visible. There is no auxiliary apparatus in the room, not a pipe is visible above the engine-room floor, and the cables are all concealed, including even the main generator cables, which enter the bottom of the flywheel pit and make connections at the bottom of the generator frame. Even in this pit a pier is built to within 18 inches of the generator frame to conceal as much of the cables as possible. The switchboard is all of white marble, and there is nothing to suggest electrical connections, except the switches and the instruments on the front of the board. The floor is laid with marble and on the walls a wainscoting of white-enameled terra cotta rises to a hight of 11 feet. The gallery is similarly finished, and in front is inclosed by a handsome brass railing. Five structural columns of the building are also covered with the white-enameled terra cotta, and the walls above the terra cotta are tinted. The ceiling is paneled and around the border is studded with glazed incandescents, so that the room, minus the machinery, might readily be mistaken for an elegant banquet hall.

To give the machines a setting, both the engines and generators are raised from the floor and rest on 8-inch capstones. Brass railings inclose the flywheels and generators, the floor stands to operate the throttle valves are polished, as is also the

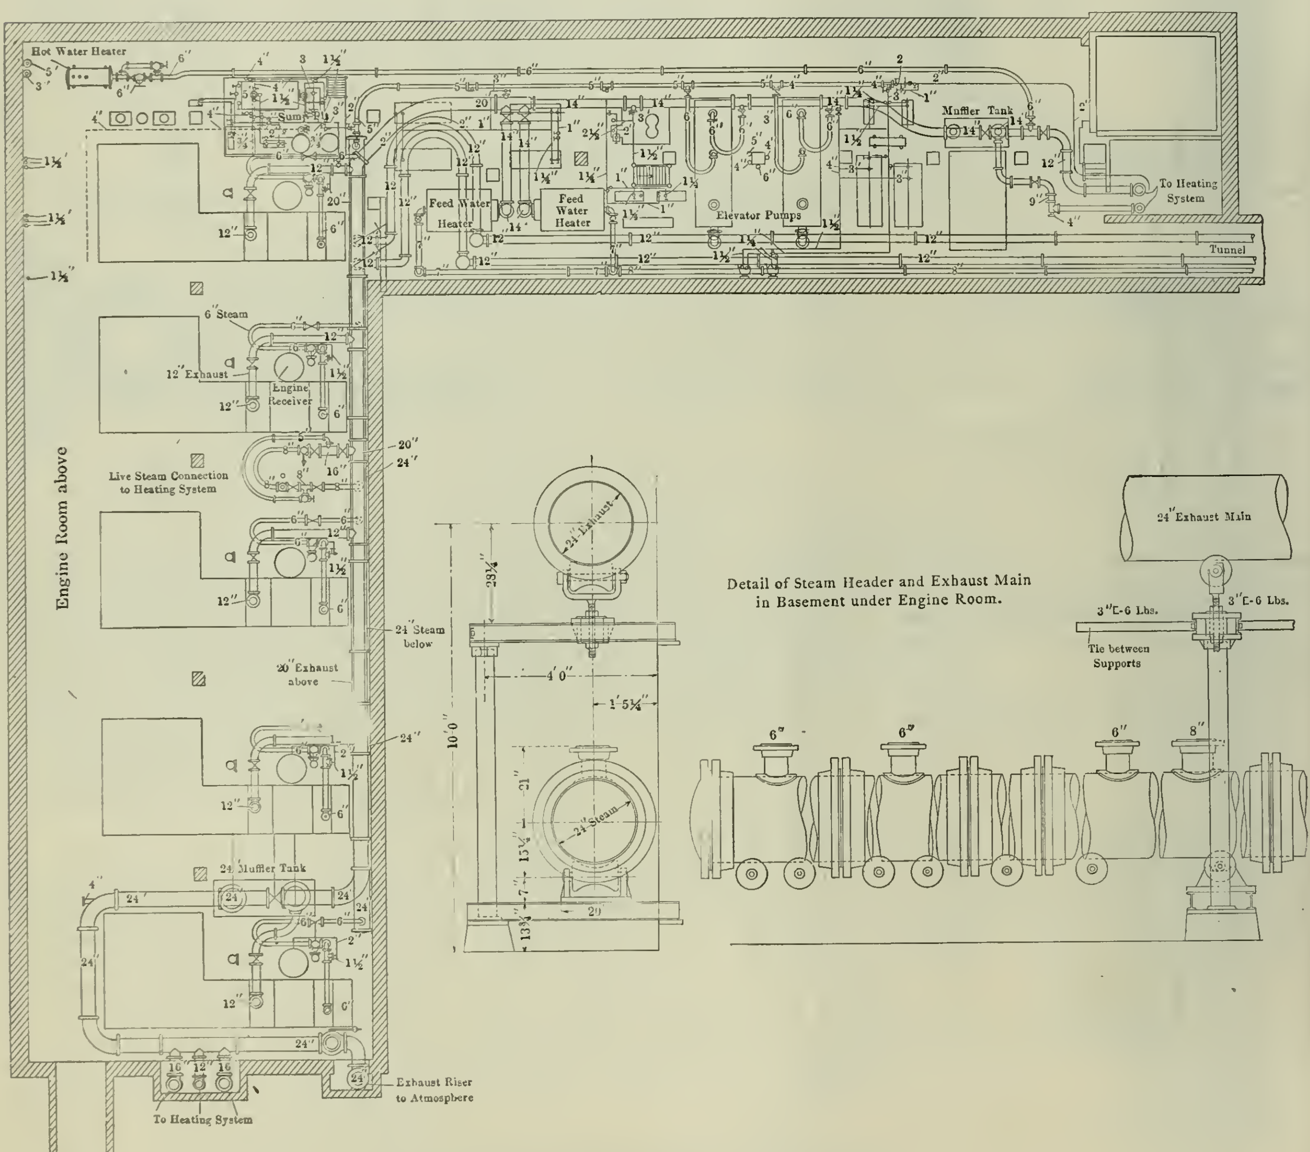

FIG. 7. PLAN OF PIPE CELLAR AND ELL EXTENSION AND STEAM AND EXHAUST HEADER DETAIL

Every little detail has been given attention, and the result is an engine room of surpassing beauty. The room is 45 feet 7 inches wide by 106 feet long, and has a clear head room of 24 feet. The engine-room floor is at a level 40 feet below the main floor of the building, and the location is such as to secure an abundance of daylight from a large open court. The generating units are spaced uniformly throughout the length of the room, and at valve gear, and the small oil piping to the bearings and cylinders is nickel-plated. Gold trimmings on both engines and generators add to the attractiveness of the machines, and the oil stands seen in the photograph have been specially designed for the plant and are made of highly polished brass. The combined effect of all these little features is most pleasing to the eye, and the universal verdict of visitors to the plant would in all probability be, "the most attractive engine room in the country."

This neatness and the extreme care of detail has not been limited to the engine room. In the tunnel the floor, walls and pipes are washed, and even the tops of the boilers and the steam piping above are cleaned at regular intervals. By no possibility must a piece of coal or a little ash be allowed to remain on the floor, and a can of grease or anything at all unsightly "dare not show its face." Even the firing tools are all concealed in a case provided for the purpose. This extreme cleanliness has made even the boiler room just as attractive to lady visitors as the

independently. A Rites centrifugal-inertia governor controls the speed. Richardson sight-feed oilers are provided for cylinder lubrication, and Lunkenheimer oil hand pumps are provided for emergency. A Schaeffer & Budenberg tachometer mounted on a floor stand and belted to the main shaft indicates the speed of the engines, which normally is 120 revolutions per minute. A Monarch speed limit, set for 130 revolutions per minute, is included in the equipment, and a Monarch engine stop is connected with each throttle. The stop is operated electrically at three different points, a push button being provided at the engine-room door, one on

system. The oil from the crank pit is drained to a set of Burt oil filters, and to prevent any oil from dripping to the engine base or the floor, the crosshead guides are similarly drained to a smaller set of filters of the same make. The oil is elevated by small pumps to a tank above the engine room, and provision is made for the usual gravity flow, the connections to the bearings and various points on the engine units being made by means of nickel-plated piping brought up through the engine-room floor.

ELECTRICAL EQUIPMENT

To the engines 300-kilowatt National

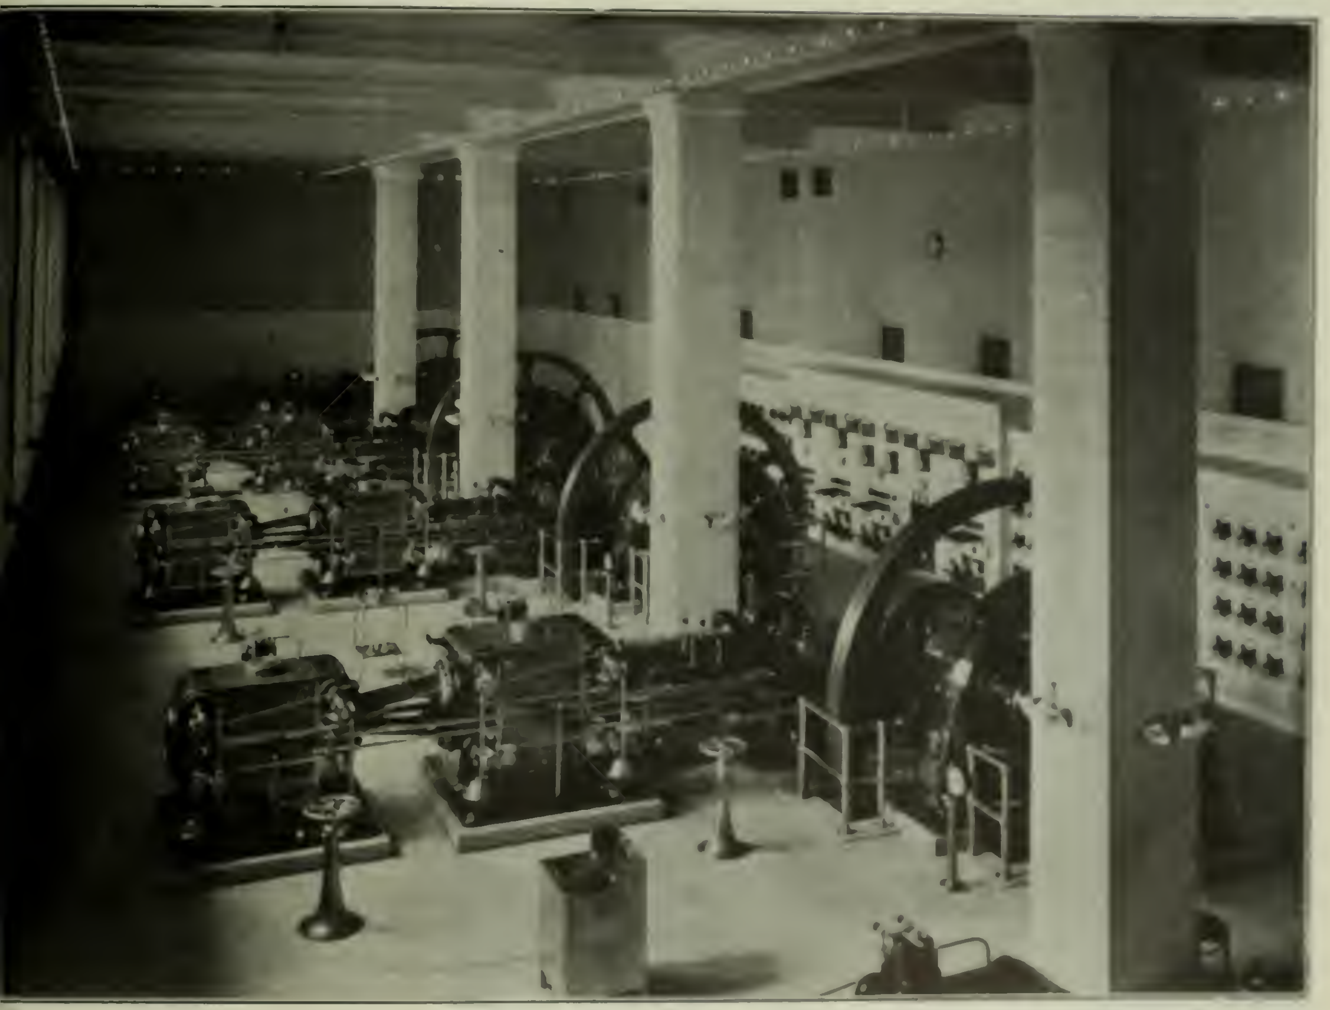

FIG. 8. ENGINE ROOM

art galleries or museums, and in going through the building, instead of receiving their last visit, it is usually the first place they go to.

The equipment of the engine room is five Rice & Sargent tandem compound engines, 18x26x36 inches. As is usual in the tandem compounds of this make, a third eccentric is provided, so that the valves may be operated by direct eccentric movement and no wristplates employed. One eccentric works all four steam valves, and each of the other two a pair of exhaust valves, so that the exhaust from each cylinder is controlled

the column near the engine and still another on the switchboard. In addition the stop is automatically operated by the governor, and by means of a lever on the floor stand can be cut out for the time being and the throttle closed by hand. It is the usual practice to shut down by means of the engine stop, alternately using the different points of control to insure that the system is always in working order. Four seconds is the time taken to close the throttle, and the closing within this time was demonstrated on different occasions for the writer's benefit.

Lubrication is effected by the gravity

Electric generators are direct-connected. These deliver 2400 amperes at 125 volts and operate in parallel to carry the load. The switchboard, which is located near the wall and is indicated in the cuts, has 14 panels—five for the generators, which are located in the center of the board, and the feeder panels on either side. The panel front is of white Italian marble, and as special pains have been taken to space the instruments and switches, the board has an unusually attractive appearance. The generator panels project some 6 inches from the feeder panels, and [illegible] running the entire length of the board and a base raising the panels about 8 inches from the floor add to the appearance of the board. Each generator panel is equipped with a Weston ammeter and voltmeter and a recording ammeter made by the French firm, Chauvin & Arnoux, of Paris; a circuit breaker on each side and the main knife switch for the generators. On No. 3 generator panel there is also a recording voltmeter of French make. The feeder panels show nothing but I. T. E. circuit breakers controlling the various circuits of the building, which are all two-wire. These circuits are further protected by Noark inclosed fuses at the back of the board and are provided with an electromagnet, which in connection with an annunciator board will immediately show, in the event of trouble, whatever circuit is out.

At the end of the engine room there is also a meter board of white marble containing 14 Standard brass-cased gages for indicating pressures of ammonia, air, steam and water, the steam gages indicating both boiler and heating pressures.

In addition to these instruments, there is a handsome recording board in the superintendent's office, some 200 feet distant. This contains five Whitney column-type recording ammeters, one for each generator, and one recording voltmeter made by Chauvin & Arnoux. These instruments are all inclosed in square glass cases resting on a marble base supported by brackets. In the space below these meters are some Standard pressure gages, one to indicate the pressure of the heating supply, another the pressure of the heating returns, a third to indicate the water pressure for elevator service and still another to show the air pressure for the Johnson system of temperature control.

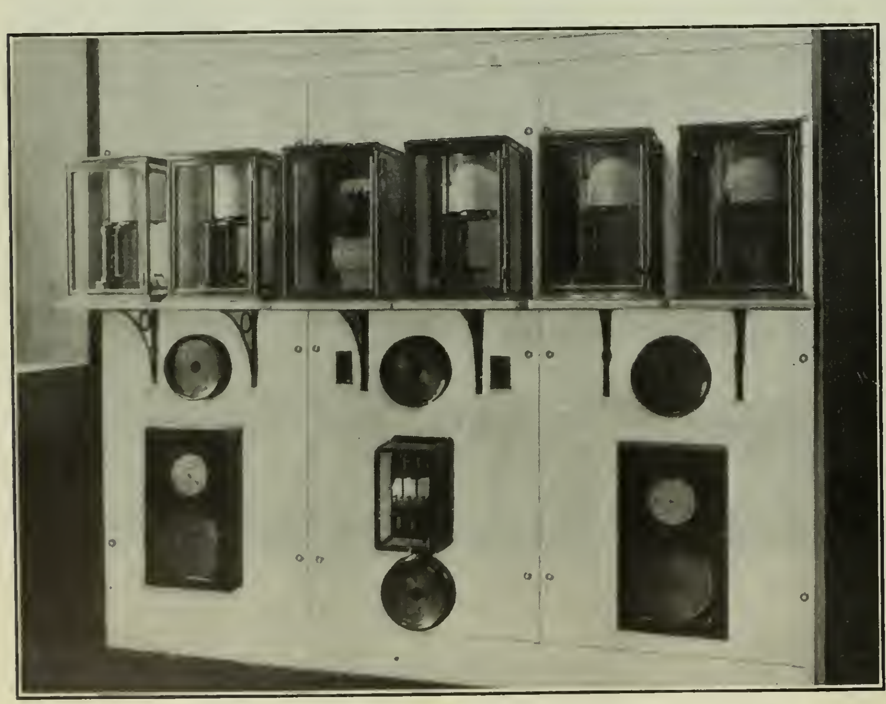

FIG. 9. RECORDING BOARD IN SUPERINTENDENT'S OFFICE

There is also a Dibble telethermometer to record the temperatures in the music hall 350 feet away, and a Queen & Co. telemanometer for recording the boiler pressure, and in addition a recording instrument to show the length of time each generating unit is on.

Both the French and Whitney meters are handled by Machado & Roller, of New York City, and were furnished on account of their accuracy and the small amount of current required to operate them. The French instruments are of the d'Arsonval type, equipped with mechanism of unusual size so that the torque is unusually large when compared to the friction of the pencil. The Whitney instruments are operated from the same shunt as the French recording ammeters in the engine room, that is, the two recording ammeters for each machine are operated in parallel, and the Whitney instruments at a distance of 200 feet from the shunt.

The operation of the Whitney meters is somewhat unusual, but broadly speaking, the principle on which the meter is based consists in causing the variations in the current to be measured to control the variations in pressure of a body of air in a closed vessel, these variations being in turn indicated by the rise and fall of a column of oil of comparatively large diameter, carrying a hollow float which supports the recording pen at its extremity. The chart drum is rotated 1 inch an hour by internally placed clockwork. The pen has a stroke of 6 inches and the drum a circumference of 24 inches. Fig. 10 shows the construction of the meter, and its operation may be explained as follows:

Air at a fairly constant pressure of about 1¾ pounds to the square inch is delivered to the pipe *A*, enters the chamber *B* and then flows through a series of porous diaphragms made of filter paper, whose prime function is to serve as an air resistance and incidentally to remove any dust particles. The air then enters the passage *D*, into which is drilled the opening *E* capped by the valve *F*. This valve

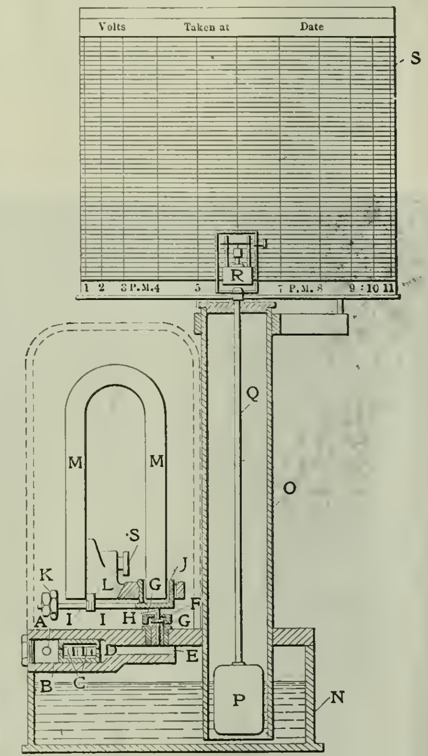

FIG. 10. CONSTRUCTION OF COLUMN TYPE METER

is a small flat disk resting on a circular seat with escape ports *G* below it and a pin *H* resting on top. On the pin rests a spool *J* carried on one end of the lever *I*, on the other end of which is the counterweight *K* by means of which the effective weight on the pin *H* can be adjusted. The spool is wound with wire through which the current to be measured is passed, this being done by means of the two thin, short copper ligaments *L* which support and form the pivots about which the lever can oscillate. A magnet *M* furnishes a field of force of such strength that the reaction between it and the current forces the spool down, with a force increasing as the current increases. The valve *F* is thus a variable-loaded safety valve whose blowing-off point is constantly and proportionately varied by the current variation. The counterweight *K* on the lever is so adjusted that when no current is passing through the spool, the weight on the valve pin is such as to give a zero reading on the scale. The air pressure cannot give a higher reading, as any tendency to increase simply results in lifting the valve slightly higher, whereupon more air escapes and the pressure falls back, and *vice versa* with the opposite condition, due to the constant flow of air from the high-pressure supply at A. The total motion of the spool is less than a hundredth of an inch, and the only work that the varying current has to perform is to control the air pressure. The actual energy required to move the liquid and to show the variation in current readings being supplied by an independent source. With these conditions, the instrument is extremely accurate and a drop of from 20 to 25 millivolts for full scale indication is all that the meters require.

Steam Supply and Exhaust

Below the engine room there is a pipe cellar and an ell extension which afford ample space for all the piping connections. In this cellar is located the 24-inch steam header and receiver which connects to the expansion loops at the end of the 12 inch supply mains and supplies all live steam used in this division of the plant. The header is 110 feet long and is supported 3 feet above the floor on roller blocks. Each engine is fed by a 6-inch branch taken from the top of the header and carried up with a long radius bend to a gate valve, which is operated by hand, and thence through a return loop to the throttle valve, which is controlled from the floor stand in the engine room and in nearly all cases is operated by the Monarch system of engine-stops. As the lines to the engines rise from the top of the header, no separators are required, and from each a 2 inch connection is made to the engine receiver for reheating purposes. To all the auxiliary equipment steam is supplied by a 5 inch branch, to which six lines are tapped to supply the various units. To the elevator pumps there are two 3-inch connections, another 3-inch to the two smaller elevator pumps, two 2½-inch pipes to the vacuum pumps and ammonia compressor, and a 2-inch tap extending to the drip-receiver pump and the two small pumps for oil circulation. There is an 8-inch connection to the main header to supply live steam to the heating system. The connection to the heating mains is made through two pressure reducing valves in tandem; usually live steam is not necessary, but this provision has been made so that in the case of extreme weather the boilers may be called into service to supply the demands of the heating system.

Exhaust from all the steam-using machinery is collected in a common main serving as the low-pressure supply to the heating system. The main is supported above the steam header in much the same way as the supply lines in the tunnel. In the ell extension to the pipe cellar it is 14 inches in diameter, increases to 20 inches as it enters the engine room, and again to 24 inches toward the west end of the room. Each of the engine units is provided with a 12-inch exhaust, two 6-inch mains connect the large elevator pumps to the exhaust main and a number of smaller connections to the 14-inch end of the line relieves the remaining equipment of exhaust steam.

From both the 14-inch and 24-inch ends of the exhaust main, delivery is made to the heating system through Utility combined grease extractors and muffler tanks. On the large end of the main the muffler tank is 5 feet in diameter by 14 feet long, and from a continuation of the 24-inch main past the muffler, two 16-inch and one 12-inch heating mains are taken off, and beyond this the exhaust may escape to atmosphere through a Kieley back-pressure valve into a 24-inch exhaust riser. At the smaller end of the exhaust main the muffler tank is 4 feet in diameter by 9 feet long, and from this tank connections are made to a 9-inch and a 12-inch heating main, and also to a 5-inch line supplying a hot-water heater. At the end of the 20-inch section of the exhaust main two 14-inch connections are made to the Webster heaters located in the ell extension. The system of piping just described is thoroughly dripped by means of traps which discharge to the sewer.

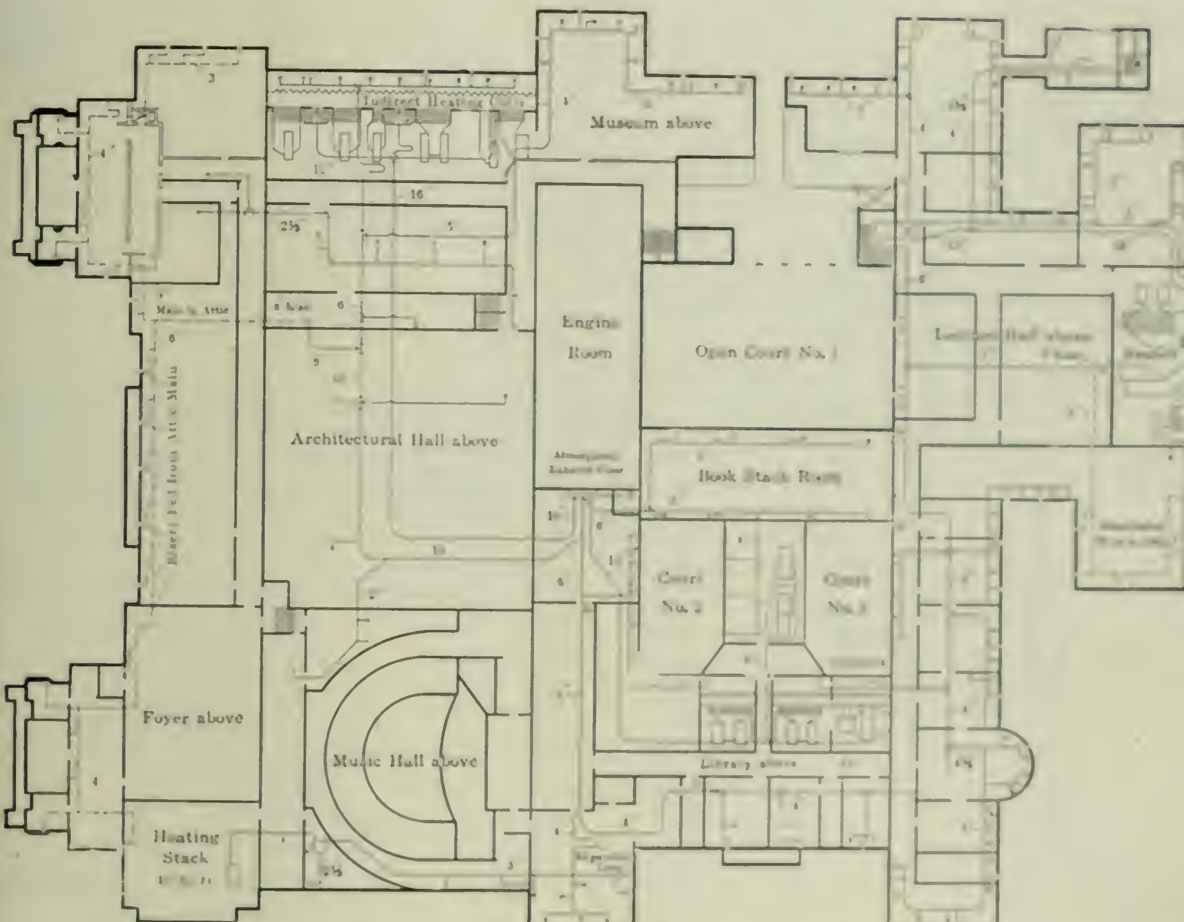

FIG. 11. GENERAL OUTLINE OF HEATING SYSTEM

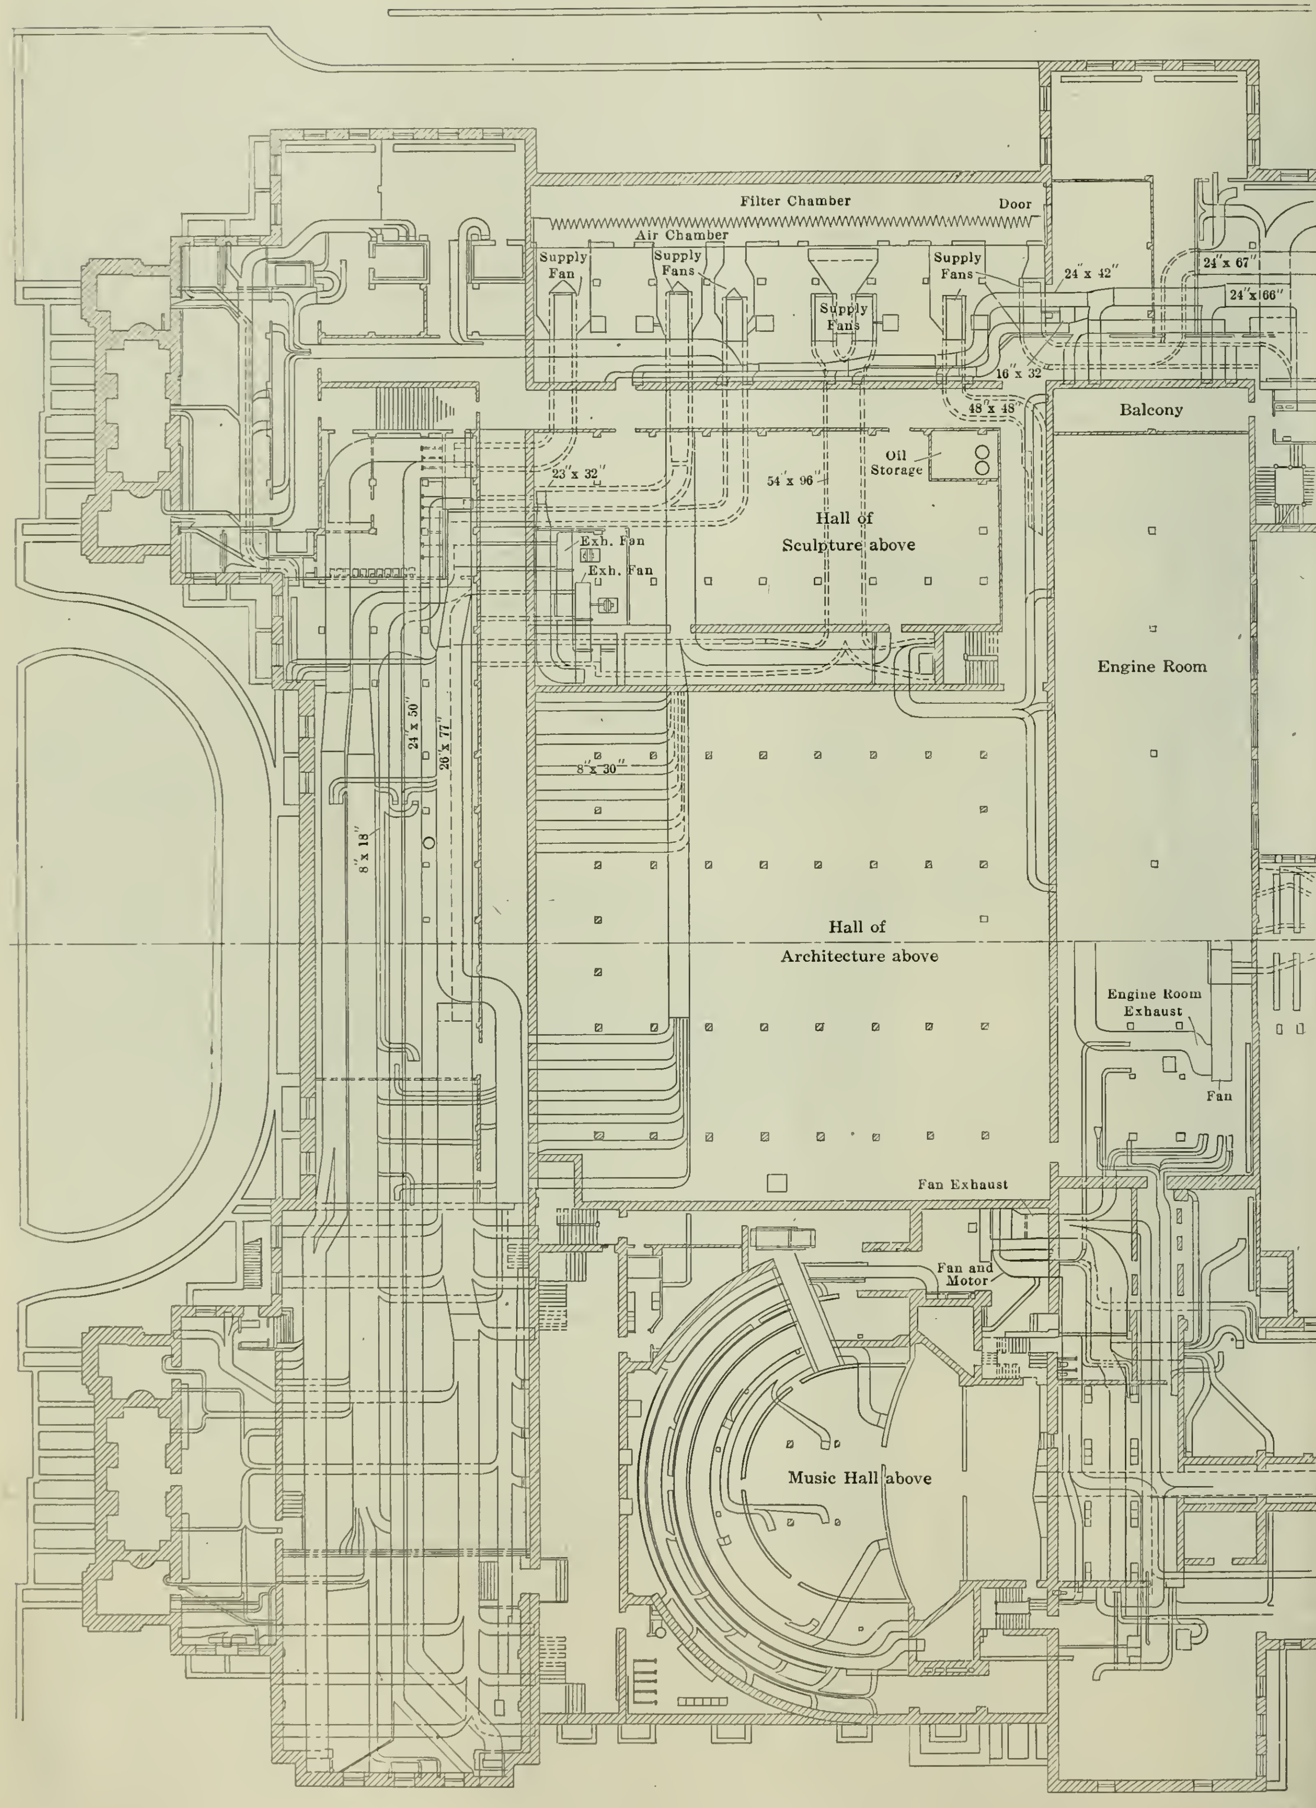

FIG. 12. VENTILATING SYSTEM IN LEFT HALF OF BASEMENT

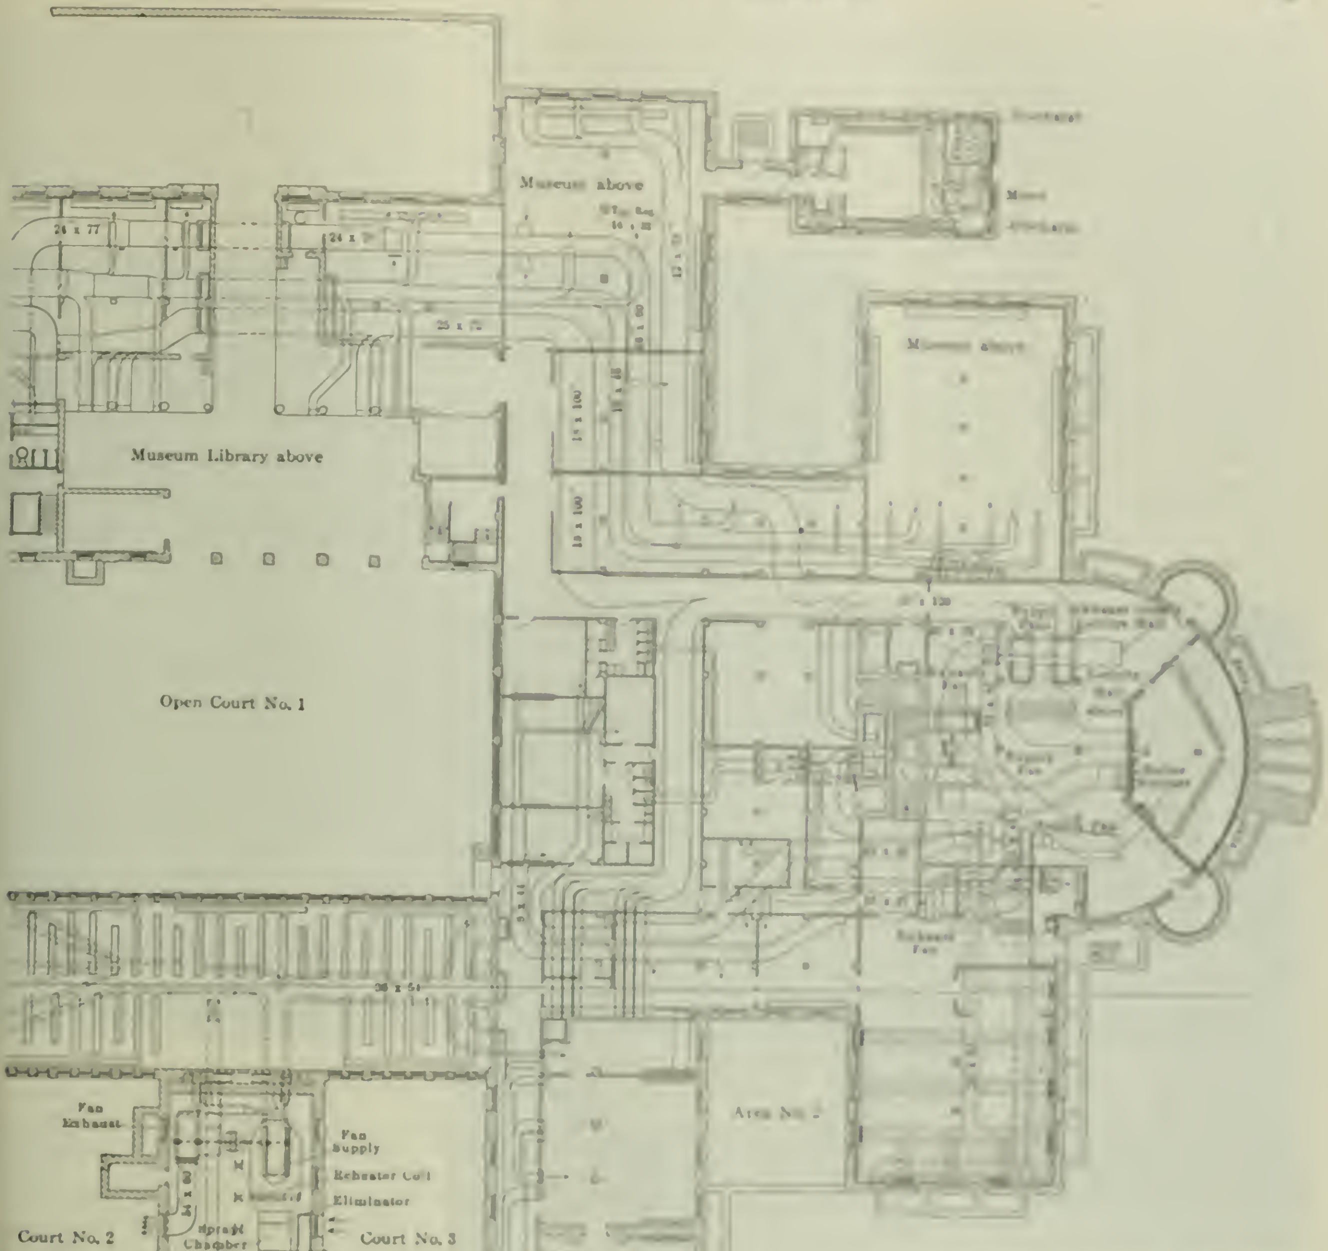

FIG. 13. VENTILATING SYSTEM IN RIGHT HALF OF BASEMENT

and all pipes, both high- and low-pressure, are covered with 85 per cent. sectional magnesia covering. On the exhaust this is 1 inch thick, and on the live-steam mains the covering is doubled.

Heating System

With the exception of the music hall, the entire building is heated by direct radiation, and the design of the system provides for maintaining the temperature at 70 degrees Fahrenheit during zero weather. To make this possible, over [illegible] square feet of direct radiation was required, necessitating an extensive system of steam supply and return piping. The supply system consists of nine distinct mains, three of which supply the tempering coils of the ventilating system. Two of the three lines are 10 inches in diameter, and the third is a [illegible] main. The other six lines, one 10 inches, one 8 inches and four 6 inches in diameter, lead from the [illegible] to the distributing mains which supply the risers to all parts of the building. The supply and distributing mains are suspended from the ceiling of the basement, and all are properly dripped, covered with magnesia pipe insulation, and ample provision has been made for expansion.

In all, 116 risers supply steam to over 36,000 square feet of radiation upon the upper floors, which is subdivided into units, varying from 42 to 972 square feet each. The risers vary in size from 1¼ to 2½ inches and are all drained at their lower ends. The pipes are anchored at the base, expansion upward is provided for, and all are concealed in chases in the walls, branch connections to the radiators being made in nearly all cases under the floors. Throughout the building the supply mains are paralleled by the returns, of which there are 114 returning to a header in the engine-room subbasement. All but nine of these return lines are ¾ inch in diameter; four of the nine are 1-inch pipes and five are 1¼ inches in diameter.

Bundy standard radiators, fitted with Jenkins radiator valves on the supply and Webster thermostatic release valves on the return end, are installed throughout the building. In some of the larger rooms Bundy circular radiators are used, this type being preferred when the side walls were required for exhibiting works of art. Radiators up to 40 square feet of heating surface are supplied with steam by ¾-inch pipes, from 40 to 90 square feet by 1-inch pipes, and from the latter size up to 250 square feet the pipes gradually increase in diameter, in proportion with the radiating surface, up to 1½ inches. Above this limit 2-inch supply connections are made. Up to the limit of 250 square feet of radiating surface, the returns are all ½-inch, and radiators larger than this are fitted with ¾-inch return connections.

The radiation is all operated on the Webster vacuum system, and from the return header in the engine-room subbasement the air and condensation is pumped by a duplicate set of Knowles 8x14x16-inch vacuum pumps to a 3x6-foot steelplate air-separating tank, which is provided with a 4-inch vapor connection to the roof. From here the condensation flows by gravity to the Webster open heaters, of which there are two, rated at 1500 horsepower each. From the heaters the condensation is taken as boiler feed and carried to the boiler room, as previously described.

All radiating surface is controlled by the Johnson system of temperature regulation; 333 thermostats of the Johnson pneumatic type are installed throughout the building, and these control a total number of 646 heat sources. In a large number of the smaller rooms a single thermostat controls all the radiators provided for their heating, while in the larger rooms a few thermostats control a large group of radiators, and are so placed as to secure the average temperatures of the rooms. Pneumatic pressure for the thermostats is supplied at 15 pounds pressure by a duplicate set of Marsh compressors in the pump room. A feature in the installation of thermostatic control was introduced in the form of push buttons to regulate the skylight radiation.

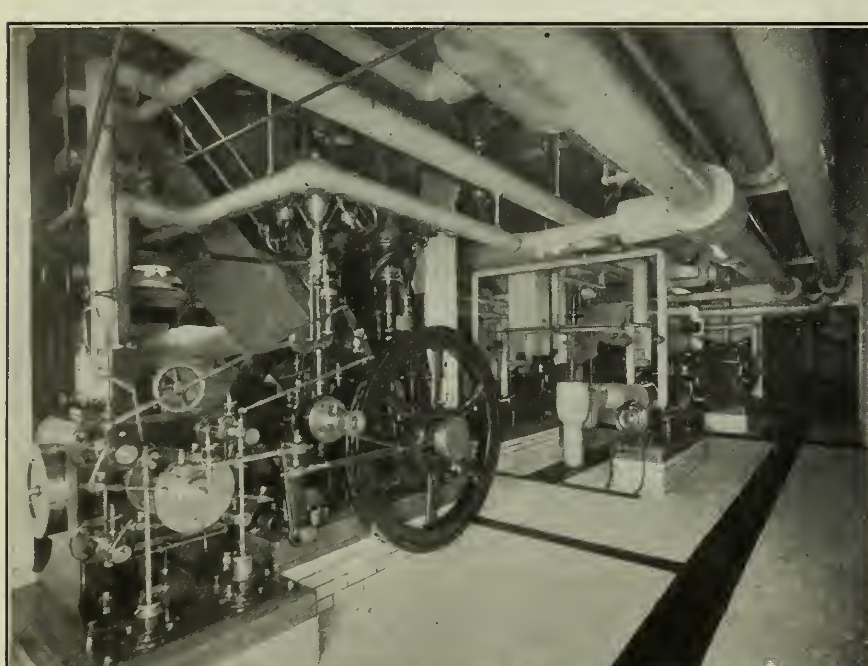

FIG. 14. AMMONIA COMPRESSOR IN PUMP ROOM

Ventilation

The entire building is ventilated mechanically, and the installation of fans required to supply the fresh air and exhaust the foul air is one of the largest ever placed in a single building. The supply fans have a capacity of over 600,000 cubic feet of free air per minute, and the exhaust fans a capacity slightly greater. For convenience, the fresh-air apparatus is arranged in 15 stations, containing in all 19 fans, and the exhaust equipment in 21 stations containing 30 fans. The equipment is Sturtevant, driven by C. & C. direct-current motors of the slow-speed multipolar type. The motors are direct connected to the fans and may be varied by field control from two-thirds to full speed. The fan wheels vary in diameter from 2½ to 10 feet, depending upon the service required.

For convenience in making duct connections the 19 centrifugal blowers are arranged in three general divisions: the first division including Systems 1 to 6; the second, Systems 7, 8 and 10, and the third, Systems 9, 11, 12 and 13. Even in this case some of the connections are 500 feet in length, but on the whole a convenient installation has been secured. In the first division all the fans have a common intake from a large continuous air filter, which is provided with fresh air from nine large outer windows. Within the intakes and between the filtering chamber and the fans are tempering coils, which, like the direct radiation, are controlled by thermostats. The air filters are of the usual cheesecloth type, with frames mounted in racks zigzagged to secure the maximum area of filtering surface. The areas of the filters for the different divisions are proportioned for velocities of 30 to 45 feet per minute.

For System 9 an air-washing equipment was provided instead of the usual type of filter. This consists of a spray chamber, an eliminator to separate the particles of water from the air and two sets of tempering coils: one to raise the temperature of the air above the freezing point in very cold weather, and the other for tempering the air the desired amount. The spray chamber consists of a system of piping, with a series of nozzles in staggered rows, which spread out the water in a thin sheet perpendicular to the direction of flow, and with the nozzles distributed in this manner a continuous sheet of water is provided for the air to pass through, which it does in this particular installation at a velocity of 10 feet per second. The water from the nozzles is used over and over again and is circulated by a small motor-driven centrifugal pump. When it becomes too dirty for further use, it is discharged to the sewer and a fresh supply taken. Between the spray chamber and the fan intakes is the eliminator, consisting of a number of rows of inclined baffle plates, which are in reality vertical strips of sheet copper 6 inches wide, provided with hook edges on the side toward the fan to catch the particles of water.

All of the supply systems except one are provided with tempering coils, which have a total heating surface of 87,042 linear feet of 1-inch pipe, and for the most part are 1-inch pipe screwed into manifolds on the steam and return ends on 2½-inch centers. From the fans to the flues making connection with the various sections of the building, connections are made by means of brick ducts underneath

FIG. 15. WATER FILTERS, COOLING TANK AND VACUUM CLEANING APPARATUS

the floor, or by means of galvanized-iron ceiling ducts. In general these connections are proportioned for a velocity of flow of about 1200 feet per minute, and the vertical flues for a velocity of 500 to 600 feet per minute. In practically all cases the ducts have been run below the piping system, so that it would not be necessary to pass the pipes through them. In the basement all fresh-air duct work is covered with magnesia block 1 inch thick, this is wired on and is covered with 10-ounce canvas. All flues at points above the basement are covered in the same way, and the tempering coils and fan casings and the connections between them, as well as the centrifugal exhaust-fan casings are covered with the same material 1½ inches thick. In practically all cases the registers in the various rooms are located in the upper portions, and the supply of fresh air directed downward.

For the exhaust system a total capacity of 640,000 cubic feet per minute, distributed among 30 fans, has been provided, and these are more generally distributed throughout the building than are the supply fans. Some of the equipments are located in the basement, but a larger number have been installed in the attic at points convenient to the exhaust flues.

Disk fans of the Blackman type were used wherever conditions would warrant, and in all there are 21 equipments of this type; 10 of these are located in the attic and are arranged to draw through vertical flues, the air escaping through roof discharge hoods. The other nine equipments were by necessity centrifugal exhaust fans, due to the long gathering duct lines and the long vent risers discharging the air.

REFRIGERATION

Some refrigeration for cooling the drinking water and for service in a kitchen to be installed in the building was made necessary, and a system of [illegible] tons capacity has been installed. A vertical Frick compressor, driven by a horizontal Corliss engine, compresses the ammonia which cools the drinking water. For this purpose the ammonia is expanded directly in coils in a [illegible]-gallon tank and cools the water to 42 degrees Fahrenheit. The water is circulated to the various outlets in the building by a Gardner piston pump, [illegible] inches. In the kitchen brine circulation is to be employed, and the brine tank and pump are ready for this service.

HYDRAULIC ELEVATORS

In this department there are three [illegible] plunger elevators for carrying passengers. These have a lifting capacity of [illegible] pounds each and were designed to run at a speed of 250 feet per minute. There is also a freight elevator, with a platform 13 feet 6 inches by 17 feet 9 inches. At the usual working pressure of 150 pounds per square inch, this elevator will lift [illegible] pounds, but its capacity can be doubled by the use of a jack pump, which is a Wilson-Snyder, [illegible] inches, of the duplex type. The regular pressure on the system is turned into this pump and is increased to 300 pounds, giving the freight elevator a lifting power of [illegible] pounds. The usual pumping equipment is a duplicate set of Wilson-Snyder outside-packed plunger pumps, which are duplex tandem compound, with dimensions [illegible] inches. Another elevator pump of the

FIG. 16. [illegible]

same make, [illegible] inches, has been provided for night service. The pumps all discharge into a large pressure tank [illegible] feet in diameter by [illegible] feet long, and the returns from the elevators are collected in a large open tank having a capacity of approximately [illegible] gallons.

Vacuum Cleaning

To be thoroughly uptodate, the building was equipped with a vacuum-cleaning system installed by the Vacuum Cleaner Company, of New York City. This is used principally to clean the floors and to draw dust from rugs and all upholstered work. The equipment consists of a double filter, in which the coarse dirt is removed first, and the air with the finer particles of dust is discharged under water into the second filter. A duplicate set of suction engines, 12x15 inches, is provided.

Compressed-air Supply

There is considerable use for compressed air in the plant. It is used to blow dust out of the generators, from the plumage of stuffed birds and similar uses, and is also required in the elevator pressure tank. The installation supplying the air is a National Brake and Electric Company compressor, which is single-stage and compresses the air to 90 pounds. It is driven by a 35-horsepower National Electric motor, running at 150 revolutions per minute, and at this speed the compressor has a capacity of 200 feet of free air per minute. The motor is automatically controlled from a Cutler-Hammer board. The air is stored in a reservoir 3 feet in diameter by 10 feet long, and is uniformly maintained at 90 pounds pressure by an automatic control.

Baker, Smith & Co., of New York City, were the engineers and contractors in charge of the entire installation, and to them much credit is due for the excellent arrangement and design of the plant.

In discussing the function of oxygen in the corrosion of iron Prof. W. H. Walker said that internal protection of boilers could be provided by merely keeping out the oxygen, ordinarily carried by feed water, by a preheater and a dry-vacuum pump.

Relative Rate of Heat Transfer to Water At and Below the Boiling Point

By W. M. Sawdon

The writer was much interested in the article entitled "Tests on Live Steam Feed Water Heating," by Sydney Bilbrough, in a recent number of Power and The Engineer. One of his statements is "that the rate of heat transmission through a boiler plate is exactly the same from a fire or flames to cold water as it is to boiling water."

On carefully reading this article it appeared that such broad generalizations on so simple and crude an experiment were not justifiable. This is especially true when we consider that his deductions are exactly contrary to the most modern thought along the lines of heat transfer. Mr. Bilbrough does not explain how he prevented radiation nor how he corrected for it and from his conclusions it would appear that he either forgot or neglected that very important factor. It does not seem fair, therefore, that such conclusions should be allowed to stand without further consideration and proof.

The heat lost by radiation from a small piece of apparatus not properly insulated is likely to be large and is in no wise to be neglected. It depends upon the character of the apparatus as well as upon the time or rate of heating. Unfortunately, tests for radiation corrections are difficult and likely to be misleading, but it is self-evident that when the temperature of the water and the surrounding air are the same, radiation will be *nil,* and that when the water is boiling, radiation will be greatest. Mr. Bilbrough's own experiments might then be used as proof of the falsity of his conclusions, since he found the apparent transfer of heat to be the same at the high temperature, when there was much radiation, as at the low temperature when the radiation was slight.

For the purpose of determining to what extent such experiments could be depended upon and wherein Mr. Bilbrough had failed in his observations, some simple tests of a similar character were made in the laboratory of Sibley College.

*Boiling.

Apparatus

The apparatus was somewhat similar to that employed by Mr. Bilbrough and will be clearly understood by reference to the photograph, Fig. 1. The tank was made from an old Carpenter calorimeter from which the bottom had been removed. A stirring device, consisting of a ring of sheet metal turned down at the edge for stiffness and having a small rod soldered on for a handle, was inserted and then a new bottom soldered on. This left three holes in the top, one through which the stirring rod passed, one for the thermometer and the third for the steam to pass out.

A rectangular piece of asbestos board, 10½x12 inches and ¼ inch thick, was put cut at the center so as to fit closely over the outside of the calorimeter. This was slipped on so that the bottom of the board was flush with the bottom of the calorimeter. It served the double purpose of defining the heating surface (0.165 square foot) and of protecting any insulating material which might be placed around the calorimeter.

The heat supply was a gas flame from a special burner belonging to the Junker calorimeter and the pressure of the gas was kept constant by a pressure regulator. This pressure was equal to 10 millimeters of water and the gas was from the city mains.

The thermometer had a range of 220 degrees Fahrenheit, was graduated in degree divisions and could readily be estimated to ¼ degree. Readings closer than ¼ degree were not thought to be justifiable in this experiment and were not attempted.

The calorimeter was placed on two small square rods upon an iron stand and this, together with the burner, rested upon a small platform scale. The scale was graduated to [illegible] of a pound, permitting reading to hundredths of a pound.

METHOD

Two pounds of water was carefully weighed on an accurate balance and poured into the calorimeter. After allowing this to stand for a sufficient length of time for the temperature conditions to become steady, it was thoroughly stirred and the temperature taken. The gas was then quickly lighted and the time, temperature and weight noted. Readings were taken at short intervals until most of the water had boiled away.

The log and results of these experiments, both with a hair-felt jacket on the calorimeter and with no jacket, are shown in Tables 1 and 2, respectively.

Tests were also made for radiation by proceeding as before, but in this case the gas was turned off at the instant the water began to boil and the loss of heat from that time noted. The log and results for these two tests are shown in Tables 2 and 3.

RESULTS

The results of tests (Tables 1 and 2) are shown graphically by curves a and b in Fig. 2. The total heat above initial is the heat of the liquid above the initial plus the heat passing off with the steam.

*Boiling

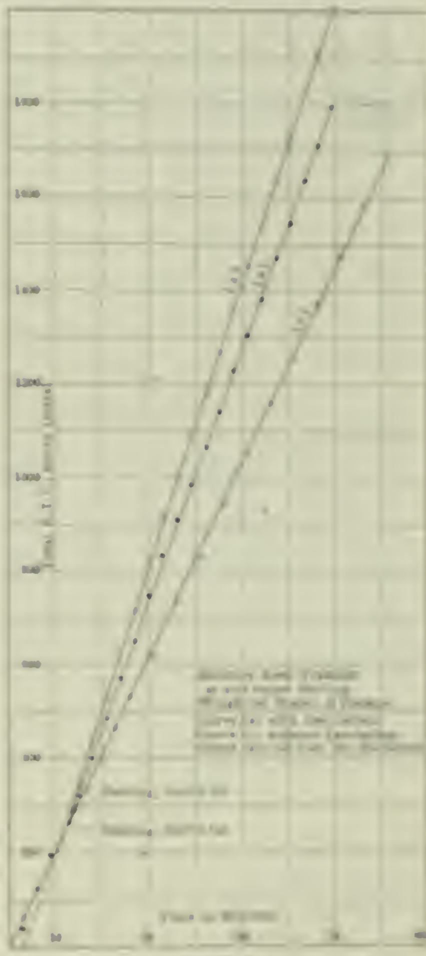

FIG. 2

This is used as ordinates and the time in minutes as abscissas in plotting the curves. Curve *a* is made up of two straight lines which meet in an angle at the boiling point and clearly shows that the rate of heat transfer is greater above than below this point. The dotted line is an extension of the upper end of *a*. Curve *c* is plotted in the same way and is one continuous straight line. This shows that with no insulation and no correction for radiation the rate of heat transmission remains the same. This result corresponds to that of Mr. Bilbrough and shows plainly wherein he failed.

In order to make the radiation correction, the mean difference in temperature of water and air for each small interval of time and the corresponding loss of heat per minute were calculated. These were then plotted as shown in Plate 2. As might be expected, the upper ends of

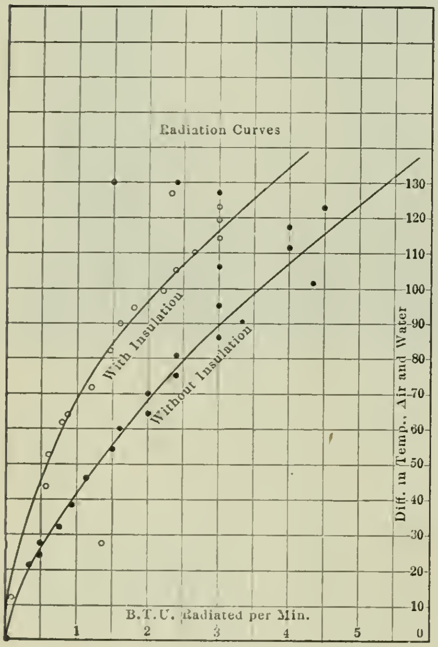

PLATE 2

these curves afford little definite information of the radiation at the higher temperatures. The reason for this is that parts of the apparatus such as the iron stand, the asbestos board and even the lower end of the hair-felt jacket acquire a temperature much higher than that of the water and these parts yield up heat to the water for a considerable time after the gas is turned off, and the radiation through this period appears to be only a small part of what it really is. The water equivalent of the apparatus might be found, but this would be useless since the temperature of the several parts could not be easily measured.

The best that can be done, then, in the way of correcting for radiation is to produce the curve found for the lower part of the range where it is consistent. This is the manner in which these curves were drawn and while they are not absolute they are conservative, especially in the case of the noninsulated test. From these curves the radiation was taken and applied to tests (Tables 1 and 3) and a curve *a'* so corrected was drawn on Plate 1. The corresponding curve for *c* falls so close to curve *a* that it was omitted.

If the efficiency of the heating surface remained the same with the jacket on the calorimeter as without, then these corrected curves should coincide, since the B.t.u. supplied times efficiency of transfer equals B.t.u. in liquid above initial plus B.t.u. carried away with the steam plus B.t.u. lost by radiation.

It is quite probable that the efficiency of transfer is slightly greater in the case of the insulated test since the hair felt near the bottom would become heated and transmit some heat to the water.

Summary

(1) Test with calorimeter jacketed, radiation disregarded. B.t.u. absorbed below boiling point (12.5 minutes) = 262.5 B.t.u. per hour =

$$\frac{262.5 \times 60}{12.5} = 1260$$

B.t.u. absorbed above boiling point (56.5 minutes) = 1535 B.t.u. per hour =

$$\frac{1535 \times 60}{56.5} = 1630.$$

Gain by hot water over cold,

$$\frac{1630 - 1260}{1260} = 29$$

per cent.

(2) Test with calorimeter bare, radiation disregarded. B.t.u. absorbed below boiling point (14 minutes) = 290.5 B.t.u. per hour =

$$\frac{290.5 \times 60}{14} = 1245$$

B.t.u. absorbed above boiling point (67 minutes) = 1399 B.t.u. per hour =

$$\frac{1399 \times 60}{67} = 1253.$$

Gain by hot water over cold,

$$\frac{1253 - 1245}{1245} = 0.64$$

per cent.

(3) Test with calorimeter jacketed and corrected for radiation. B.t.u. absorbed below boiling point (12.5 minutes) = 277 B.t.u. per hour =

$$\frac{277 \times 60}{12.5} = 1329$$

B.t.u. absorbed above boiling point (56.5 minutes) = 1728.5 B.t.u. per hour =

$$\frac{1728.5 \times 60}{56.5} = 1835.$$

Gain by hot water over cold,

$$\frac{1835 - 1329}{1329} = 38$$

per cent.

Weight of water actually evaporated = 1.61 pounds.

Weight of water evaporated per hour per square foot of heating surface =

$$\frac{1.61 \times 60}{69 \times 0.165} = 8.48$$

pounds.

TABLE 4. RADIATION TEST, WITHOUT JACKET ON CALORIMETER.

*Boiling, gas turned off.

Conclusions

(1) That with no protection from radiation the loss of heat may be sufficient entirely to eclipse the gain by boiling water.

(2) That there is a gain in the rate of heat transfer by boiling water over cold water of at least 38 per cent. in an apparatus of this kind. Actual boiler tests in the Sibley laboratories have confirmed this latter conclusion. As to whether this gain is due to rapid circulation of the water remains for future experiments to prove.

Coal; Its Composition and Combustion*

General Discussion of the Elements which Combine to Promote Combustion; How to Ascertain the Degree of Combustion Attained

BY WILLIAM H. BOOTH

It is usual to speak of heat under various names. It is thermometric, specific, or latent. By the first is meant that property of heat which sets up molecular vibrations in a substance, which are capable of transmission to surrounding bodies by radiation or by contact.

By specific heat we mean the amount of heat energy that is necessary to set up a certain degree of thermometric heat in a unit or mass of some body. The same addition of heat to a pound of lead that has made a pound of water comfortably warm would enable the lead to burn a hole through a man's hand.

By latent heat is understood heat that has become converted into energy of condition without thermometric manifestation, as when heat added to ice at 32 degrees Fahrenheit enables that ice to exist as a free liquid and still only to affect the thermometer to 32 degrees Fahrenheit. Here, heat represents mobility of the molecules.

In a wide general sense every chemical reaction may be cited as a combustion. Certainly the converse is true—combustion is a chemical reaction. All substances are, in a broad sense, fuels. Many are difficult to ignite. Many have already entered into combustion or are results of chemical processes so energetic that it is difficult to establish any other reaction. Lime, for example, is the product of a combination of the metal calcium with the gas oxygen, and the energy of union is so great that the metal calcium, though one of the most common of nature's so-called elements, is hardly known except as an oxide or a carbonate.

Aluminum is a metal that unites so firmly with oxygen that it will usurp the place of iron in a mass of burned iron, and convert a mass of mill scale into pure iron by itself becoming an oxide. Hence the thermit process. The fuels that are commonly regarded as fuels are wood and coal and mineral oils. These are found free in nature, and are easily burned and give out considerable heat. Ages of experience have taught us that air is necessary to combustion. The fire of wood burns the better when the wind blows upon it. The wind we can feel, if we cannot see it. The effect is to blow away the CO_2 and leave the fuel freely exposed to fresh supplies of oxygen.

Carbon gas is ideal only. Carbon exists as gas in the electric arc at 3500 degrees Centigrade. When carbon is burned to monoxide, CO, there are set free 4415 B.t.u. per pound. When this monoxide is burned to dioxide a further heat of 10,232 B.t.u. is set free. Why the difference? Physicists say that the first oxidation also generates at least 10,232 B.t.u. or 5817 units more than is thermometrically discoverable. They say that the 5817 units have become latent because the carbon which was solid is now gaseous in the CO. Therefore, the total heat of combustion of carbon gas, if carbon could be taken in its gaseous form, is $10{,}232 \times 2 = 20{,}464$ B.t.u. per pound.

Now, in CO_2 there are 12 degrees of C and 32 degrees of O, or

$$C : O = 3 : 8$$

Then

$$20{,}464 \times \tfrac{3}{8} = 7674$$

B.t.u. produced by the combustion of 1 pound of oxygen.

Now, for combustion with hydrogen. One pound of this gas gives 62,100 B.t.u. The ratio of the two elements H_2O is 1 : 8.

Now,

$$62{,}100 \times \tfrac{1}{8} = 7763$$

B.t.u. This is almost exactly the heat developed when oxygen is destroyed by gaseous carbon.

In each case three volumes of gas become two volumes, so there is no difference due to a different degree of condensation. Let there be next taken the heat of combustion of a series of hydrocarbons: C_2H_2, C_2H_4, CH_4, C_6H_6 and C_6H_6. These are shown in the second column in B.t.u. per pound of the hydrocarbon.

	B.t.u.		B.t.u.
C_2H_2 =	[illegible]	× [illegible] =	[illegible]
C_2H_4 =	[illegible]	× [illegible] =	[illegible]
CH_4 =	[illegible]	× [illegible] =	[illegible]
C_6H_6 =	[illegible]	× [illegible] =	[illegible]
C_6H_6 =	[illegible]	× [illegible] =	[illegible]
(as gaseous vapor)			
C_6H_6 =	[illegible]	× [illegible] =	[illegible]
(as benzine liquid)			

In the third column is the ratio of the oxygen consumed, and in the fourth the heat units per pound of oxygen used. This table gives room for thought. It shows, in the first place, a gradually decreasing result in heat set free per pound of oxygen destroyed. Between C_2H_2 and C_6H_6, two hydrocarbons with exactly the same proportions of carbon and hydrogen, using up exactly the same weight of oxygen per pound of each, there is a difference of heat set free of 17 per cent (nearly). Burned as vapor and burned as liquid, benzene or C_6H_6 gives a different amount of heat again. The figures become confusing when thus treated, and it is necessary to deal with them by the molecule, as they are treated by the chemist.

How coal is formed cannot be said with absolute certainty, but the probability is that the coal plants accumulated like the accumulation of the peat bogs and became buried in sand and gradually sank to a considerable depth in the earth. There under the influence of heat and pressure, the vegetable matter changed its nature. Its watery constituents were driven off and the remaining portions carbonized, and then were also set up those reactions that produced what we term the bituminous quality. There is no bitumen in coal, but what we mean by bituminous is known to all. Some coal was so much heated that its hydrocarbonaceous matter was driven off to be absorbed in other rocks, such as certain clay shales, or it escaped to the surface and was lost. Thus possibly the Welsh coal was formed with its short flaming qualities that earn for it the term "smokeless," because, though not smokeless in all circumstances, it can be burned without smoke if any simple precautions are taken. Exposed to still greater heat or pressure or both almost all the hydrogenous matter is driven off and the coal is converted into anthracite, a fairly hard variety of carbon.

If samples of coal be examined their composition cannot be regarded as so different as is their behavior. There is a substance found in parts of the West Indies which resembles anthracite in appearance, but it is plastic beside. It is said not to contain more than 1 per cent of hydrogen to 99 of carbon. Yet this 1 per cent entirely changes the nature of the carbon, producing a smoky fuel and the capacity of becoming soft with but a moderate heat. Ordinary bituminous coal contains very much more hydrogen but does not soften at the same low temperature, and when it is exposed to heat it softens or ignites and gives off its vapors. Nothing is known really of the chemical composition of coal. It can be found out easily and with close accuracy just how much hydrogen, how much carbon, oxygen or sulphur a piece of coal does contain, but how the atoms of these

*Abstract of paper read before the Association of Engineers-in-Charge (England), December 9, 1908.

elements are joined together seems quite beyond finding out. Thus, if a piece of coal be exposed to distillation in a retort and the different things collected that are produced, there will be found tar, creosote, carbolic acid, cresylic acid, hydrogen, various light and heavy hydrocarbon gases, and so much water and ammonia. But it cannot be said these substances are present in the coal. They have simply been built up or broken down from the material of which coal is really formed, and for anything known to the contrary, a piece of bituminous coal is homogeneous throughout in chemical composition and only splits up into many and various bodies when heated. But since it cannot be known what this substance is there is no reason further to inquire into it. And it may be inferred that if the coal begins to split up as soon as heated so it will continue to split up as more heat is applied, the material splitting up more and more into lighter and heavier portions so that nothing but pitch remains in the still, and after a little further heating, even this is resolved into coke and vapor.

When coal is burned in a fire exposed to air, there is a perhaps more complicated set of reactions put into operation. These are operations both of distillation and combustion. An experiment first shown by Horace Allen was the sprinkling upon a red-hot plate of porcelain of some finely divided bituminous coal. At once vapor commences to be given off and a dark spot surrounds each bit of coal. The coal does not glow so long as the vapor is coming away from it. When the vapor ceases to escape the coal begins to get hot and the dark spots on the plate disappear. The coal now begins to glow, to sparkle—in fact, to oxidize and disappear.

Now, from this experiment much may be learned. First, that the primary effect of heating coal is to drive off its volatile portions. Actually, of course, heat renders the coal partly volatile and drives this part away. The vaporizing of this demands heat and the vapor renders so much heat latent that it dulls the surface of the plate. When this chilling effect is finished by the escape of all vapor, the remaining bit of coke gradually becomes hotter. But it does not oxidize brightly until it has attained a high temperature. These actions teach that coal upon a grate will be very seriously cooled if fresh coal is thrown upon it, and that the volatile matter must be thrown off any piece of coal before its carbon skeleton will begin to burn. In a thick bed of coked coal on a grate the chilling effect of fresh coal may not extend right down to the grate surface and the fuel next the grate will burn with the incoming air at the same time as the gas from the green coal burns on the surface. If the fuel bed is thin, the carbon dioxide first produced on the grate comes to the surface as dioxide, and hinders the combustion of the volatile matter. If the fuel be thick the dioxide may be converted into monoxide in its upward passage through the fuel, and this will again hinder the combustion of the volatiles. The final gaseous mixture above the fuel will be very complex, and usually it will be by no means very hot. Experience tells, as explained by Mr. Swinburne, that this mixed mass ought to be kept hot in a nonabsorbent furnace until combustion is complete.

What now deserves attention is a simple means of examination of a fire with the object of ascertaining to what degree combustion has attained. This is blue glass of a deep tint. Blue glass will not permit the passage of light of a wave length greater than blue. It is because it will not permit this that it is blue. High-temperature radiation has the shortest wave length. Violet light has double the number of waves per inch that represent red light, and red light has millions of times the waves per inch of sound notes. Sound would become visible to a man moving fast enough toward its vibratory origin. Low-temperature flame is red, orange, yellow; blue is hot; violet is so potent that it brings about various chemical reactions, as in photography. A red-hot brick seen through blue glass becomes drab, and gives no illumination. A brilliantly incandescent brick-lined furnace seen through blue glass appears of a light French gray, and is of illuminating quality.

Now, if a dull flaming fire be observed, such as is obtained if badly mixed gases rise directly upward from the fire to pass among cold tubes, there will be seen through blue glass no illumination above the fire beyond about 6 inches. The flames are resolved into dark streams of gas; no light comes from them. But if the interior of a furnace be observed when properly lined with brick, and with suitable direction of flow and air mixture, the whole will be illuminated. Streaks and splashes of dark gas will be seen coming forward over the fire, and these melt away as they travel, and burn and help to keep up the temperature. The dark streaks are simply gas not hot enough to give violet light. They are red or yellow flames of burning gas ready to produce smoke if sent upon cold surfaces. Kept off cold boiler plates, they complete their high temperature combinations, and may then be used for heating anything.

It is not that blue glass marks the state of combustion beyond which one must pass, but it seems certain that if a properly mixed gas attains this temperature before exposure to cold surfaces, it will be properly burned. It would be interesting to experiment with red, yellow, and green glass, so as to find how these help in analyzing the state of a fire. It is certain that if blue glass cuts the flame very short there is imperfect combustion.

Now I have not told you much about coal, for I know nothing myself of the way it is put together. All I can infer is that a very small amount of combined hydrogen will change the physical nature of much carbon. Analysis of coal seems to point to the presence of oxygen as the patent cause of so-called bituminosity. Knowledge of the phenomena of heat—such as latency—teaches that the fuel bed must be chilled when fresh coal is giving off vapor.

On the supposed atomic arrangement of hydrocarbon, speculation may be indulged in on the facts that hydrocarbon is first attacked by the oxygen, and that the carbon is set free by itself or in some different combination with hydrogen, and so readily condenses on the first cold surface. And so it is learned to mix atoms of oxygen in excess of what the hydrogen atoms will snatch up and to maintain everything hot until the carbon has had its chance to find its own atoms of oxygen. And as it may be inferred that a thick fuel bed implies shortness of oxygen above the fire—for the fire has perhaps been converted into a gas producer—so it may be learned not always to regulate combustion at the chimney damper, but to keep this open sufficiently to pull in all the air we need as a maximum above the fire, and to regulate the combustion by combined movements of the door grids and ashpit dampers.

Safety valves are locked up from tampering; why not also lock the chimney damper? It should be locked, for it is not fit to be used as a regulator of the combustion of bituminous coal, for this is a double process, the coal burning partially as solid fuel on the grate and partly as gas above the fire, and each operation requires separate and yet conjoint air regulation.

Ordinary coal has a calorific capacity of about 14,000 B.t.u. per pound. The volatile matters distilled from it have a capacity of 18,000 to 24,000 B.t.u. The extra 4000 to 10,000 heat units they now possess are borrowed from the heat of combustion of the solid fuel on the grate, and when the green gas is wasted unburned it is carrying with it the latent heat of distillation. Assuming 20,000 as its average heat value and assuming one-third of the coal to be volatile, the green gases carry off nearly half the heat value of the coal.

Though the molecular structure of coal may not be discoverable, there can be no doubt as to the results of the systems of combination ordinarily adopted. If fired on the coking system, the gas is driven off more or less steadily and continuously, and places less of a tax on the surface at any one moment in respect of maximum air supply above the fuel to burn the gas than is levied when fresh coal is spread heavily over a fire at more or less wide intervals of time.

The heat of combustion of carbon and hydrogen together is sometimes more and sometimes less than the heat necessary to liquefy or gasify the carbon and to liquefy the hydrogen.

In solid fuel the carbon has not changed its state, but any hydrogen has been somehow rendered solid by its combination with carbon.

The gaseous hydrocarbons become liquid when their molecular weight gets up to about 70 to 80, and solids begin to appear when the molecular weight reaches 128 or 136.

The trouble with coal is that it is not simply a hydrocarbon of even unknown proportion, or a mixture of hydrocarbons. It contains oxygen built into its solid structure, and this oxygen is not necessarily there as water with some of the hydrogen as H_2O. But it is there, and it comes off in distillation, and forms that complex substance—tar. Tar contains phenol, which is C_6H_6O, the carbolic acid basis; and there are phenols with eight and nine carbon atoms, and even ten.

It would fill this whole paper only to name the known carbon organic compounds containing the three elements C, H and O variously hooked together. But with all the knowledge of the many substances given out from tar, it cannot be said they are present in coal in the form they take on. But the main facts of physics can be relied on. Heat is swallowed up when solids are liquefied or liquids gasified, and these are the things that happen to coal when burned. They retard its perfect combustion, and the engineer who can best fit practice to meet nature's laws on proper conditions will best utilize coal as regards economy and cleanliness. The knowledge of what happens thermochemically in the life history of the hydrocarbons furnishes ample explanation of the failure of ordinary methods of burning it without heat or temperature conservation. The behavior and properties of the gaseous hydrocarbons may be regarded as the gaps in the bounding walls of knowledge through which glimpses may be had sufficient to serve as the jumping-off point of the flying machines of speculative imagination; and after all it is imagination which differentiates the engineer from the mere mechanic. Armies are never likely to be conveyed by either balloon or flying machine, but both these frail craft may serve to point the way by which an army may best proceed. The mere speculative engineer will not perhaps carry out work so well as the constructional man who follows beaten paths, but his speculative habit of mind does enable him to point the way for others to follow.

Individual Motor Drive for Woodworking Machinery

In the town of Sheffield, Penn., the Central Pennsylvania Lumber Company has located a new lumber mill for sawing rough boards, as well as finished lumber. The total capacity of the plant is about 175,000 feet of lumber per day, largely hemlock. The mill is of concrete construction throughout, securing as great protection from fire as is possible in a woodworking mill.

As is the case with nearly all new mills, electric power has been determined upon for driving the entire equipment. Wherever possible the machines are direct-connected to their driving motors. Three-phase, 60-cycle, 440-volt, alternating current was decided as the most satisfactory under all the conditions of service, and a complete power equipment, including boilers, engines, generators, motors, and all the necessary measuring instruments and controlling devices, has been installed and arrangements made to burn the refuse from the mill under the boilers.

The logs are conveyed up the incline from the pond by a "log chain," or "log jacker," into the mill, the jacker being driven by a 15-horsepower back-geared motor running at 850 revolutions per minute.

FIG. 1. MOTOR DRIVING AN 8-FOOT BAND SAW; 150 HORSEPOWER

The chain is 190 feet in length and carries 22 steel dogs for gripping the logs. From the top of the incline the logs are rolled either to the right or the left, as the equipment is provided in duplicate; that is, on the right are band mills, gang edgers and trimmers arranged for receiving the lumber from the left, and there is a similar equipment on the left for receiving lumber from the right.

The logs are first sawed into lumber by the 8-foot band mills, each of which is operated by a 150-horsepower motor running at 580 revolutions per minute. From both the band mills the sawed lumber is carried by live rolls and transfers to the re-saw mill. Each set of [illegible] live rolls is operated by a [illegible]-horsepower [illegible]-revolutions-per-minute motor through a back gear on the motor.

The re-saw mill cuts the lumber into thinner planks and boards, except in the case of the larger sizes, where the first cut by the band mills is sufficient. The re-saw is driven by a 150-horsepower motor, 580 revolutions per minute. On this re-saw mill are two 8-foot band wheels with 14-inch face. The motor is connected by belt to the lower band-wheel shaft and gives to the saw a speed of about [illegible] feet per minute.

From the re-saw the 1-inch and 2-inch material is carried by transfers to the two gang edgers, which saw the broader boards into standard sizes, as 10¼ inches, 8¼ inches, 6¼ inches, [illegible] inches, or [illegible] inches, etc. Each gang edger has eight saws, 24 inches in diameter, and is operated by a 50-horsepower, 1200-revolutions-per-minute motor, direct-connected to the shaft of the edger. After the lumber has passed through the edgers it is

FIG. 2. TRIMMERS DRIVEN BY 30-HORSEPOWER MOTOR

carried by line rolls to the trimmers, which consist of a row of saws mounted on swinging arms driven by belts from a line shaft. from which they are hung. The saws are spaced for trimming off the lumber ends, leaving standard lengths. One trimmer has eight saws and the other ten. Each set is operated by a 30-horsepower motor running at 840 revolutions per minute. The motor also operates a No. 2 Clark Brothers pintle chain for conveying the lumber away. The ten-saw trimmer is known as the 6 to 22-foot automatic trimmer, and will handle material up to 6 inches in thickness. The eight-saw trimmer is rated as a 6 to 24-foot automatic trimmer for use on material up to 11 inches thick.

After being trimmed the lumber is conveyed on a chain through the assorting shed where it is loaded onto cars by manual labor. The chain travels at the rate of 32 feet per minute, being driven by a 15-horsepower back-geared motor running at 1120 revolutions per minute.

Provision is also made for the removal of the refuse material by means of conveyers from the different mills. All sawdust is conveyed directly to the boiler room and automatically fired. From the band mills and the edgers the slabs are carried to slasher saws, which are saws

FIG. 3. RIGHT-HAND BAND MILL DRIVEN BY 150-HORSEPOWER MOTOR

mounted on a shaft and 4 feet apart. From the slashers the 4-foot lengths are taken, together with other refuse from the mills with the exception of the sawdust, by conveyers to a machine known as a "hog." A certain percentage of this material, however, before reaching the hog is taken out of the conveyer by hand and loaded into cars for shipment to paper manufacturers. This pulp wood is used in the manufacture of paper and must have a length of 16 inches and over. The balance of the refuse is cut into chips by the hog, from which it is dumped into cars for shipment to nearby tanneries.

The slasher is operated by a 30-horsepower, 840-revolutions-per-minute motor, which also operates six conveyer chains, each 100 feet in length. The hog is driven by a 75-horsepower motor, 690-revolutions per minute, direct-connected. It has a large rotating element weighing approximately 2000 pounds, which carries 24 knives on a diameter of 60 inches. Owing to the weight of the moving element of the hog, the starting conditions are particularly severe, but the motor, which is of the slip-ring type, brings the machine up to speed quickly without undue overload. The main refuse conveyer for carrying refuse to the boiler room is operated by a 10-horsepower, 1120-revolutions-per-minute motor.

The woodworking equipment was supplied very largely by Clarke Brothers, and the motor equipment by the Westinghouse Electric and Manufacturing Company.

The Small Fan in the Engine Room

By W. H. Wakeman

Many engine rooms are too hot to be comfortable, because no attention is paid to proper ventilation, but by locating a

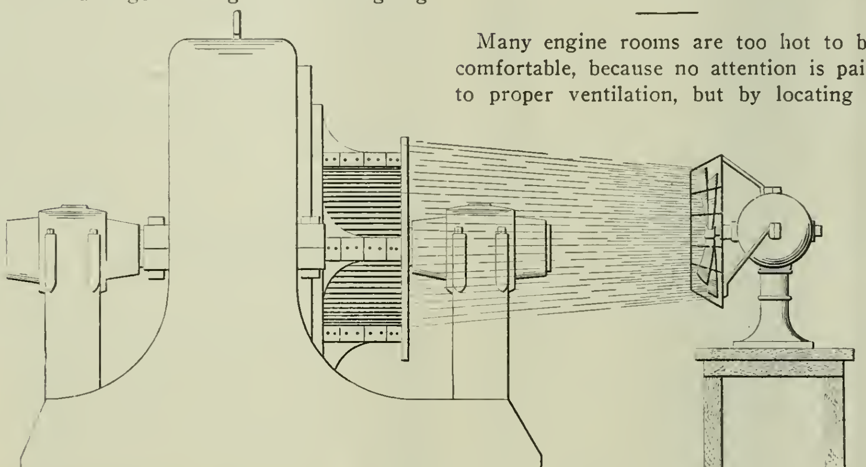

FIG. 1

small fan near a desk where the daily log is written, or if it can be moved from place to place in order to be near various repair jobs, it will add much to the comfort of those employed in this work, not only by admitting fresh air, but by keeping that which is already in the room from stagnation.

The brushes and commutator on one of my dynamos were running quite warm, and it was not practical to shut down or reduce the load. A small fan was located where it could circulate air rapidly over these parts, as shown in Fig. 1. By holding a hand in this air blast, not only near the fan but also after it had passed the dynamo, the difference in temperature was plainly felt, thus showing that much heat was dissipated by the swiftly moving air. In a short time the brush holders were as cool as before the machine was started. This is also a very good plan for blowing out dust that accumulates in the armature and field coils of dynamos and motors.

The success of this experiment suggested similar action when a main bearing began to heat and the result was very satisfactory. This is illustrated in Fig. 2, and it is much cleaner and better than the barbarous plan of turning a stream of water on a bearing that is warmer than it ought to be.

As the air blast carried off much heat in these two cases, why will it not do good work in the case of a gas engine, as illustrated in Fig. 3? It might not be sufficient for hard service, but it is worth trying, as it will save some or all of the expense of water for the jacket, and this is a comparatively large item in some cases.

Fig. 4 illustrates a fan blowing air on the cylinder of an air compressor, thus preventing an excessive accumulation of heat where it is not wanted. There are other places where the air blast from a portable fan will facilitate operations, or

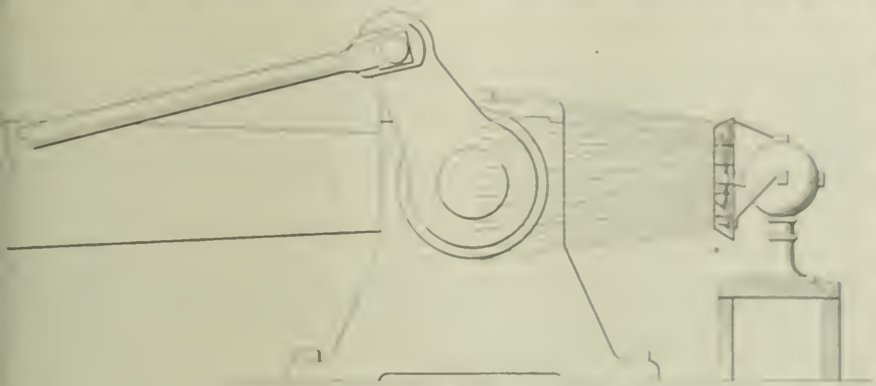

FIG. 2

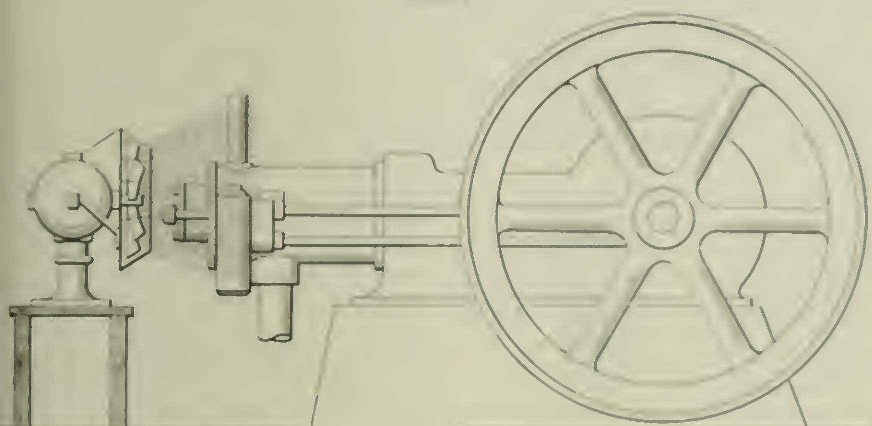

FIG. 3

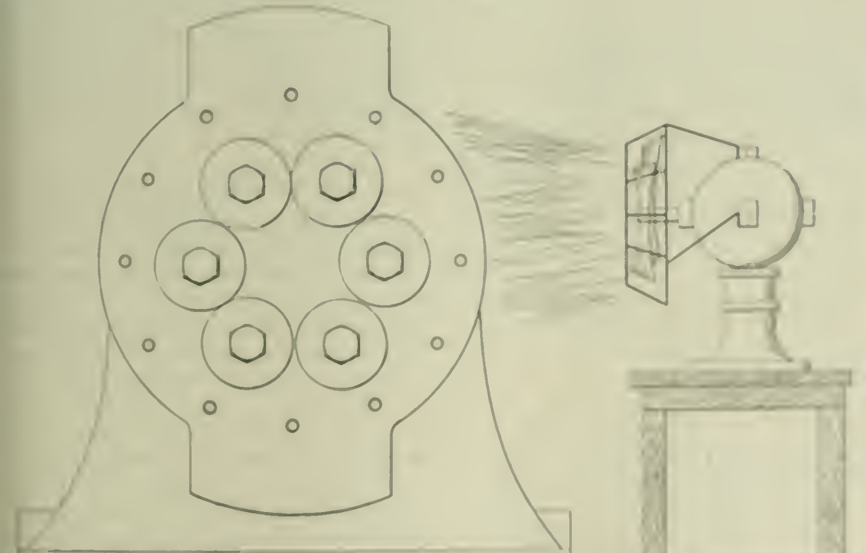

FIG. 4

render disagreeable work more comfortable, the details of which will occur to those engaged in such work after considering the foregoing incidents and suggestions.

The Operator for the Gas Producer

By J. C. Miller

The discussion that has been going on as to what grade of man is required to secure the best results from the gas producer, is very interesting to the writer and should be to anyone else who has started and operated different types of gas producer and had to secure satisfactory results from them.

The one element that must be considered above all others in gas-producer operation is reliability. Economy, ease of operation, adaptability to load and other good qualities fade into insignificance when compared with reliability. Reliability in a producer plant means, first, an ability to furnish a regular supply of cool gas of a uniform quality; second, a gas of uniform heat value regardless of the quantity supplied; third, means for cutting, removing ashes and clinkers and supplying water as required, without affecting the heat value or quantity of gas furnished.

The writer is convinced by his experience that more judgment is necessary for the proper operation of the gas producer than for that of the steam boiler. In the case of the steam plant, water must be kept at a certain level; the gage glass shows this. Pressure must be maintained; the steam gage shows what it is. Inspection of the fire may be made at any time by opening the fire door; ashes may be removed and the fire cleaned when the fireman wishes and while the plant is operating. With the boiler there is a guide for all operations and judgment is needed only in emergencies. The gas producer is a different proposition. The operations are concealed; no good view can be had of the fire; the heat value of the gas is a matter of judgment, and good judgment, too. No continuous record is at hand to guide. Gas-storage capacity is small, so the producer must be constantly in good condition to secure quick response to demands. The quality of the gas is affected by the depth of the fire, the steam supply, the demand, and atmospheric conditions, all of which are points upon which judgment must be exercised.

Salesmen's Unwise Claims

The salesman often tells the buyer that he can put in a charge of coal once or twice a day and leave the producer to its own care. This is untrue in practice and the claim is not necessary in order to sell the goods. If the demand for gas is uneven or if the heat in furnaces is to be maintained at constant value, attention at frequent intervals is necessary.

The gas-producer plant has no place for a cheap operator without judgment. The engineer of a steam plant will make the best man for it, if he comes with no prejudice. He will lead the novice in power-plant practice by all he has learned previously in boiler and fire management. If he operates a gas engine in combination he will find more place for judgment than in his steam plant.

Steam applied to the piston of an engine will produce motion and the engine will operate. With the gas engine it is different. Several operations must take place in perfect unison in order to make the engine operate and more things are liable to get out of order. Better judgment is needed to operate a gas-engine plant than a steam plant.

Some Recent Steam Engine Failures

Description of a Number of Interesting Accidents Which Were Reported by the Engineering Expert of a Casualty Company

BY HOWARD S. KNOWLTON

Four or five months ago, in Power and the Engineer, a number of steam-engine failures were presented, as drawn from the practice of one of the large accident-insurance companies during the past two or three years. A number of additional failures have since come to hand from the same source. Every casualty company dealing with accidents to power-plant machinery has exceptional opportunities to point out instances of poor practice and their remedies, and these practical considerations are independent of the locality in which the machinery is operated, in great measure. In the following notes upon some typical accidents to steam engines the report of the casualty company's engineer has been followed closely, and a few sketches have been included by way of illustration.

Condenser Water Backs up into Cylinder

One notable failure was of an engine of the cross-compound type, with cylinders 26½x40¼x54 inches, making 40 revolutions per minute with a boiler pressure of 80 pounds. Each cylinder had a slide valve at each end, and gridiron expansion valves of automatic type were used on the high-pressure cylinder. At the time of the accident the engine began to gain speed suddenly. The engineer shut the stop valve and the speed fell, but before motion ceased the bedplate on the low-pressure side broke and the crank pedestal was forced forward ½ inch. The piston was driven 1/16 inch up the cone of the rod, the cotter bent and the crank pin loosened. The speed increase was due to the governor losing control of the valves through the slackening of a set screw. The damage was caused by water in the condenser, as the engineer did not shut off the injection or break the vacuum. The speed was so slow that the water was forced into the condenser more rapidly than it was removed by the air pump, and thence flowed back into the cylinder through the exhaust pipe. An automatic cutoff gear and a vacuum breaker have since been installed at the suggestion of the casualty company.

Crack in Crank Pin

In another case an accident occurred to a horizontal tandem-compound engine with cylinders 20x43x54 inches, normal speed 52 revolutions per minute, and a boiler pressure of 125 pounds. The crank was of forged wrought iron or steel supposed to be shrunk upon the shank of the crank pin, which was also secured by a key. The journal of the pin was 9½ inches long by 6 11/16 inches in diameter, and the shank 7¾ inches long by 7½ inches in diameter; and between the two was a collar, as illustrated in Fig. 1. As far as was known the pin was put in when the engine was built, but it was not known when the key was put in. The large end of the connecting rod began to run warm and to knock, and red oil began to ooze out of the crank eye around the pin and key. A faint crack was noticed on the end of the pin at the back of the crank. The key was taken out, refitted and driven up tight; the bleeding continued and the crack extended until it reached entirely across the end of the pin.

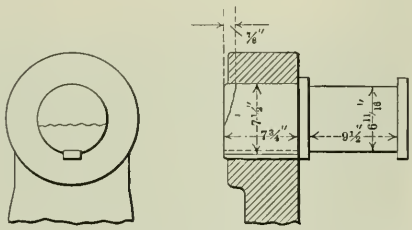

FIG. 1. CRACK IN SHANK OF CRANK PIN

As the pin was evidently slack and moving, it was thought best to take the pin out for examination, particularly as the extent of the crack was unknown. After some trouble and heating the crank eye with gas, this was done. It was then found that the shank of the pin had been bearing at the back and front at opposite ends of the diameter, lying in the plane of the line of centers of the engine, and that it had been moving and had worn the crank eye oval. A wedge-shaped piece had also been split off the end of the shank. The only probable solution was that the pin was turned out of an old crank shaft with a crack in it, which gradually extended when the pin began to get slack, and the pressure of the crank eye upon it became concentrated on the semi-detached piece.

Piston Bent by Closing Stop Valve before Breaking Vacuum

A case of piston bending occurred in a high-speed inverted triple-expansion engine making 383 revolutions per minute, with 14x20½x30x14-inch cylinders. The engine was direct-connected to a dynamo. The exhaust steam from the engine was led through a valve in the exhaust pipe to a jet condenser, or when this valve was closed, through an automatic atmospheric-relief valve to the outer air. The condenser was cleared by a pair of Edwards air pumps driven by an electric motor, the latter receiving current from the dynamo driven by the engine. Water for the condenser was taken from a pond whose surface was about 15 feet 7 inches below the centers of the cylinders. Thus, if the air pumps did not clear the condenser, the water from the pond would be forced into the low-pressure cylinder if the pressure in it were less than 8 pounds absolute per square inch.

The usual practice of shutting down was to close first the engine stop valve and then the valve in the exhaust pipe to shut off the condenser. On the evening of the breakdown this practice was followed, but the engine, instead of coming gradually to a standstill as usual, stopped suddenly as the engineer was about to close the valve in the exhaust pipe. The cause of the stoppage was an inrush of water from the condenser into the low-pressure cylinder, which bent the piston and stretched the bolts in both ends of the connecting rod. The accident was caused by the closing of the engine stop valve before the vacuum was broken. If the engineer had destroyed the vacuum, either by closing the injection valve, or shutting off the condenser, or by opening the atmospheric valve before touching the engine stop valve, the accident would not have happened.

Imperfect Weld in Piston Rod

An accident occurred to a 1500-horsepower horizontal tandem-compound engine, the normal speed of the engine being 39 revolutions per minute with a boiler pressure of about 100 pounds per square inch. The low-pressure cylinders were next the cranks. The piston rods, 5¾ inches in diameter, were cottered into the crossheads at the front ends and swelled at the back ends to receive the pistons. The enlarged ends were also bored to receive the front ends of the high-pressure piston rods, which were secured by the same cotters as the low-pressure pistons. One morning the rod of the low-pressure cylinder on one side broke without warning, about 22 inches in front of the piston. The cover at the back end of the cylinder was driven off, leaving pieces of the flange upon some of the studs. The other studs were broken. The high-pressure cylinder was split at the back in two places, and a piece measuring about 20x18 inches was knocked out of the side. The back cover was broken in pieces, which were blown against the end of the engine house, damaging the wall. Curiously enough, the pistons were undamaged save for the breaking of the rings. The rod was of steel and had been welded four years ago on account of a crack at the cotter hole at the back end. The appearance of the fractured surface showed that the weld had been very imperfect; the two pieces broken had been joined only upon the surface.

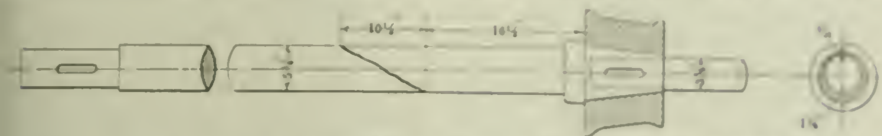

FIG. 2 BREAK IN LOW-PRESSURE PISTON ROD DUE TO IMPERFECT WELD

Crank Shaft Breaks Repeatedly

A case of shaft breakage occurred in a high-speed inverted vertical noncondensing double-acting two-crank engine, cylinders 9x15½x8 inches, direct connected to a dynamo and running 425 revolutions per minute, the boiler pressure being 140 pounds per square inch. The engines were installed in 1900. In 1905 the crank shaft was found to be slightly bent and was replaced, the old shaft being kept as a spare after being trued up by skimming up the bearings in a lathe. In 1907, after having run less than two years, the new shaft broke through the web of the crank next the dynamo, and a third shaft was ordered, the spare shaft first mentioned being used to keep the engine in service. The cause of the breakage was not ascertained. The company's inspector reported the shaft to be hard and brittle, but the makers of the engine stated that it was made from their standard quality of steel, of about 32 tons tensile strength. They considered the breakage to have been caused by the bearings being out of line or level, and advised that these bearings should be lined and adjusted before a new shaft should be put in. The dynamo armature was accordingly lifted, the brasses were relined with white metal and leveled, and the new shaft bedded upon them. Eight weeks later the new shaft broke in the same place as the old one. The two surfaces of the fracture were quite close when the inspector saw them, but when the shaft was taken out two patches of white metal were found imbedded in the crack. The makers of the engine again attributed the fracture to the bearings being out of line, but the casualty company's engineer decided that it came from improper treatment of the steel during manufacture.

A test gave an ultimate strength of 31.1 tons per square inch, an elongation of 18.5 per cent. in 2 inches, with a reduction of area of 41.56 per cent. The carbon was 0.36 per cent. The appearance of the fractured surfaces indicated overheating of the steel, though it was possible that with a speed of 425 revolutions per minute it might have been the result of excessive stress produced by cumulative vibrations synchronizing with the period of the engine.

Crack in Valve Chest

Another accident occurred to a horizontal triple-expansion engine installed in 1902. The high-pressure piston was 20 inches in diameter and one low-pressure piston, 37 inches in diameter, was coupled to the crank pin of the other, the cranks being set at right angles to one another. The stroke of all the pistons was 60 inches, and the speed about 62 revolutions per minute. The boiler pressure was 160 pounds per square inch. The high-pressure cylinder consisted of a plain cast-iron liner shrunk into an outer casing, with which were cast Corliss valve boxes and connecting passages. Longitudinal and transverse sections taken through the middle of the cylinder are shown in Fig. 3. After working five years, steam was observed coming from below the lagging, and on removing the latter a crack 31 inches long was found as indicated at *A A*. The weakness of the design, notwithstanding the cross ribs which stiffen the flat top of the steam passage, is self-evident and the fracture is not surprising. The danger of admitting steam at high pressures into cylinders and valve chests of weak design cannot be overestimated. In the case described a new cylinder was the only remedy, and while its construction was pending the old cylinder was kept in operation by strengthening the flat surfaces by clamps and stay-bolts.

was encountered in the instance of an engine, with 22x32x48-inch cylinders, making 52 revolutions per minute under 120 pounds boiler pressure. A new low-pressure cylinder was fitted to this engine which was a rather old machine. The cylinder was a casting about 8 feet long and of rectangular cross-section 45½ inches wide and 15 inches deep, the back, front and sides being flat and varying in thickness from ¾ to ⅞ inch. It was divided vertically by a flat portion of the same thickness into two passages, one next the cylinder of about 24x4½ inches internal measurement, which received the steam from the high-pressure cylinder and led it to the top and bottom steam valves, the other being farther from the cylinder, 24x7½ inches, for leading the steam from the top and bottom exhaust valves to the exhaust pipe and condenser.

The partition was stayed to the front and back of the casting by ribs near the top and bottom, but a central portion of more than 3 feet was unstayed. The pressure in the steam passage was about 25 pounds absolute, and the pressure in the exhaust passage about 3 pounds absolute, so that the unbalanced pressure on the partition was about 22 pounds per square inch, and on the front of the casing about 12 pounds per square inch. During the temporary absence of the engineer a piece 38x24 inches was blown out of the partition dividing the steam from the exhaust passage, and a corresponding piece of nearly the same size was blown out of the front wall of the casting dividing the exhaust passage from the air. The vertical cracks in both occurred at the junctions of the flat surfaces with the side walls of the box and extended the full length of the central portion unstiffened by the ribs. All were old, and those in the partition had worked their way through the full thickness of the metal for a length of about 18 inches on each side. Those in the outer wall had not penetrated very deeply. The defect was evidently brought due to working stress variations of pressure and possibly undue pressure when starting the engine. The final fracture was brought about by the low water level, the lever on the end of the bottom steam valve

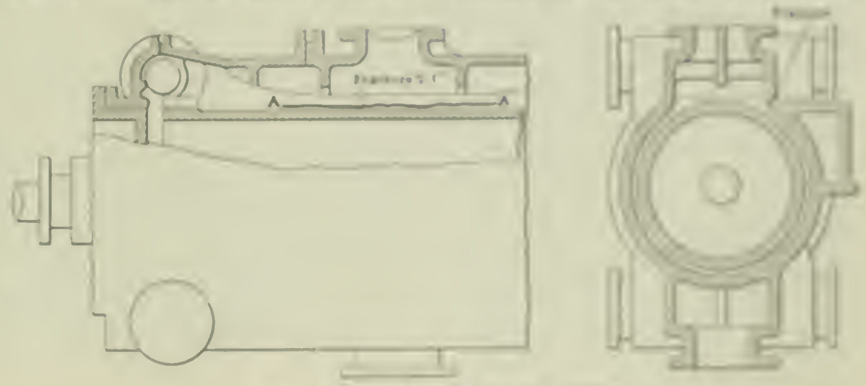

FIG. 3 LONG CRACK IN VALVE CHEST

Disadvantages of Rectangular Castings

An important case of cylinder breakage

spindle becoming loose and falling out, leaving the valve stationary and, as it happened, covering the port, so that the steam discharged from the lower end of the cylinder could not get into the lower end of the condensing cylinder, but remained in the cracked casting, practically doubling the pressure in it. The accident illustrated the great disadvantage in using rectangular flat-sided castings for holding steam. The existence of the cracks in the partition and of the incipient cracks in the outer wall, all running vertically up the junctions of these surfaces with the flat sides of the box, prove the inferior design of this form of cylinder even when stressed within the limits of ordinary practice, while the accidental loosening of a key is but one of the many other accidents which may occasion dangerous rises of pressure in the valve chests of the low-pressure cylinders of compound engines.

A Distorted Cylinder

Another engine to suffer accident was a vertical triple-expansion unit with 20¾x33x53-inch cylinders having a 36-inch stroke, running at 110 revolutions per minute and supplied with superheated steam at a pressure of 180 pounds per square inch by water-tube boilers. The engine was placed in service in the summer of 1907, and almost at once the high-pressure piston rings began to break and the piston to show signs of scoring. The trouble was attributed to priming, which was admitted to have occurred. The piston was taken out, filed smooth, and fitted with new rings. Later on these broke, and it was noticed that the piston and cylinder were scored at each end of a diameter and not all around the circumference. To shorten the stoppage in case of the rings again breaking a complete new piston was made, and to lessen the risk of binding the allowance between the diameter of the cylinder and piston was increased to 0.0265 inch. This piston was installed and appeared to work well. A little later the cylinder cover was taken off to test the tightness of the valves. When the steam was turned onto the valve chests, leakage was observed near the lower end of the cylinder bore, and a circumferential crack 8½ inches long was discovered. The cylinder was found to be scored in the vicinity of the crack and diametrically opposite it. The corresponding parts of the piston were also deeply grooved. Evidently the cylinder had changed its circular form when heated and became oval, the allowance made on the piston not being sufficient to compensate for its own expansion and for the deformation of the cylinder barrel. This allowance was increased to 0.04 inch when the new cylinder was put in. The deformation is readily accounted for, as the cylinder casting was very complex, containing not only the cylinder barrel, but four chests for drop valves, steam and exhaust nozzles and brackets for attachment to standards to which it was bolted. The position of the crack was just below the top of the bottom steam-valve box. Whether it was the result of heating or of stresses set up during the cooling of the casting is uncertain, though the former is probably the cause, for such circumferential cracks are not uncommon when there has been "seizing" between cylinder and piston.

In another case the horizontal low-pressure cylinder of a compound engine was found grooved and cracked in the same way after working for a short time with a piston 0.012 inch in diameter less than itself. The grooving was clearly traceable to the distortion of the cylinder bore, since it occurred in two places diametrically opposite each other. Similar circumferential cracks were found cutting through the grooves scored in the liner of the cylinder of an internal-combustion engine where the piston had evidently been too large, and having run hot had seized the cylinder wall. In this case the cracks

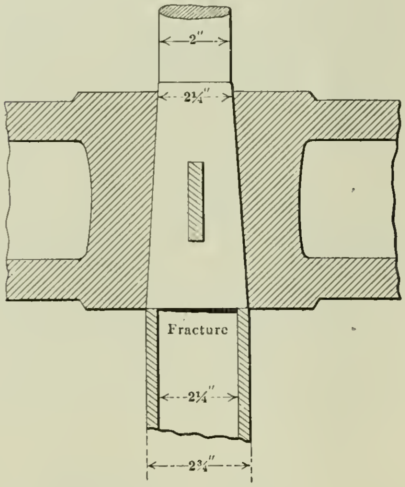

FIG. 4. FRACTURE IN PISTON ROD OF AIR PUMP

had clearly not been the result of cooling strains, as the liner was a simple pipe. These cases indicate that in turning pistons for cylinders of complex shape, allowance must be made not only for expansion due to the heat of the working fluid, but also for the distortion resulting from the unequal expansion of unsymmetrical shapes.

Fractures of Rod and Beam

A case of rod fracture occurred in an air pump run in connection with a horizontal cross-compound engine making 73 revolutions per minute. The air pump, single-acting, vertical, 19x21 inches, was driven from the low-pressure piston-rod crosshead by links, bell-crank levers and links to the pump crosshead. The crosshead was cottered into a cone upon the rod, as shown in Fig. 4, and the rod was guided below the crosshead by the gland in the air-pump cover and above by a brass bushing in a cross arm fixed to the engine bedplate, and not by the method of slide blocks on the crosshead arms. The upper part of the rod which passed through the guide bushing was 2 inches in diameter. The conical part on which the crosshead was cottered tapered from 2¼ inches at the upper end to 2¾ inches at the lower end, and the part below the crosshead was reduced to 2¼ inches in diameter, the shoulder at the junction of this part with the lower end of the cone being square. The lower part of the rod was sheathed with brass ⅜ inch thick. The rod broke at the abrupt change of diameter at the lower end of the cone where the brass sheathing began. The appearance of the surfaces of the fracture showed that the rod had been cracked nearly half way through before the final break. The fracture was caused by the bending stress produced by the horizontal component of the diagonal thrust of the links connecting the bell-crank levers to the crosshead, intensified by the abrupt change of section. Air-pump rods guided like this one, above and below the crosshead, but not by the crosshead, frequently break, but generally through the cotter hole, the hole being usually driven, as in this case, in a plane passing through the center line of the engine, so that the bending stress is concentrated at the edge of the cotter hole where there is little material to resist it. This is a typical case.

Another case of a broken beam may be cited, not as an illustration of the effect of overloading, but by way of a hint to those who have engines connected by shafting or gearing to other engines or turbines. In this case the engine, a condensing beam unit, with cylinders 28 inches diameter by 48 inches stroke, running at 33 revolutions per minute, was coupled to a water wheel by shafting and gearing. On the occasion of the breakdown, the water wheel was, as usual, started first, and immediately the engine beam broke off short between the air-pump gudgeon and the main center. Whether the breakage occurred before the piston had completed its first up-stroke or immediately after the driver had begun to open the stop valve to admit steam was not known, but it was clear that the water caused the trouble—presumably accumulation of condensed steam leakage on the top of the piston. There were no safety valves on the cylinder.

Wherever there is a line shaft attention should be given to keeping the shaft clean. Aside from other considerations an accumulation of dust and grease on the shaft is an added fire hazard. The easiest way to prevent dirt and dust from collecting is to provide each shaft with loosely fitting disks of strawboard, leather or other material, which are free to whirl, and as the shaft rotates, will travel back and forth preventing any deposit or accumulation of dust or oil.

Dimensions and Capacity of Rectangular Tanks

While tables are published showing the capacity, in gallons, of cylindrical tanks of standard size, the same is not true of rectangular tanks, for the possible combinations with three variables is so great that a complete table would be both cumbersome to handle and difficult to use.

The accompanying chart is designed to show graphically the dimensions of tanks having capacities up to 1500 gallons and multiples thereof. It being very easy in case the tank is of such dimensions as to contain over 1500 gallons, to halve one or two of the dimensions and multiply the capacity by two or four, as the case may be, or to find the capacity for 1 foot in hight and multiply by the hight. The chart may also be used where the capacity is given and the size is desired, or where the capacity and one or two of the dimensions are given and others are required.

The two following examples show how the chart is applied: What is the capacity in gallons of a tank 4x9x2½ feet? Starting with 2½ feet on the right-hand scale, read up to the line designated as 4 feet, then across to the 9-foot line and down to 675 gallons.

What is the hight of a tank 6x9 feet, to contain 1200 gallons? Starting at the 1200-gallon point, read up to 6 feet, then across to 9 feet and down to 3 feet.

W. L. D[illegible]

Brooklyn, N. Y.

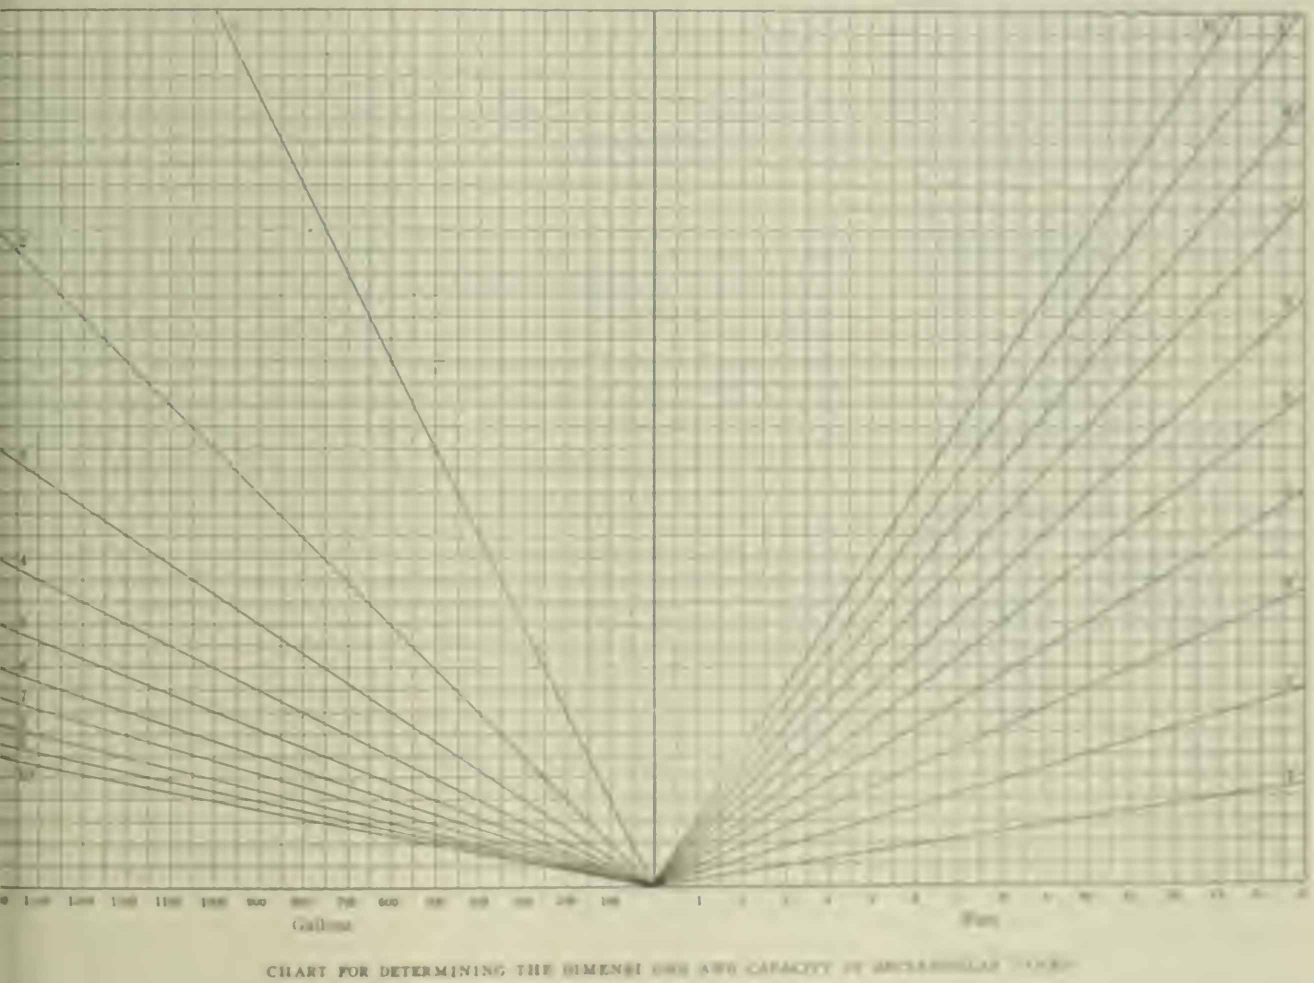

CHART FOR DETERMINING THE DIMENSIONS AND CAPACITY OF RECTANGULAR TANKS

To Handle Wood Economically

We are burning from 600 to 800 cords of wood per month. It is delivered by contract, as near the plant as possible to pile it, and we find that the rehandling from the pile to the boilers is an item of considerable expense. The plant is located on the side of a mountain, the inclination of which, at the point, is [illegible] as 45 degrees.

I hope that some of the readers will make suggestions as to the economical handling of such an amount of wood from piles on the mountain side to the boiler room, where [illegible] space allows only six cords to be piled at a time. The wood is cut [illegible] inches long.

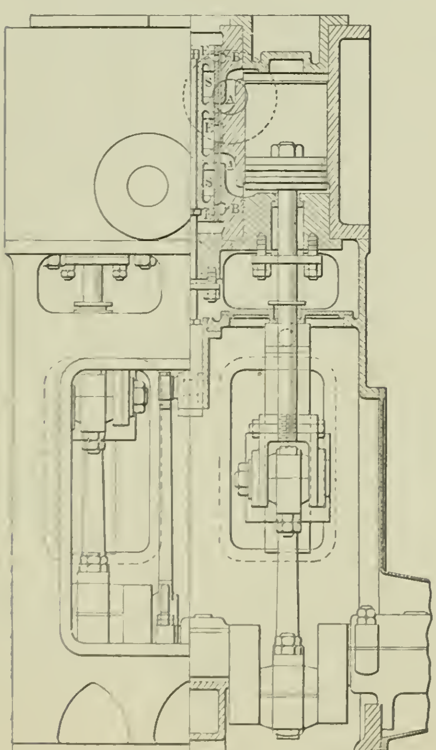
[illegible]

[illegible]

Central Valve Engines

Having seen in a recent issue an illustration of a central-valve engine of English design, I am inclosing a sketch of an American product which has proved to be very practical. The cranks of the engine are set at 180 degrees, as shown, with the single eccentric mounted on the shaft between them. The valve travels in a removable bushing, in which the ports are accurately machined; the valve, as shown, is in its central position. The spaces *S* are in communication with the steam pipe, while the spaces *E* lead to the exhaust pipe. At *A* and *A'* are ports to the right-hand cylinder, while *B* and *B'* lead to the left-hand cylinder.

The action of the valve is similar to any slide or piston valve, and if displaced upward an amount equal to the steam lap, steam will be admitted on one side through the port *A'* and on the other side through the port *B*, the exhausts at the same time being through ports *A* and *B'*, respectively. Cutoff and compression follow on the return motion of the valve.



AN AMERICAN CENTRAL-VALVE ENGINE

In practice the steam lap is a trifle greater for the top end of the cylinders and the exhaust lap greater for the bottom end. This in a measure offsets the irregularity due to the connecting rod and gives an earlier cutoff at the top and more compression at the bottom, as is customary in vertical engines.

Hyde Park, Mass.

The Centrifugal Pump

In the December 1 issue, George P. Pearce takes issue with my statement in a previous number that when the discharge opening of a centrifugal pump is closed no further power is required by the water within the impeller after having been brought up to speed. As pointed out in the original article, a certain amount of

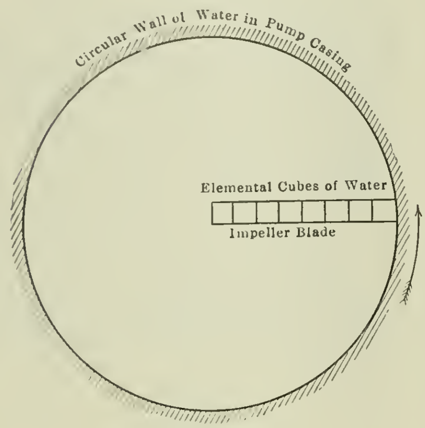

FIG. 1

power would still be required to overcome friction and to supply the energy wasted in eddies, but, as I understand Mr. Pearce, that is not in question and need not be discussed.

Mr. Pearce's position, and that of a number of other contributors, is indicated in the following paragraph from his letter:

"Surely a centrifugal pump running with suction open and discharge closed is operating under a considerable load, for the shape of the impeller is such that it is constantly trying to throw more water into the outer casing, and as this is impossible then it is forcing its way through the water against the resistance due to the pressure built up in the casing, due to its circumferential velocity."

No power or expenditure of energy is required to withstand a pressure as long as there is no flow, in the same way that no mechanical work is performed by a man carrying a hodful of brick on a level walk. The man does work in a mechanical sense only when he begins to climb the ladder and to create a flow of bricks from a lower to a higher level.

To put the case more graphically, consider Fig. 1. Let the radial line be one of the impellers of a centrifugal pump, and let the circle at its extremity be a solid circular wall of water in the casing of the pump. The little squares on the radial line represent cubes of water. Now, when the impeller is rotated the cube on the end will press outward by reason of the fact that it is continually constrained to change its direction of motion, and will exert a pressure upon the circular wall of water in the casing. The next cube will similarly exert a pressure on the first cube, and so on down to the center o[f] rotation. Each cube will try to push tho[se] ahead of it off the impeller, the resu[lt] being a certain definite pressure pe[r] square inch between the outside cube an[d] the stationary water in the casing. A[s] long as the impeller is rotating with uni[-] form speed, this pressure will be main[-] tained, and if it is assumed that the who[le] space within the circle be filled wit[h] water, there will be uniform pressure a[ll] around the circle. If it could be mad[e] a further condition that there would b[e] no friction between the outside cubes an[d] the surrounding wall of water no powe[r] would be required, once the mass of wate[r] in the impeller were brought up to spee[d] and at the same time the pressure woul[d] be maintained.

What actually happens is that a certai[n] amount of power is lost in skin frictio[n] in overcoming viscosity and in the pro[-] duction of useless eddies, both within th[e] impeller and in the surrounding cham[-] ber, but this consumption of power neve[r] amounts to as much as the power re[-] quired by the pump when delivering wate[r]. In fact, this loss of power due to frictio[n] and eddies remains, roughly the sam[e] whether any water is being delivered o[r] not, but an increased amount of power [is] required for accelerating new masses o[f] water as soon as delivery begins.

It is probably true, as Mr. Pearce state[s] that the eccentric casings used with som[e] centrifugal pumps cause an increase of th[e] losses due to eddies. On the other han[d] however, the casings of all, except th[e] last stages of most multistage pumps, ar[e] concentric with the shaft.

Mr. Pearce also refers to the shape o[f]

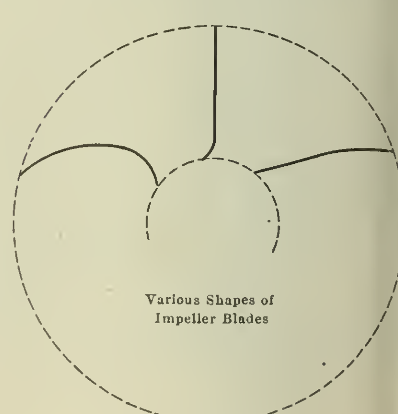

FIG. 2

the impeller being such that it is co[n]stantly trying to throw water into t[he] casing, and he will therefore probably [be] surprised to learn that the blades of i[m]pellers may have different shapes, [as] shown in Fig. 2, and that as long as t[he] delivery pipe is closed off these sha[pes] have little influence upon the amount [of] power consumed or upon the pressu[re] generated. As soon as flow begins, h[o] r, pumps with the different impellers ibit different characteristics.

Ir. Pearce asks if the charts which ompanied my first letter, showing that power required falls off as the flow is uced by throttling the discharge, were tted from actual tests or from theoreti- formulas. They were plotted from s and nearly all charts, wherein the ver consumed by centrifugal pumps is tted as one coördinate and water de- red as the other, show the same thing, power consumed at no load being newhere around a quarter or third of power consumption at the point of timum efficiency, upon which the nomi- rated capacity of the pump is usually ed.

Interesting Indicator Diagrams

Tracing Fig. 1, it will be noticed that both ends are joined. I have noticed several diagrams like these for five years past. None of us has been able to give the cause, although various arguments have been advanced. In the present case

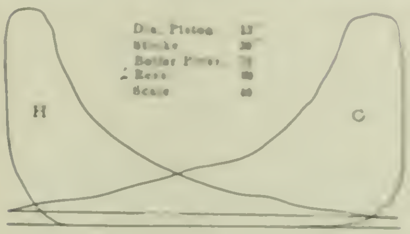

FIG. 1

the instrument was an outside-spring Tabor indicator, with Houghtaling reducing motion. The piping was ½ inch, with an angle valve at each end and there was an indicator cock between the indicator and piping. My assistant could not help making these diagrams, while I could not make one after him. I could not detect

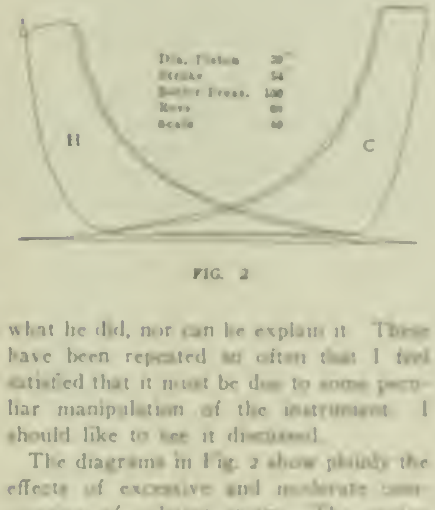

FIG. 2

what he did, nor can he explain it. These have been repeated so often that I feel satisfied that it must be due to some peculiar manipulation of the instrument. I should like to see it discussed.

The diagrams in Fig. 2 show plainly the effects of excessive and moderate compression of exhaust steam. The engine was an old one which had just been re-

FIG. 3

fitted. The condition of the engine can be considered fair. There was a marked difference in economy of fuel and possible load to carry. As refuse (wood) was the fuel used, I have to accept the report from the owner and the engineer that such is the case. The engine ran perfectly smooth in the last condition.

In Fig. 3, as the engine was with excessive compression, it ran jerkily. As left, it ran like a clock, as the saying is. The fuel here was mixed. In the last condition very little coal was required. I am told that the saving was about two tons per week.

J. R. Lamb[illegible].

Graphite in Boilers

One of the jobs I had in my earlier experiences was that of boiler washer in a plant containing six 250-horsepower water-tube boilers. These boilers were washed out every six weeks. When I close up a clean boiler, I put 2 pounds of flake graphite in each drum.

When a boiler was opened up after this treatment, and the turbine cleaner run through the tubes, the scale came off very readily. By examining the side of scale which was next the tube, graphite could be seen clinging to it. The same condition was found existing in the drums.

Since I received my license and had charge of boilers, I have used this same idea and find it works fine, especially in return-tubular boilers, where the tubes are harder to clean.

Chicago, Ill.

Storage Battery Troubles

In a recent number J. M. [illegible] states that he is having trouble with his storage batteries and that the plates were buckled when he received them. If that is the case, the batteries had been charged at some time, and very probably emptied of the electrolyte without properly discharging the batteries. In placing new separators they should be of the proper thickness, but the plates should not be scraped off to make them thinner. The plates should not have stood in the acid an appreciable length of time without charging, which should commence when the electrolyte is placed in the cell.

In reference to the batteries becoming dead, if sulphating has occurred it can be determined by the plates being lighter in color than they were originally, and pure white sulphate flakes may form over the affected parts. To remedy this the batteries should be charged for a long time at about one-fourth the normal rate. This must not be done unless it is positively known that sulphating has occurred, as low charging is harmful to batteries.

The batteries should also be examined to see that there is no deposit in the bottoms of the cells. The plates should not rest on the bottom, but should be raised enough to allow room for a reasonable amount of deposit under them. Careful examination of the connections between the batteries should be made, as a poor joint will corrode and, although the battery may be fully charged, it will be impossible to get any current.

Short-circuiting is a very prolific source of trouble. If current has been taken from only a few of the batteries instead of the complete set, it may be possible that those used most have been discharged too low. By connecting these batteries in the circuit they could be brought up and then placed in service again.

If 1.210 electrolyte is used, it should not go below 1.170 in density. When water is added, the electrolyte should be stirred with a glass tube, as the water is lighter and may remain on top.

C. A. DAVIES.

Cincinnati, O.

Some Indicator Diagrams

One feature of F. L. Johnson's article, entitled "Some Indicator Diagrams," needs to be discussed. It can hardly be denied that compression does lower the maximum output of an engine, but the

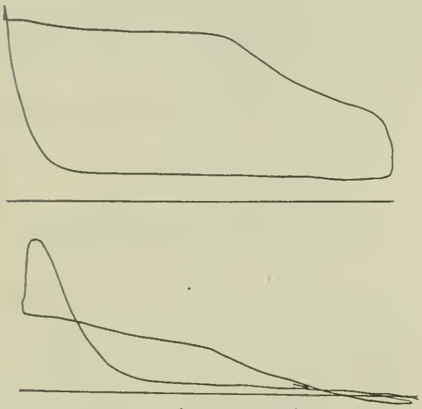

FIG. 3 (REPRODUCED)

case he cites, of an engine that was unable to carry its load after losing the vacuum, is not a fair argument against compression. The valves could have been set so as to retain the compression and a greater load could have been carried.

My idea would have been to ignore equal distribution of load between the cylinders and adjust the low-pressure cylinder cutoff equal to the ratio between the high-pressure and low-pressure cylinders. This would result in little or no drop between the high-pressure cylinder and the receiver and, although the low-pressure compression would be more than desirable, it would not rise above the admission line and make the loop (in his Fig. 3), which is negative. The loop at the other end of the card would also be eliminated, and the engine could carry a heavier load than it did under the conditions mentioned.

A. L. HOYLE.

Philadelphia, Penn.

I should like to know why the admission line leans in above the atmospheric line in Mr. Johnson's Fig. 4, which is a low-pressure card. I get practically the same result from the engines I am running.

WILLIAM HOPKINS.

Hastings, Mich.

[In the case mentioned the valve was set with little lead; the piston, therefore,

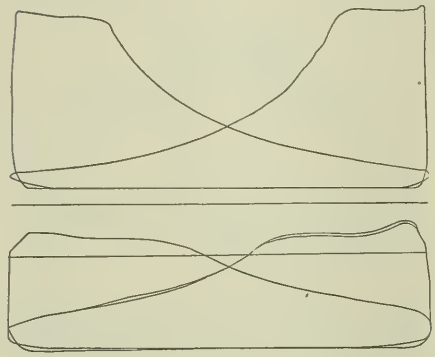

FIG. 4 (REPRODUCED)

began its stroke before the valve opened the port enough to supply the steam pressure necessary to produce a vertical line to the top of the diagram.—EDITORS.]

Location of Steam Traps

In Fig. 1 is shown the ordinary arrangement of the small trap, in connection with the steam separator, which is a fair example of the way they are found in active practice. I have observed, in

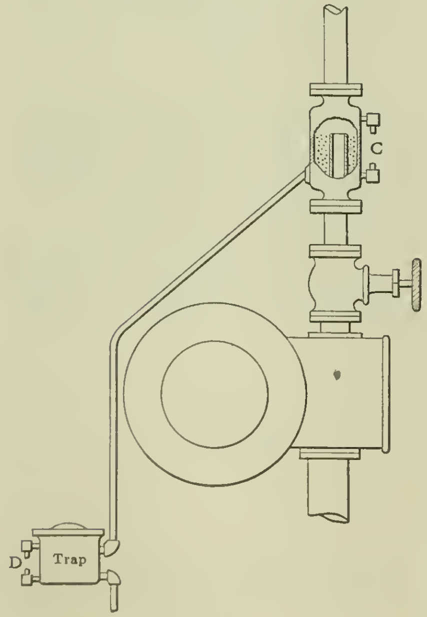

FIG. 1

connection with the placing of traps, that a long pipe of small size is run from the separator to the trap. While the trap may discharge the accumulated water quickly, the new discharge has to come through this small pipe. Some bad water wrecks have occurred from this arrangement.

A steam separator or trap should be no larger than necessary to do the work, as the two appliances present radiating surfaces which are wasteful even though they are well covered. This is no reason for selecting one so small that it will not work satisfactorily, however.

The placing of the steam drums to be drained by the trap may be so as to give the trap more advantage and facilitate the safe working of the whole system. An example is shown in Fig. 2. A better arrangement would be to have the steam drum as shown in Fig. 3; this is a much safer drum and costs no more than the other type.

The entering pipe should not be placed too close to the lower surface, as room must be allowed for the collection of the condensed water going to the trap, otherwise a counter current might be started

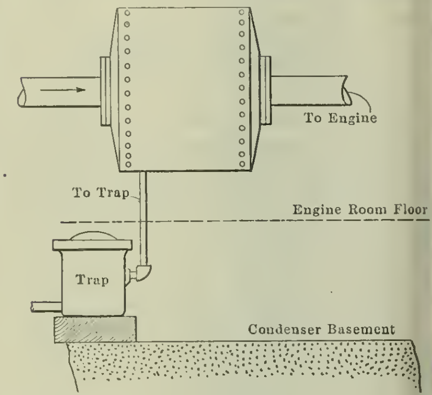

FIG. 2

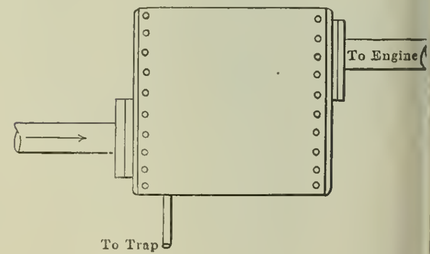

FIG. 3

and carry the water through the main t the engine.

C. R. McGAHEY.

Lynchburg, Va.

Probable Cause of Air Compresso Explosions

On one occasion I had to look for th cause of two air-compressor explosion The air was compressed to 17 pounds pe square inch. In both cases the pipe were ruptured. Various theories wei investigated, such as simple failui of the pipe, oil spray in the pip oil ignition at the extreme end, po grade of oil, leaky discharge valves. Tl last-named offered the most plausible e: planation, as air which had been con pressed evidently leaked back into tl cylinder where it became recompresse This recompression will make it hott ıd hotter until it either reaches a point here radiation will take the heat faster an the temperature can rise, or the temerature will rise until the oil catches e. The best of oils will take fire if eated enough.

xtraneous Supervision of Power Plants

The recent quotation from a pamphlet nt out by the Engineering Supervision ompany, of New York, and which Power w fit to comment upon editorially in the ecember 29 number, needs more than a ssing glance.

The statement made in reference to gineers being led astray by ambitious ents to the extent of receiving from 10 50 per cent. of the cost of work done d possibly of supplies purchased is aritable to the engineer, because he has en led by the ambitious agent. Such statement is an insult not alone to the gineer, but also the agents. A wide perience with engineers and supply ents, combined with a practical experice of more than 20 years, forces me to ate that the author of the pamphlet in estion should quickly join the famed nanias club. The statement that more an one-half of the plants are afflicted such practice is most absurd and shows nclusively the attempt of the company belittle the engineer in the eyes of his nployer simply to gain the business they ek. Such tactics are contemptible and neath the consideration of any fairinded man. A concern which tries to cure business by any such methods is neath the consideration of business men, ho readily recognize the despicable arguents as being in keeping with some busiss firms which try to injure competirs by just such tactics.

Any concern which feels that it is not ing used right by the engineer has the ivilege of making a change at any time, d while there may be some engineers ho are out for graft, the percentage is r from the 50 per cent. mark referred in the circular. The practice may have en in vogue in years past, but today the gineer realizes that the better the relts produced by himself the more valuae his services are. He knows this beuse he sees his fellow associates being evated to higher stations, and while he looking for advancement he knows full ell it cannot be attained by following up e methods referred to.

Agents who have meritorious articles r sale are able to make good without ying to bribe the engineer. They realize w impossible it would be to do it, for eir association with engineers has educated them to the realization that engineers are as honest a body of men as exists in the world today. An agent will hesitate before trying to sell a worthless article by any such methods, for he fully realizes that the law is waiting for him; he also realizes that a sale made under such conditions means that he can control the business only until some other man like himself underbids him. The cost to a firm conducting business under the specified conditions is beyond recompense where an article of any worth is sold, and the sale of an unworthy article is followed, as it would work a serious injury to the man recommending the purchase.

The attempt to belittle the competency of engineers by referring to them as nontechnical, is somewhat modified by reference to their practical knowledge received through hard knocks.

Experience has told the employer that the man who has received practical education is the man to employ, if results are desired. Men of this class have their minds broadened by the world's greatest teacher. While they have no sheepskin to show that they graduated from some engineering college, they are in the large majority capable of giving engineering advice about the installation and operation of plants that will be worth more than that given by the technical man without practical experience. Practical experience is only gained by the work required in actual operation of a plant. It cannot be obtained by casual observation, or from a few days spent now and then in making some test. The president of one of the largest technical schools in the world once said that they did not turn out engineers, but simply prepared them, and out of the graduates not 50 per cent. ever became engineers. There is good reason for the above statement, for unless a man has an aptitude for engineering he will never be a success, whether he be college bred or practical.

The technically educated man has an advantage if he will only improve it. To do so he must of necessity start at the bottom of the ladder and work his way through the hard school of practical experience and with the advantage of his early training he will reach the goal far in advance of his less fortunate brother and be a far better man, provided he is adapted for an engineer's life. Such a man will be able to give to his employer the very best there is, but until technical men are willing to start in a menial position and work their way up, the present type of practical man, who has some technical education obtained by home study, by absorption from the mechanical press and through the engineering associations, will prove far more efficient. Possibly a little more coöperation on the part of an employer, by the devotion of time to consider the problems that confront his engineer, would be profitable.

The proposed scheme of supervision would lead to the complete control of the various plants. As the pamphlet has decidedly stated that more than one-half of the engineers are grafters, it might not be amiss to suppose the supervisors to be slightly affected along the same line. It is a possibility so to supervise that the employing firm would in a short space of time be forced to expend a large sum to bring the plant back to its past efficiency. It would make no difference to the supervisors, as they would have theirs and that is all they are looking for. It is no charitable game, just business which they are trying to obtain by false representation. It is a serious proposition to be considered by engineers in general and also by business firms before accepting any proposals from such a concern. The engineer will be forced to lower his station in life to that of a mere businessman. His compensation for a like service will be less than the common laborer gets. The business firm which enters into a contract with such a company will be badly stung and the end will be a return to present methods. A competent engineer with coöperation on the part of the employer makes a combination that cannot be beaten.

T. N. Kelley.

Lowell, Mass.

What Reversed the Polarity

In answer to the recent inquiry under the above heading the writer wishes to state that he has had the same experience on three occasions in operating a 75-kilowatt DeLaval steam-turbine dynamo set, consisting of two 37½-kilowatt 125-volt generators connected to a three-wire system, for the operation of lights at the mills and a motor or two. In each case the trouble manifested itself on attempting to start the set in the morning.

I therefore concluded that the polarity was reversed in shutting down, due to a poor connection in the armature or field circuit of one machine, which caused the voltage to drop more rapidly on this machine than on the other. With any other motors running, or any other apparatus on the 250-volt mains, the machine with the lower voltage would naturally be reversed.

After three tests occurring calls to get this machine to generate correctly, I decided to supply the field windings of both machines from one of them, and I have had no trouble from this source since. As more than two years have elapsed since this experience, I feel that it is a permanent remedy for the trouble cited.

The Plunger Hydraulic Elevator

Operation of the Valves in the "Standard" Plunger Freight Elevator Clearly Explained; How the Lifting Cylinder is Designed

BY WILLIAM BAXTER, JR.

For the operation of freight elevators the Standard Plunger Elevator Company provides simple hand-rope-operated valves. These valves are made to be moved by a lever if the car speed is very low, by single-geared rack and pinion for moderate speed and by a double-geared rack and pinion for high velocity; they are also of the balanced and unbalanced types. An

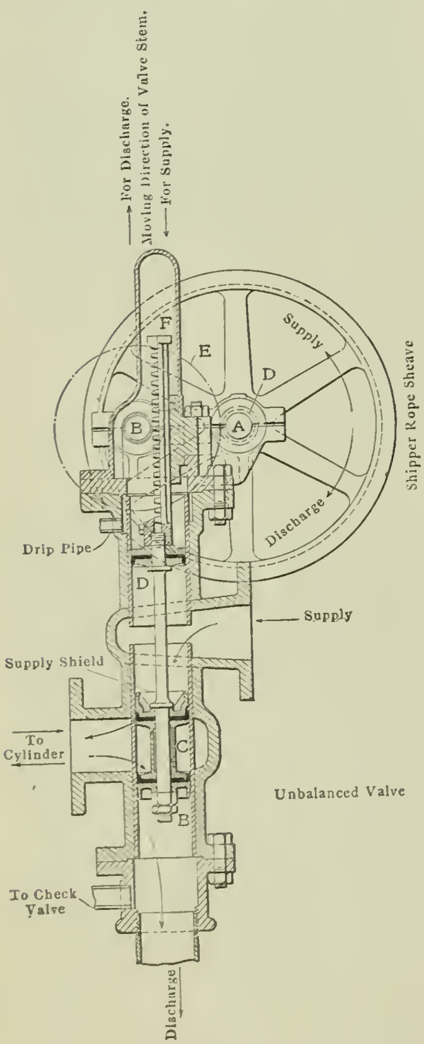

FIG. 287

unbalanced-type valve with double-geared rack and pinion is shown in Fig. 287, and a balanced valve of similar design in Fig. 288. The unbalanced valve is not, strictly speaking, unbalanced; it is only so when used in an installation where the discharge tank is located higher up than the valve. Looking at Fig. 287 it can be seen that if the pressure acting upward against the under side of piston *B* is the same as the pressure acting downward on piston *D* the valve will be perfectly balanced, because the pressure from the supply tank acts equally against the under side of *D* and the upper side of *C*. The pressure of the atmosphere acts on top of *D*, and if the discharge tank is on a level with the valve, the same pressure, or nearly so, will act under *B*; therefore, the valve will be fully balanced. If, however, the discharge tank is several feet above the valve, the pressure acting under *B* will be greater than that acting down on *D*, and the valve will not be fully balanced. The valve in Fig. 288 is fully balanced, no matter whether there is a back pressure from the discharge tank or not, because this pressure acts equally against the under side of piston *B* and the upper side of piston *A*; and the pressure of the atmosphere acts equally against the under side of *A* and the upper side of *D*. For slow-speed cars this type of valve is better than the complicated pilot valve, with its accompanying automatic stop valves, because it accomplishes all that the more complicated and expensive construction can accomplish and, being far more simple, is not as liable to get out of order. It is not desirable for fast-running elevators, however, because the movement of the car cannot be controlled with as great precision by means of the hand rope, owing to the rapid motion of the car and the long distance through which the rope has to be pulled to effect a stop. This is the only advantage of the pilot valve with car-lever control. With it a fast-running car can be stopped even with the floors of the building by anybody after a few days' practice, but with the hand-rope control only the most experienced car operators can obtain results that are at all satisfactory in large office buildings.

Lifting-cylinder Design

The casting that forms the upper end of the lifting cylinder is made in several designs by the Standard Plunger Elevator Company, one design being shown in Fig. 289, which is a vertical sectional view. The main casting is marked *A*; at *B* is the stuffing box and *C* is the upper end of the top-pipe section of the cylinder. The casting *A* is provided with a brass sleeve *D* that fits the lifting plunger and serves as a guide for it. This sleeve fits tightly at the upper end all the way around the circle, but at the lower end it is held in the central position by means of radial webs *A' A'*, which are narrow enough to afford free passage for the water but at the same time firm enough to give the sleeve proper support. Their construction is more clearly shown in Fig. 290, a horizontal section through the lower end of *A* and *D*. The stuffing box *B* is pro-

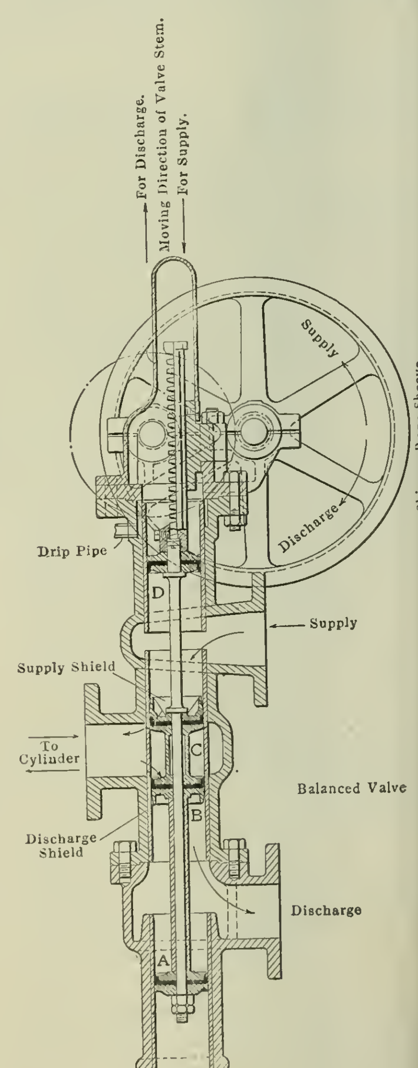

FIG. 288

vided with a gland *E* pressed down by studs *F*. The box itself is secured to *A* by studs *F'*. The packing may be of hemp, or any good, soft packing material, but usually a special design of double cup packing is used. The stuffing box is made with a rim *B'* which forms a basin to catch any water that may leak out of the cylinder. A drain pipe *B"* is tapped in

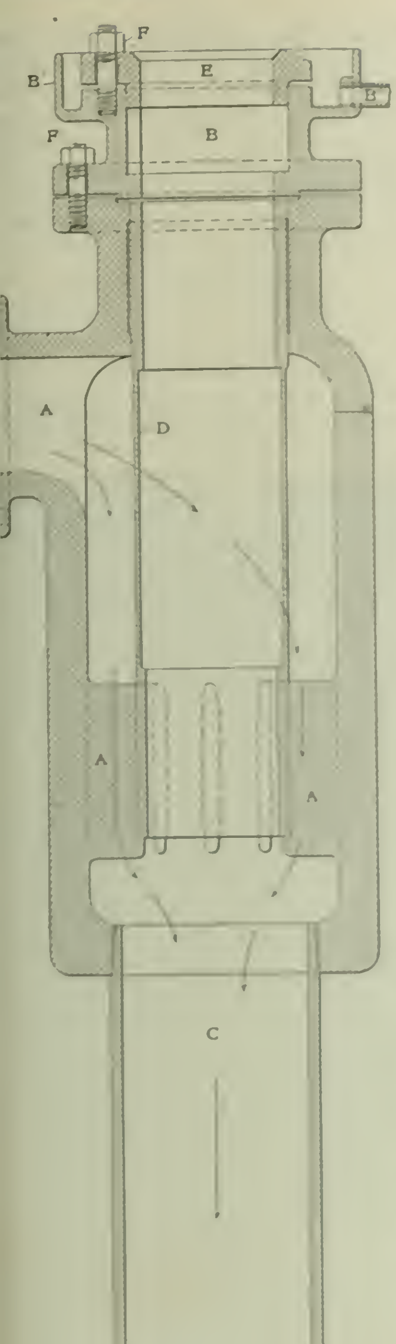

FIG. 289

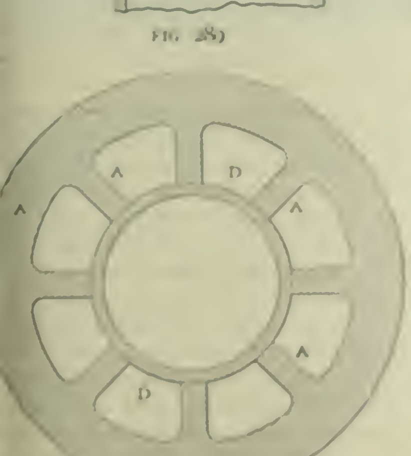

FIG. 290

on one side to remove the water as fast as it accumulates.

Fig. 291 is a vertical section of the plunger end used in connection with the cylinder top shown in Fig. 289. This end is made up of the parts *A*, *B*, *D* and *F*, which are held together by a long central bolt *G*. The upper part *A* is screwed into the lower section of the plunger *P*. The parts *B*, *D* and *F* are pressed tightly against each other by the bolt *G* and nut *C*, and all these parts are held firmly against *A* by screwing the end of *G* into *A*, as shown. The parts *A* and *D* are made of cast iron, which would rust in time, as this part of the plunger does not ordinarily run up into the sleeve *D* of the cylinder-top casting, Fig. 289. On this account these parts are incased in brass, as shown at *A'* and *E*. The construction of the upper part *A* is simple, but the part *B* is better illustrated in Figs. 292, 293 and 294, the first being a view similar to that in Fig. 291, the second a horizontal section through *L L*, Figs. 291 and 292, and the third another horizontal section on a line just above the nut *C*.

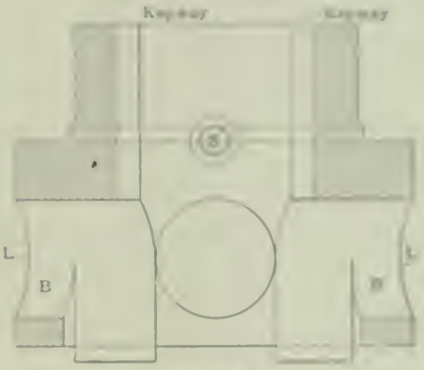

FIG. 292

Fig. 291. This piece, it will be noticed, has four holes marked *B'* that radiate from a central opening larger in diameter than the bolt *G* opposite and below these holes. Above the holes the center hole of *B* fits the bolt *G* and the latter is kept from turning in it by the two keys *K K*, Figs. 292 and 294.

The part *D* is simply a cylindrical piece shaped at its ends to fit over a projection depending from the under side of *B* and into a recess bored in the upper end of *F*, this construction being designed to bring the parts central when the bolt *G* is screwed up into the part *A*, as may be seen in Fig. 291. In this latter illustration it will be noticed that a screw *S* is run into the joint between *B* and *A* so these two parts cannot turn around with reference to each other and work the bolt *G* loose. The keys *K* prevent *G* from turning in *B*; as all these parts are securely locked, therefore, the nut *C* cannot turn, but even if it did it could do no harm because after bolt *G* is screwed up tightly in *A* the nut is not depended upon; in fact, its principal object is to hold the lower parts together when this

FIG. 291

are disconnected from part *A*. The lower casting *F* has a longitudinal opening through it considerably larger than the bolt *G*, and this opening has lateral connections with the exterior of the casting. As the part *D* is also hollow, there is a free passage through the end of the plunger from the bottom of the casting *F*

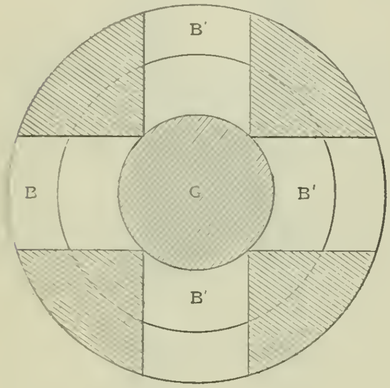

FIG. 293

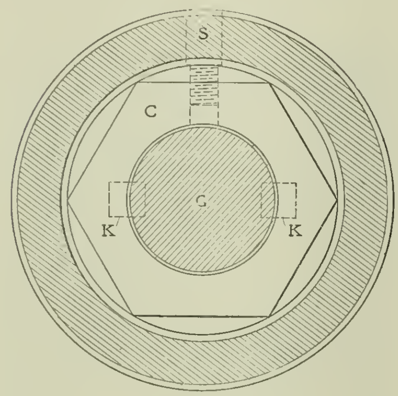

FIG. 294

to the holes *B' B'* in the part *B*. The object of this construction is to provide positive means for stopping the upward movement of the elevator car before it reaches the overhead beams, if for any reason it should fail to stop at the upper floor. When the elevator is in perfect running order, the top automatic valve will stop the car even with the upper floor and then the holes *B' B'* will be some distance below the stuffing box in Fig. 289, but if the stop valve fails to operate and the car continues upward, it will not rise far enough to strike the overhead beams before the holes *B'* will pass above the stuffing box, the water in the cylinder will find an outlet and the plunger will rise no farther.

Saturated Air as a Cooling Agent

By Arthur Pennell

Whenever it is desired to liquefy steam or other condensable vapor, some cooling agent must be employed which has the ability to absorb the heat evolved by such condensation and act as a vehicle for its disposition by some natural means. Cold water, the most obvious agent for the purpose, is often unattainable or too expensive. Air, which is omnipresent in unlimited quantity, also possesses properties which render it an efficient cooling agent.

Some Properties of Air

Absolutely dry air does not exist in the lower strata of the atmosphere. It always carries, mechanically mixed with it, more or less water vapor. Air is said to be saturated with water vapor when a cubic foot thereof consists of a cubic foot of water vapor at the elasticity due to the temperature and a cubic foot of dry air whose elasticity is the difference between the barometric pressure and the elasticity of the water vapor. The humidity of such air is 100 per cent. The two mixed form one cubic foot of saturated air at barometric pressure.

Everybody must have witnessed a white fog in a valley on a bright summer morning. The air in the fog must have been completely saturated inasmuch as minute vesicles of liquid water were visibly floating therein. As the sun rose higher and higher, the fog gradually dissipated. Sufficient heat had arrived both to vaporize the liquid vesicles and warm the air sufficiently to be able to absorb it. If, at such moment, the shade temperature was 62 degrees Fahrenheit and the barometric pressure 29.92 inches of mercury, each cubic foot of such air would have weighed 0.0761 pound and consisted of a cubic foot of water vapor at an elasticity of 0.556 inch of mercury weighing 0.000881 pound, and a cubic foot of dry air at an elasticity of 29.92 —0.556 inches of mercury, weighing 0.0747 pound. Further, each pound of dry air present would have carried 0.01179 pound of water vapor. By noon, we will assume the shade temperature had risen to 82 degrees Fahrenheit. The air was no longer saturated but carried the same load of water vapor in a state of superheat. If such air had the opportunity of passing

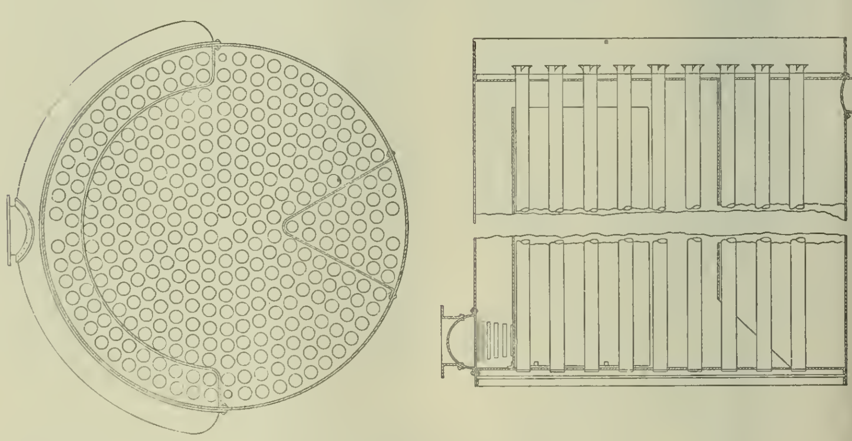

FIG. 1. SURFACE CONDENSER USING AIR AS COOLING AGENT

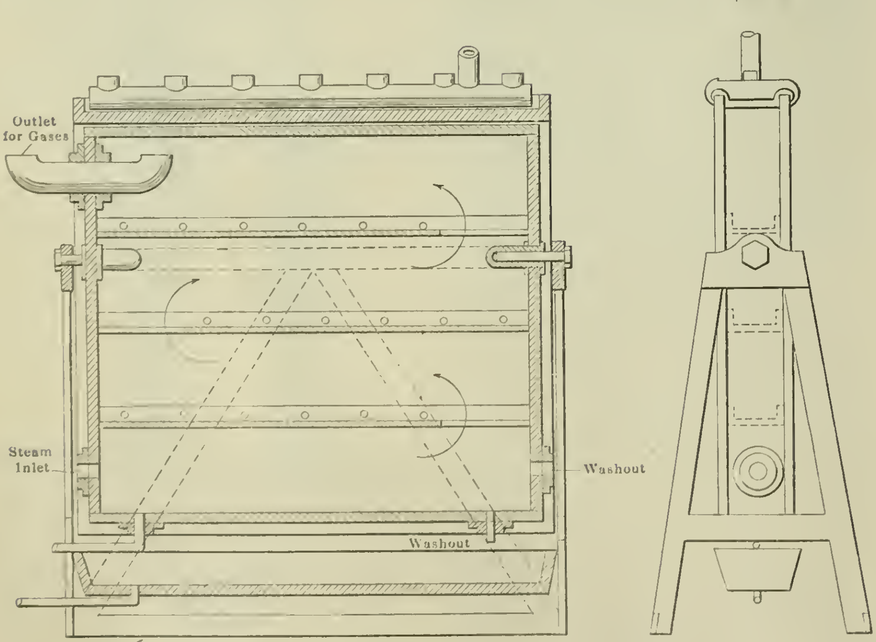

FIG. 2. SINGLE UNIT OF PENNELL FLASK-TYPE STEAM CONDENSER

over a wet, hot surface, it would absorb water vapor at the expense of the heat of the surface. Should it succeed in saturating itself with such water vapor at 82 degrees, the pound of dry air would be mixed with 0.02361 pound of water vapor and would have absorbed 0.01182 pound of water vapor from the hot, wet surface. A familiar practical example of the foregoing occurs whenever a freshly sprinkled street pavement is drying under a hot breeze.

Some Test Data

Fig. 1 shows sections of one of a pair of condensers using saturating air as a cooling agent, erected on the premises of the Armour Packing Company, of Kansas City. They were designed to condense, at atmospheric pressure, the exhaust steam from a number of simple engines developing a total of about 1100 horsepower. As one of them, while clean, was able to perform the duty, and a compound engine was being installed, the second outfit was equipped to condense the steam from the compound engine. The results of a [illegible]-hour test follow, this condenser operating upon a York cross-compound refrigerating engine, 30x58x48 inches, running at a speed of 45 revolutions per minute:

Average steam pressure at engine gage, lb.	[illegible]
Average vacuum per engine gage, in.	[illegible]
Average temperature in condenser, deg. F	123.7
Average temperature of circulating water, deg. F	118.4
Average temperature of city water, deg. F	52
Average temperature of outside air, deg. F	81
Average temperature of saturated air at condenser, deg. F	108
Average draft in stack of condenser, in.	0.1
Average humidity of outside air, per cent.	87
Total amount of steam condensed, lb.	71,[illegible]
Average amount of steam condensed per minute, lb.	12[illegible]
Total amount of circulating water used, 16,700 cu.ft., or lb.	[illegible]
Average amount used per minute, 235.17 gal., or lb.	1911.22
Total amount of city water used, [illegible] cu.ft., or lb.	31,[illegible]
Average amount used per minute, [illegible] gal., or lb.	[illegible]
Ratio of circulating water and steam condensed	[illegible]
Ratio of city water and steam condensed	[illegible]
Average horsepower per hour as engine during trial, per indicator cards	[illegible]
Average pounds of steam used per I.H.P.	[illegible]
Average horsepower required to run air pumps	[illegible]
Average horsepower required to run circulating pump	[illegible]
Total amount of condensing surface, sq.ft.	[illegible]
Amount of steam condensed per sq.ft. surface per hour, lb.	[illegible]
Cost of city water for [illegible] hours [illegible]	[illegible]
Cost of circulating condensing water [illegible]	[illegible]
[illegible]	[illegible]
Cost of water for 500 indicated horsepower for 24 hours, under existing conditions, $	[illegible]

FIG. 3. AN ICE-PLANT INSTALLATION OF THE [illegible] CONDENSER

Assuming water being pumped direct from the Kaw river at a temperature of 75 degrees Fahrenheit, a lift of 40 feet, and the condenser requiring 9.2[illegible] pounds of circulating water per pound of steam condensed. Five hundred indicated horsepower (7075 pounds steam) will require 65,[illegible] pounds of circulating water per hour, or, 1,088.75 pounds per minute; lifting 1088 pounds per minute would require 1.32 horsepower; adding 50 per cent. for friction, 1.98 horsepower, which at 15 cents per horsepower for twenty-four hours, would cost 29.7 cents.

The elasticity of vapor at this condenser temperature, 123.7 degrees Fahrenheit, is 3.827 inches of mercury, which deducted from the average barometer reading for this day, 28.98 inches, shows the ideal vacuum would be 25.153 inches; however, this ideal is impossible to obtain by mechanical means. About 21½ inches should be obtained under best conditions.

It will be noted that the total weight of steam, condensed at a temperature of 123.7 degrees Fahrenheit, was 71,530 pounds. The condensation was effected by the atmospheric vaporization of [illegible] cubic feet, or 31,130 pounds, of water. The weight of water atmospherically vaporized was only 43.5 per cent. of the weight of the steam condensed. This result will be corroborated by the result of another test made elsewhere, several years later, on another type of condenser.

The amount of steam condensed per square foot of surface per hour was [illegible] pounds, when the condensing temperature was 123.7 degrees, while the initial and final temperature of the circulating water was 118.4 degrees. This figures out [illegible] B.t.u. transmitted per square foot of surface per hour for 1 degree of difference. The surface was somewhat coated with scale. The draft, due to 40 feet of flue was 0.1 inch of water. Manifestly, to obtain the low condensing temperature necessary for high vacua, artificial draft, capable of supplying three times the volume of air, would have to be installed.

A new field is now being opened for a suitable modification of this type of condenser in oil refineries, for condensing petroleum vapor. As these vapors arrive at temperatures ranging from below 100 degrees Fahrenheit to over 600 degrees, the facility of controlling the cooling agent is of considerable economic value.

Fig. 4 represents a flash type of condenser for steam at atmospheric pressure for use in ice plants. The steam enters near the bottom, follows the course indicated, condensing as it goes toward the outlet at the far end of the top line, where the noncondensable gases escape into the air. The condensation water is led away from an outlet at the bottom. The circulating water is caused to flow in a thin sheet over the surface, thoroughly wetting it down, to be received in a collecting trough and thence into a catch can, from which the circulating pump returns it to the distributing system on the top.

Conditions were such that only 10-minute tests were practicable, the results of one of which is appended:

Time, Min.	Surface, Sq. Ft.	Condensed Water Entering Hot Well, Gal.	Decrease in Connecting Can, Gal.	Temp. Circulating Water, Deg. F.	Temp. Issuing Gases, Deg. F.
10	24	6	3	183	150

It will be noted that the circulating water reached a temperature of 183 degrees or 19 degrees below that of the condensing steam inside. In this case, the surface was new and absolutely clean. Calculation shows that 416.4 B.t.u. were transmitted per hour per square foot for each degree of difference. Further, the amount of water required to "make good" will be noted. The atmospheric vaporization was 50 per cent. of the amount of condensation water delivered. In this case the steam came direct from the boiler and was probably more nearly dry than in the other test. The amount of "make good" water varies with the weather conditions, probably ranging from 33 per cent. in zero weather to 66 per cent. in hot, dry summer weather.

Power Transmission in Great Britain

By W. H. Booth

A paper read some time ago by Mr. Snell before the Institution of Electrical Engineers in London appears to be the first public recognition by an electrical engineer that the electrical transmission of energy has limits to its commercial application. The fact that electrical driving of machinery can very often be shown to have effected enormous economies and often to have resulted in better work and improved output has too frequently been confounded with electrical-transmission economies. In order to transmit electricity a power plant must be laid down consisting of steam engines and boilers much in excess of the power sold, and of costly electrical generators also in excess of the power sold, for there must be a plant to make up the various losses of transformation and transmission. But the power user may himself be in as good a position to manufacture electricity as is the big supply station and the power user can adopt electric driving just as easily as if he purchased current. In Great Britain electricity has been attempted to be transmitted to users who are themselves as well placed in respect of fuel as is the power station, and whose load factor is far superior to the best load factor ever yet obtained by any power station. Power-transmission enthusiasts, encouraged by the economy of electric driving of the isolated scattered machinery of an iron-works, a shipyard or a system of docks, have imagined they could obtain equal economies in driving cotton-spinning mills, with their steady loads and load factors of 92 per cent., and they have overlooked a most important factor of the problem.

Excepting only a few of the warmer days of summer, a spinning mill requires to be constantly warmed by artificial heat. Approximately one-tenth of the heat value of all the coal burned for power appears as heat in the factory, for practically no work gets out of the factory and all the power taken by the machinery appears as heat, and, in really hot weather, provides more heat than is wanted. But every night, Sundays, and all the time for three-fourths of the year, there must be additional steam heat which the mill owner must generate in boilers, no matter how he obtains his main power. Thus, if he purchase transmitted electrical power, he must still have a couple of boilers. Even if small, he must pay a fireman, build a chimney, and must pay for main power, to a profit-making company, so much per unit as will pay that company for the coal they burn in generating electricity at a poor load factor, and for the large capital sunk in transmission lines. Now it is not possible under equal fuel conditions for any such power station to compete with a steady load of 1000 indicated horsepower produced by the user's own plant; for the cost of the user's plant is not more than the cost of the plant at the power station per 1000 horsepower, and there is no costly transmission line. The user practically saves nothing in wages, for he must have a heating plant, and he can borrow money at 4 per cent. on bonds or debentures, and that is less than the usual interest that power-transmission companies have to pay for borrowed capital.

Cotton factories in Great Britain are very usually placed along canals for the benefit of condensing water and there seems no reason why a group of mills should not obtain power from a common power station near to each member of the group; so near, in fact, that artificial heat would be supplied from the same center, thus saving every mill the expense of boilers and chimney and the wages also, for one fireman at a central station could probably supply heating steam for a dozen mills. The load factor of the central station would be better than that of any one of the factories and might be 95 per cent.

Ordinary central power stations owe their poor load factors of 25, 30 or 40 per cent. to the very bad load factors of their very few customers. The central-station man goes to the little user and says: "I can supply power for 4 cents per unit which costs you 12 cents." So the little man says he will take it and then there begins an attempt to explain the maximum demand system of charging. The little man goes away from the interview understanding that his current will cost anywhere from 4 to 16 cents, more probably the latter, but that he may hope to approach but never get down to the former figure if he will keep the small drill and the forge fan at work from 7 to 9; run two light lathes from 9 to 11, the big lathe on a light cut from 11 to 12, warm the shop and boil coffee from 12 to 1, and so on throughout the day, endeavoring to keep a steady load all day with no peak in it. The result is he does not become a customer, nor do four thousand other little would-be users of current, all of whom the central-station man insists upon fining heavily because he himself has failed to grasp the true essentials of successful business. Every electrical supplier ought to receive some training in an insurance office so that he may grasp the significance of the great laws of average.

There are four thousand little users with perhaps 20,000 horsepower of plant, and if the power station could get hold of them all they would give perhaps a load factor of 80 per cent. on a plant of 500 or 1000 horsepower and current could be sold at a flat rate of 6 cents to every little user.

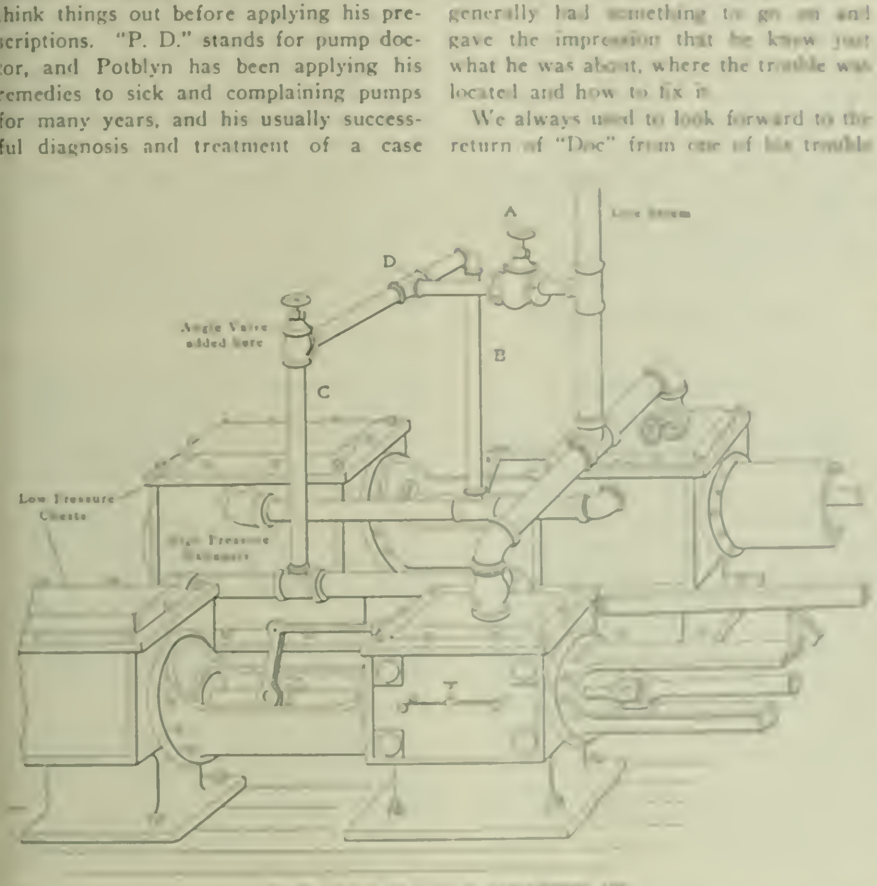
Power users differ from light users, for light users practically use light at the same moment, and numbers do not greatly reduce the abnormal peak load. This can only be dealt with by an enormous plant excess above average demand, or of a system of cheap storage such as the gas people possess. It is certain that the paltry little power stations of small municipalities cannot be expected to compete with a user's own plant when there is the added difficulty of heat supply to contend with, nor can big stations successfully supply current to large users with a high load factor. These facts, combined with the paralyzing effect of the maximum demand system of charging, and the too optimistic views of power-distribution companies, have brought the business to its present poor condition. Power stations have even been put up to sell current to coal mines and others who had their own plant and simply purchased any excess power they happened to require. Coal-burning stations have been erected to produce power in the middle of a lot of blast furnaces whose waste gases would have been equal to the supply of many times the power.

The paper of Mr. Snell much resembles a bomb in the camp, for it points out to electrical engineers facts against which they have shut their eyes and ears, and which have finally compelled recognition.

Potblyn, P. D.

By John Watson

No institution of learning had ever given him permission to write M. D., Ph. D., or anything else after his name, nevertheless the school of hard knocks, common sense and experience had surely given him the right to sign his name "Potblyn P. D." Do not suggest the addition of "Q" to the title, for the old "Doc" was not noted for the celerity of his movements, but, on the contrary, was rather slow-going and took his time to think things out before applying his prescriptions. "P. D." stands for pump doctor, and Potblyn has been applying his remedies to sick and complaining pumps for many years, and his usually successful diagnosis and treatment of a case



HOW THE PUMP WAS CONNECTED UP.

surely entitle him to some sort of a doctor's degree.

We have had "troublemen" working for the concern, whose idea of fixing an unsatisfactory pump was to go at it the first crack with wrench and hammer, open it up, slam around, and give a great impression of being busy and doing something. Old "Doc's" method was quite different. He might be sent to a plant where everyone, from manager to oiler, was swearing at a pump that appeared to be incapable of performing the service for which it was bought, and perhaps it was pounding and slamming and making noise enough to disturb the whole neighborhood. "Doc" would saunter in, present his card and have a cheerful "Good morning, glad to meet you" for office boy, manager, superintendent, chief engineer and everyone he met as he passed down the line. On reaching the pump room one would think that pumps were the least of all his interests. You all know the kind of cheery, old family doctor who, when he enters a sick room, starts a general conversation on the topics of the day, meanwhile studying the patient out of the corner of his eye. So "Doc" would leisurely take off his coat and start talking politics or prize fights, or anything but pumps. His eyes and ears were all wide open, taking everything in and sizing up the situation so as to have some idea of where the trouble lay before he made any move. He was a "wise old guy," for when he did get started he generally had something to go on and gave the impression that he knew just what he was about, where the trouble was located and how to fix it.

We always used to look forward to the return of "Doc" from one of his trouble trips, for he always came up to the drawing room to talk it over. Aside from the entertainment and amusement afforded by his descriptions, we always got some valuable information in regard to points which should be covered in future constructions. It was a rather poor trip when "Doc" did not "invent" something and have some new scheme to show to us. I remember one time in the early days of his employment with the company, before he had acquired the wisdom and skill which have made him such a valuable man, when we were especially anxious to hear his story.

We had a large compound condensing direct-acting pump working against a low head in a far Western city. In spite of all that the running engineer could do the pistons would hit the heads at every stroke. They wrote about it a number of times and everybody from chief engineer to blueprint boy took a shot at the solution of the difficulty. We sent them a number of suggestions as to the cause and remedy, but all failed to give relief. We went over the drawings very carefully (as we thought), but could find nothing in the design that would account for the trouble. Potblyn was called into the office and asked if he had any suggestions to offer. Not a suggest.

"Can you fix it?" said the manager.

"Yes," replied "Doc."

"Then go out there and don't come back until you get it fixed."

"All right, sir."

The easy confidence of youth would tackle any job and although it involved a large expense to send a man such a distance, it seemed to be the only chance of locating the trouble. In a few days we had a letter reporting his arrival and stating the conditions as he found them, but nothing about a remedy. This was followed by daily reports detailing all of his experiments and investigations. He opened up all of the cylinders and examined the vitals, juggled the "lost motion," pumped air into the air chamber, put on a larger suction chamber, plugged the suction re[illegible], varied the speed up and down, and tried everything that he could conceive. He took indicator cards and sent them home, asking for suggestions. They appeared to be all right and we had no further suggestions to offer.

Potblyn was "clean discouraged" and began to figure on some "boom pieces" kind of a network of piping and valves to provide a live-steam cushion for the low-pressure pistons. At the shop we started to lay out a cutoff arrangement to be applied to the high-pressure cylinders. We had it all planned out and the drawings made, just ready to go into the shop, when a telegram came in:

"The mystery solved. Potblyn."

That was all that we heard until, several days later, "Doc" strolled into the drawing room with his hat cocked over one ear and his mouth spread east and west so far that the corners were out of sight.

"By Tobey, you're a pack of chuckle-headed clams," was his greeting. "You fellers here get second prize for dunce heads."

"What about first prize?" the chief draftsman asked.

"Oh! I've got that medal myself, and all of the medals that go with it; just you wait until I go down to the shop and tell everybody down there a bit and then I'll come back and tell you all about it."

We cornered him, however, and made him tell his story. He had to tell it in his own way and there was no use trying to pin him down to the part we were anxious to hear about until he reached it in the course of his narrative. He described all of the experiments which he had tried and finally reached the point where he said that he was ready to give up.

"I sat down on the floor that afternoon with my back against the wall and as I smoked my after-dinner twofer I watched that cussed pump run down and bang on the end of every stroke. I wasn't much like the gay lad that came in there a week before confident that he could fix anything on earth. I was homesick. I wanted to see mama. I thought of all the gay and happy children at home, and there was I and there was that damn pump. The engineers cast pitying smiles on me as they passed. Talk about your markdowns, I felt like a left-over from a rummage sale. I was staring across the room without seeing anything in particular, when somehow my eye fixed itself on a piece of pipe leading from the high-pressure exhaust connection. Unconsciously my eyes followed it to its other connection and, say, the light that broke on me had Luna Park illumination 'skinned a mile.' I wanted to kick myself, but I thought I had better hold off until I found out whether the light was a real beacon or only another lightning bug. I couldn't do anything until the pump was shut down, but I did cheer up some, voted myself a fresh cigar and went out and threw stones at the frogs.

"Soon as they shut the pump down I went at it, broke a union, took out a section of pipe, put in a valve, and had it all done before the engineer got onto what I was doing. You bet I was on hand when he started up in the morning and, say, that darned old shebang started off and ran just as nice and quiet as a rubber-tired baby carriage when the kid's asleep.

"Not a bang, not a murmur; she's all right from then on, but as I may have remarked you're a lot of blasted idiots not to have known what was the matter, and I'm another not to have found it sooner. Some chump put in a bleeder for live steam to the low-pressure cylinders to use in starting. That's all right and worked all right, for we had to use it to start up, but the fourteen kinds of a fool connected it as shown in this drawing. [See sketch.] He put in only one valve at *A* and he connected the two branches into the high-pressure exhaust pipes, thus forming a cross exhaust from *B* to *C*. It was only a 1½-inch pipe on a 26-inch cylinder, but it was just enough to make all of the trouble and cost the company some hundreds of dollars. I put an angle valve in place of the elbow between *C* and *D* and fixed the whole trouble. Now, if the cheerful idiot that did it will come outside we will kick each other and feel better."

But, alas, "the cheerful idiot that did it" had "graduated" shortly after laying out the piping for that job. He should have known better than to make such a connection, but he slipped up on it somehow and it was such a comparatively small pipe that in checking the drawings and in erecting the pump it escaped notice. It probably would not have made any trouble but for the fact that it happened to be on a compound pump handling a large quantity of water against a low head. The momentum of the water column is liable to cause trouble under such conditions and this crossover connection, or "cross exhaust" as pump men call it, added just enough power at the end of the stroke to overcome the cushion and make the pistons strike the heads.

Do you wonder that special instructions were issued to all draftsmen to look out for all possible cross-exhaust connections however small?

Potblyn had "solved the mystery" and gained a reputation. His telegram has become a byword in the shop and whenever a pump gives trouble we suggest to Potblyn that we have another mystery for him to solve. He is very good at it and is particularly keen to spot a cross-exhaust connection, even if it is only where some engineer has failed to put the necessary valves in his cylinder-drip piping.

Some Queer Definitions

By J. E. Woodwell

Someone has said, "There is nothing new under the sun." It is certain that this person never had the pleasure and the enlightenment which comes from the perusal of civil-service examination papers. Those who have had this privilege have learned many new things, and the end is not yet. If originality is a desirable quality in electricians and engineers, Uncle Sam has an abundance of good material to select from. The writer has frequently drawn up technical examination questions, and later in reading the replies has made many startling discoveries, some of which should prove interesting to the profession.

Noah Webster was not a mechanical engineer, but we prefer his definitions to some of those given by candidates for the title. For instance, a toggle joint is variously described as: "An imperfect joint," "a bad joint," "a substantial 'soldier' joint," "a peculiar connection used in bringing two ends of the conductor together or making it as one conductor; the combination of splicing of two ends," "toggle joints are used on flexible shafts and on corner braces such as electricians use."

The definitions of an eccentric are even more eccentric than the object itself. We are of the opinion that the entire engine would be eccentric under the following conditions: "Eccentrics are used on engines, air compressors, and 'varies' other machines, and is generally connected to the piston rod." Lest any of the readers should be ignorant of the connection, we will give this man's explanation of how it is done: "A bell-crank lever is used to connect the piston rod of an engine to the eccentric." Another who described eccentric as meaning "lively; full of energy," possibly had in mind this same application.

There is evidently a difference of opinion regarding the bell-crank lever. A certain individual states that it serves to give a "Double or 'thrible' motion." Still another definition is that "A bell-crank lever is a lever shaped like a bell; a lever used to ring a bell."

In answer to the question: "Describe the construction of a self-oiling bearing on a motor or dynamo," this response was received: "Have the oil cup full of oil with a small plug in the outlet." We feel morally certain that this man does not own stock in the Standard Oil Company.

The public should not be deprived of the benefits of the information contained in the statements that:

"Armature cores are laminated to separate each layer of wires. The disks extend outwardly."

"Armature cores are laminated for their magnetic influence on the field coils. The disks extend relatively to the north and south poles."

"They are laminated in order to make the break between the positive and negative poles."

"Armature cores are laminated so as to give them more surface to 'effect' the magnetic."

The man who said that an idle pulley is "One that remains idle on the shaft" did not venture far into mechanics. Another replies, "Idle pulley: where the belt should run when the machine wants to be stopped." This machine is evidently endowed with greater intelligence than the operator.

The author of one of the descriptions of a bushing mat possesses a fine legal mind, but displays a decided lack of training. It reads thus: "A bushing is a mechanical term used to designate the part that fits into another part to separate the third part that may or may not go into the bushing; or, in other words, it is the part that separates two parts which fit into one another either tightly or closely."

The man who described a circular mil as, "A round cutter or a cutter that cuts while revolving, as a saw or milling cutter," was more of a machinist than an electrician; but the man who described it as "A table used in determining a certain value of electric current representing a part of one ohm," has not yet found his calling.

In this practical age seeing is believing, and a certain applicant in describing an ampere-turn said: "It is something I never saw on a motor." Here are other definitions of the same term:

"Ampere-turn is used to measure the voltage with."

"Ampere-turn is the turn given in its rotation around the armature."

"Ampere-turn: number of coils wound on."

"Ampere-turn is the power obtained by the resistance of a volt."

"A turn that the amperes take in a resistance coil to reduce the 'amprereage'."

"Ampere-turn is the number of turns of wire on the armature."

There is room for a difference of opinion in most of our human affairs, and there is always a chance for intelligent men to vary in their statements, but it is hard to reconcile all the following descriptions of back lash. We cannot imagine anything which would fulfil all these requirements:

"Back lash is a term applied to a strap on an engine."

"To lash and lash back."

"To throw back the table after having finished the work, making a reverse motion."

"The back lash is used in lacing a belt."

"The loose side of a belt running 'acrost' two pulleys."

A certain very cautious individual consistently avoided becoming involved in technical matters beyond his reach. He said: "Back geared means a machine constructed with gears on back instead of any other part of same."

One ambitious man, who drew from his imagination rather than his education or experience, made heroic attempts to answer most of the questions. To a portion of them, however, he hopelessly realized that this method of solution would not be applicable, and when he came to certain of the definitions and descriptions inserted, in lieu of an answer, the words: "Pass it up."

We believed this to be good advice, and have accordingly selected these few examples from a great number of papers and "passed them up" for the edification of all persons interested.

Pressure on the Eccentric and Crank Pin

By M. R. Casey

Fig. 1 shows four positions of a crank pin during one cycle. The approximate dimensions of the pin are 2 inches in diameter by 2½ inches long and 6.28 inches in circumference, which, multiplied by the length, will give the area

$$6.28 \times 2.50 = 15.70$$

square inches. As the pin only touches on one side, it has a useful area of one-half of the whole, or 7.85 square inches. With a piston 7 inches in diameter and having an area of 38.48 square inches, with a constant pressure of 30 pounds per square inch, there will be a total approximate pressure of 1154.40 pounds.

Of course, there is a period in the cycle of movement when no pressure is exerted upon the crank pin. The crank rotates at a speed of 300 revolutions per minute, and the center of the pin travels 37.69 inches in the one turn, which, multiplied by 300, equals 11,307 inches. The center of the crank pin would travel 942.25 feet in one minute, while the piston speed has been 600 feet.

Referring to Fig. 1, we find a given point C of the crank pin, and when one-fourth of the cycle has been made we find that the point C has changed its relation to the point of pressure. When the pin has made one-half of the cycle this point is opposite the working point, and at the three-fourths turn it is still farther around. The linear movement of the pin has only been 6.28 inches during one turn, while the body of the center of the pin has passed through 37.69 inches, just for one turn; the linear movement of the surface of the pin has been 1884 inches when the engine is running 300 revolutions per minute, or the surface of the pin has traveled at a velocity of 157 feet, while only approximately 78 feet has been under a working pressure. This linear velocity of the pin's surface is one reason why we can lubricate a crank pin as easily as we do.

Fig. 2 shows an eccentric, the point C of which travels at one velocity in a circular path, while the point D travels at another velocity in a circular path. In Fig. 3 the extreme extension of the eccentric travels on the line O. Being 6 inches in diameter, this point must necessarily travel 18.85 inches when it has made one revolution, and for one minute 5656 inches, or 471 feet, nearly equaling the speed of the piston. This speed is much in excess of what it is supposed to be by some engineers when running small engines.

The linear and circular velocity are working under a pressure carrying the unbalanced slide valve, the load being approximately 1,200 pounds. The surface usually pressed by the eccentric would have a total surface of 28.27 inches, and, like the crank, only being one-half under duty, would be 14.13 inches in area. Therefore, the 1200 pounds must be carried by this surface, making the pressure and velocity per square inch considerable.

The two points on the eccentric travel at two velocities, P representing the lower, this being 12.57 inches in one revolution, or for the time in question 3771 inches or 314 feet; so it is clear that the lower velocity is something more than one-half that of the piston's movement, and the true working condition might be taken as an average between the extreme movements of the eccentric. The outside or extreme point of the eccentric is constructed as working in the path shown by the outer circle in Fig. 3.

The eccentric, in many cases, works under trying conditions, and carries much more load than the man in charge gives it credit for, and at a high velocity. This is one reason why the pinned crank pin for carrying the valve gear has worked so satisfactorily on the center-crank engine. There the load becomes that of the crank motion in the movement, not in actual load, but under the same conditions. As far as velocity is concerned, it can be much lowered below the design. The one fault has been that the designer reduced the surface too much as soon as he made the crank pin a substitute for the eccentric.

The velocity of the surface of the eccentric is somewhat changed, as to the conditions under which this pressure comes,

FIG. 2

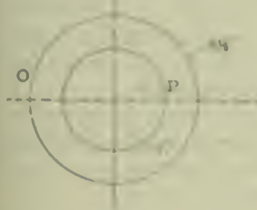

FIG. 3

FIG. 4

by the form of eccentric rod, and the length of the valve or eccentric rod has some effect on this. It can be clearly seen from Fig. 4 that the wearing condition of the eccentric strap having a rod as shown at N will be much more uniform on the eccentric than the one having a rod as shown at M, as the two velocities will blend better on the one having the long rod.

A Large Wood Pulley

The illustration shows a large wood split pulley which was furnished recently on a rush order by the Reeves Pulley Company, Columbus, Ind. It was 132 inches in diameter, 24 inches face, and had a $4\frac{15}{16}$-inch bore. The order was received at 9:40 a.m., and 28½ working hours later the pulley was loaded on a car and started to its destination.

This is the only firm, so far as we have knowledge, which builds such pulleys all wood. They have been building them for the past twelve years.

PULLEY 132 INCHES IN DIAMETER MADE IN TWENTY-EIGHT AND ONE-HALF HOURS

Catechism of Electricity

895. *How should the motor be shut down?*

Open the circuit breaker or main switch, allowing the machine to slow down of its own accord. Never stop a motor by releasing the lever of the starting rheostat, as this would burn the contacts on the box and might puncture the insulation of the field and armature coils.

896. *May the load now be placed on the motor?*

The motor, if new, should be allowed to run without load for a day or two so the bearings and brushes may have a chance to conform themselves to actual working conditions. When ready for the load, place the belt on the pulley and start the motor as before, closely watching the machine and everything connected with it so as to be ready to open the main switch or circuit breaker the instant there appears to be anything wrong.

When load is first thrown on a machine an ammeter should be in circuit for the purpose of ascertaining whether the machine is operating at its proper load, for if it is overloaded trouble may be experienced. The correct normal load in amperes is stamped on the nameplate mounted on the field frame.

897. *Mention any general precautions that should be observed after the load is placed on the motor.*

Inspect the motor frequently for the first few days, to guard against hot bearings, loose connections, etc. Keep all parts of the machine free from water, carbon dust and dirt of all kinds. Keep bearings properly filled with oil, and see that they do not leak or throw oil; also see that the oil does not overflow into the machine. Use every precaution to prevent oil from reaching the commutator or the armature windings. At first, the oil in the bearings should be changed once a week; later, two or three times a month.

Cleanliness is particularly essential, both inside and outside the machine. A hand bellows is convenient for blowing out dust, etc., from the inside of the machine, and an oily cloth for wiping dust, etc., from the outside. Cover the machine when not running, to protect it from dust.

898. *What troubles are most liable to arise in the operation of a direct-current motor?*

Sparking, heating, noise and abnormal speed.

899. *In which parts of the machine do the sparking and heating usually occur?*

Sparking at the commutator, heating at the commutator, brushes, armature, field magnets and bearings.

900. *What are the usual causes of sparking at the commutator?*

(1) The armature may be carrying too large a current, owing to an overload on the machine, or to friction such as that caused by the armature shaft not turning freely or the armature striking the pole pieces. A coil in the armature may be short-circuited or reversed, or there may be an open circuit in the armature. Too little resistance in the starting rheostat will cause sparking. If the armature or the pulley is not perfectly balanced, there will be vibrations of the machine which may produce sparking.

(2) The brushes may make poor contact with the commutator, they may have too high resistance, or they may not be at the neutral points.

(3) The commutator may be rough, not perfectly round, or may have some high bars in it.

(4) The field magnets may not be fully excited, or one pole may be stronger magnetically than another.

901. *How can one tell whether the sparking is caused by an overload on the armature?*

In case of a belted motor the tension side of the belt becomes very tight, and the belt sometimes squeaks owing to its slipping on the pulley. In either a belted or direct-connected motor an overload causes overheating of the armature, and this latter may be detected without stopping the machine; simply hold the hand in the current of air caused by the rotation of the armature and note the temperature by the sense of feeling.

To determine whether the overload is friction within the machine, stop the motor, and while turning the armature slowly by hand notice if it turns hard at a certain part of each revolution. If it turns hard there is some sort of mechanical obstruction within the machine; if it does not turn hard, the trouble, if an overload, is either a too tight belt or trying to accomplish too much work with the motor capacity available.

902. *What are the symptoms caused by a short-circuited coil in the armature?*

A short-circuited armature coil becomes much warmer than the others while the machine is in operation and is very liable to be burned out. The motor draws more current than usual and if the armature be felt when the machine is first shut down, the short-circuited coil can usually be located by reason of its higher temperature.

903. *How should trouble due to a short-circuited armature coil be remedied?*

By removing the short-circuit. A piece of metal between the commutator bars or between their connections with the armature winding is usually the cause, in which case it is easily remedied. If, however, the trouble is in the coil, the defective coil will probably have to be replaced by a new one.

Generally, the condition of a coil will readily indicate whether repairing or a removal is necessary. When a coil in a low-voltage machine has become injured through careless handling, it may be possible to repair the damage by separating the wires properly and applying a coat of shellac or some good insulating compound. Even in motors of higher voltage it is often possible in this manner to remove a small trouble without replacing the coil.

904. *Describe how to remove an armature coil.*

If a coil is entirely burned out, it may be easily removed by cutting it in two, but this should not be done unless it is certain that no part of it can be used again. Formed coils cannot be used a second time if a part of them is cut out. When, however, an accident happens to a hand-wound coil, the good wire in it may, by taking it off, be used again.

905. *Is it not advisable to keep a supply of wire on hand in the station for replacing damaged coils?*

It is important always to have in the station the proper wire for such coils as may be wound by hand on the armature or on the field coils. A sufficient amount of it to wind at least one or two coils should be provided. When a motor is built up of formed coils, there should always be within reach several coils of the different kinds that may be needed. Besides these should also be provided the shellac, oil, tape and whatever other materials may be necessary in repairing any particular machine.

906. *Explain how to replace an armature coil.*

The manner of replacing coils depends altogether on their construction and the type of the machine in question. When a coil is to be wound on by hand, care must be taken to notice how the old coil was wound on and connected, and the new one must be put on in the same manner.

A common type of formed coils used on direct-current machines, and the manner of applying them, is illustrated in Fig. 279. Such coils when supplied for repairs are usually already bent or formed, as the two shown at *a* and *c*. When this is not the case, as with the coil shown at *d*, they must be shaped to conform with the rest of the coils. When properly bent

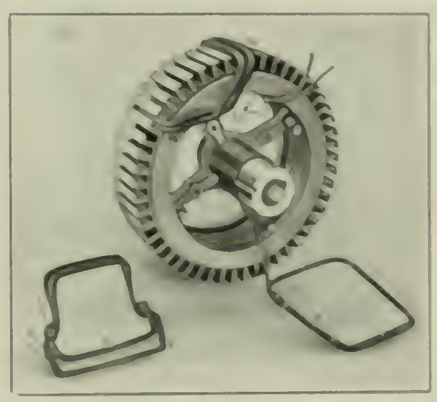

FIG. 279. FORMED COILS AND METHOD OF PLACING THEM IN POSITION ON THE ARMATURE CORE

they can be slipped in the slotted armature core as shown at *m* and *n*, their extremities being connected to the commutator bars in the usual manner.

907. *What are the symptoms of a reversed coil in the armature?*

The motor draws more current than usual, but the coil itself is no warmer than the other coils. If current be applied in the same direction to each coil separately by way of the commutator bars and a magnetic needle be held near the excited coil, the needle when applied to the reversed coil will point in the opposite direction to that when applied to the other coils.

908. *State how trouble due to a reversed armature coil should be remedied.*

By changing the terminal connections of the reversed coil so that they correspond to those of the other coils.

909. *How is it possible to know whether sparking is caused by too little resistance in the starting rheostat?*

If there is sparking from this cause it will occur only in starting up the motor. The motor will also start suddenly.

910. *What should be done to determine whether a motor has a poorly balanced armature or pulley?*

A poorly balanced armature or pulley usually causes vibrations of a stronger and more thoroughly distributed nature than those due to other causes and the vibrations increase with the speed of rotation, so that the trouble may be recognized in this way. If the indications point to the armature, the pulley, or both armature and pulley being unbalanced, they should be removed from the machine and tested separately.

The armature should be tested by placing it so that its shaft is supported at the ends upon two knife edges parallel to each other. Then, if the armature is poorly balanced, the heavy side will cause a rotation except when this side happens to be downward. By placing the armature at rest on the knife edges at different points around the shaft, the weighty side may be easily found. By providing a shaft for the pulley it also may be tested in the same way.

911. *How can a poorly balanced armature or pulley be remedied?*

Either by firmly fastening some lead on the lighter side of the core or by boring holes in, or filing off, the heavy side.

912. *If it is important that the motor be not shut down, can sparking due to vibrations of the machine be reduced temporarily?*

It can be partially overcome by giving more tension to the brushes so they press more firmly upon the commutator. This, however, is liable to develop considerable heat, both in the brushes and commutator, and should be resorted to only in cases of emergency. It may be found that the vibrations are due to an unstable base or foundation, in which case the trouble may be overcome without much difficulty.

913. *Is there not always some sparking at the commutator of direct-current motors?*

There is usually some sparking in all machines provided with commutators, but it is nevertheless a feature to be carefully watched and reduced to a minimum, inasmuch as it tends to destroy the brushes and commutator, causes trouble in the regulation of the machine and produces heat in the parts at which it occurs. A motor in perfect working condition should run without any sparking.

During the past few months the coal beds in the vicinity of Raton, New Mexico, have been investigated. The deposits have been found [illegible] 15 miles wide, extending from Johnson's Mesa westward to the mountains. Careful investigations, carried on by the United States Geological Survey, indicate that most of the coal contained in this field is a high-grade bituminous and of coking quality.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 *we printed and circulated* 1,836,000 *copies of* POWER.

Our circulation for December, 1908, *was (weekly and monthly)* 191,500.

January 5............ 46,000
January 12............ 38,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

Contents

For the Good of the Order

The opportunities for self-improvement afforded by meetings of engineers are often sacrificed or minimized by lack of sufficient preparation. Instead of having a definite program arranged for each evening, a subject selected for presentation and discussion and somebody prepared to elucidate and intelligently discuss it, a chance is taken that something will come up which will make the meeting worth while The inquiry "Has anybody anything to offer for the good of the order?" often meets with a barren response, and this part of the meeting, to which the routine business should be merely incidental, is often made a very subordinate feature. As a result the members disperse without having added anything to their stock of knowledge, without having had their interest excited, and really in a condition seriously to wonder if it is all worth while.

There are thousands of subjects any one of which will afford the material for an evening's consideration to the profit of the participants. The man who goes to a meeting and engages in the discussion and mastery of a subject which has been a mystery to him, who goes away with new ideas and an awakened interest, is likely to return and to become a valuable member and a better-informed engineer: to derive the real benefit from the association which its prospectus holds out. Many a man owes his success to the circumstance which impelled him to grasp some particular problem connected with his vocation and wrestle with it until he mastered its intricacies and made it a part of his equipment. The knowledge which the real engineer possesses has to be dug out by work and application. He cannot buy a handbook or library and sit with his feet on the desk and his pipe in his mouth and look at it and imbibe an engineering education. He cannot master principles and absorb the value of precedents by reading "easy" articles which do not make him get out his pad and pencil and think. One article which it takes a whole evening or a week of evenings to read and understand may, when mastered, be worth pages and volumes of discursive reading which has cost no effort.

The association affords an opportunity for a collective attack upon an article of this kind. Take for example the article by Mr. Jeter in our issue of January 5. This article describes a new and ingenious way of determining, by a glance at one of the charts accompanying it, whether a riveted joint in a plate of given thickness and with a given pitch of rivets will fail by tearing the plate, crushing the plate or shearing the rivets. The article while somewhat forbidding from its length and the formulas involved is very simple when one gets into it, and the instructor of any association can easily master it or refer it to somebody who can, and present it in abstract to the association, explaining knotty points and helping all the members to a thorough understanding of the subject. In order to encourage this use of the article we will be glad to loan, at no charge, lantern slides of the illustrations and charts accompanying the article to any association which desires to use them in this way.

High Boiler Efficiency

The boiler user is constantly reminded by the manufacturers of boiler compounds and tube cleaners of the inefficient results due to scaled boiler surfaces, a fixed ratio of loss to thickness of scale often being given. It has been pointed out by various authorities that such a ratio could not possibly exist, as it is a well known fact that the quality of the scale is generally of considerable more importance than its quantity. However, it is impossible to place too much stress on the necessity of keeping the inside of the heating surface clean, as not only efficiency but, what is of far more general importance, the safety of the boiler are dependent upon this condition.

When it is desired to keep the efficiency of a boiler to the highest point, the condition of the exterior portions of the heating surface is generally of more moment than the condition of the interior, particularly in the case of water-tube boilers. A thin layer of soot or ashes is a very effective nonconductor of heat and often portions of the heating surface are allowed to become banked up with soot and ashes until the effectiveness of the surface is almost totally destroyed. If similar conditions were the result of scale accumulations on the interior surfaces the metal would be at once destroyed, but in the case of external dirt no effect is produced except a rise in the temperature of the escaping gases, and hard steaming. The result is that often the cleaning of the external portions of the heating surface is neglected and the economy suffers. In many plants the periods between blowing off the external portions of the heating surface range from three days to a week. This is very much too long for economical operation where bituminous fuel is used, and in most plants once a day is hardly often enough if the highest economy is desired. The largest dividend payer in the boiler room, next to a skilled fireman, is a cleaning gang to keep the heating surfaces as nearly perfectly clean as possible. In selecting boilers the importance of this cleaning should be borne in mind, and the facilities offered by various forms of boiler or setting to accomplish proper cleaning should receive due weight in determining the kind to be selected.

Gas Power for Marine Service

The possibility of applying gas power to the propulsion of ships is becoming more and more a live question, nothwithstanding the fact that land practice has not yet attained what might be called stability. Of course the chief object in considering the internal-combustion engine for marine purposes is the saving in fuel consumption, which would reduce the cubic feet of fuel storage and thereby increase the freight space. The saving in the cost of the fuel is also a consideration, but space economy is the chief attraction. In view of the much greater space occupied by a four-stroke gas engine as compared with either a steam engine or a turbine, it would seem that the net result might not be a reduction in total plant and fuel space after all. Of course, the duration of the unbroken voyage would be a controlling factor. For a coastwise schedule, the saving in fuel space might be much less than the excess in engine space, as compared with steam.

In any event, the high value of space on a vessel of any commercial type undoubtedly points to the use of a two-stroke engine in the solution of the marine gas power problem. It is unnecessary to explain in detail the enormous space economy of the two stroke engine over the four-stroke type; everyone who is familiar with the subject knows all the points.

Provision of adequate means for going ahead or reversing suddenly and vigorously is recognized as being another serious problem. A flywheel on a large marine engine would be an anomaly, and the only other expedient for quickly applying the full power of a gas engine to its load is the combination of three or more double-acting two-stroke cylinders, or their equivalent, with a flexible transmission, such as electrical apparatus, between the engine and the load. With electrical transmission the quick application of full power in either direction would be easy, but what would become of the precious space reduction, not to mention weight and cost of apparatus?

All theorizing aside, there is much more work to be done on both the gas engine and the producer—especially the latter—before we will be prepared to tackle "long distance" marine service.

Loops in Noncondensing Compounds

With a compound engine running noncondensing the indicator diagram from the low pressure cylinder showed that expansion was carried below the atmospheric line, and all attempts on the part of the engineer to remove the negative loop by changing the length of the cutoff were futile.

Advice was sought from a consulting engineer, who thoughtlessly stated that the removal of the loop was a matter of easy accomplishment and who attempted to remove the loop from the diagram by the same means that the engineer had used in vain.

Failure to accomplish the desired result of course attended every effort in this direction and the consulting engineer finally advised a change of cylinder ratio by changing the diameter of the high-pressure cylinder. The change being made, an indicator diagram was taken and, as should have been expected, but much to the surprise of all interested, the negative loop was still in evidence and as large as ever.

It is not understood why any great difference in the terminal pressure of the low pressure diagram should be expected to result from a change in the diameter of the high-pressure cylinder. To do the work a certain amount of steam was required per stroke. This amount of steam, cut off by the cutoff of the high-pressure cylinder, fell to a pressure below that of the atmosphere when expanded to the volume of the low pressure cylinder. No change in the volume required per stroke could be made by altering the size of the high pressure cylinder, and the only way the loop could be avoided, with the same initial pressure, was by reducing the number of times the steam was expanded, i.e., by reducing the volume of the low pressure cylinder which each charge of steam eventually comes to fill. Indicator diagrams taken before the change of high pressure cylinder diameter showed that the engine was too large for the work under the conditions of operation. If the operating conditions were right, then the change to be made was a change in the size or power of the engine, and this could only be done by a change in the size of the low pressure cylinder, for it is the low pressure-cylinder diameter that is referred to in determining the power of a compound engine.

Valves for Superheated Steam

The American engineer visiting European power plants is usually surprised at the large number of globe valves used in the high-pressure steam lines, as well as the common absence of gate valves. This is perhaps more noticeable in the British isles than on the Continent, and is usually considered as a sign of the excessive conservatism of the European engineer. It may be well, however, to examine the conditions and the reasons given for this difference of practice.

A French engineer, who had long charge of one of the transatlantic liners, says:

"We use globe valves because they can be maintained tight without the use of machinery and at little expense. The discs are always ground tight to the seat under steam pressure and the shapes of the valve body and seat are better adapted to resist the destroying action of pressure and temperature than are the through or gate valves."

A well-known marine engineer from Glasgow said:

"It is vastly easier and cheaper to keep one disk and one seat tight than to keep two."

The loss from the constricted passage and the two right-angled bends in opposite directions is considered negligible in these and apparently American engineers hold the same opinion regarding throttle valves, as fully ninety-nine per cent. of the throttle valves in use are of either the globe or double-poppet design.

For line work in America the gate valve is almost universally used. Formerly the only type used for high-pressure steam was the solid wedge. This type was early preferred for steam, the double wedge being used for water only. With the advent of higher steam pressures the double-wedge and double-disk parallel-seat valves became popular and threatened to drive the solid-wedge type out of use. The introduction of superheat brought a new factor into the problem, in dealing with which the solid-wedge type appears to have an advantage. It is interesting to note that there are at least two manufacturers of globe valves for use in high-pressure superheated steam lines in this country.

It is, perhaps, superfluous to prophesy as to the valve of the future. Pressures have risen to 200 and 300 pounds gage, and it seems improbable that they will be increased. Superheat is from 100 to 200 degrees Fahrenheit, the temperature at which iron appears dull red in the dark, is certainly at the upper limit, and the signs of the times point to the more moderate temperatures of 450 to 500 degrees Fahrenheit.

Floating Central Stations Proposed

On December 29 William T. Donnelly spoke before the Modern Science Club of Brooklyn, N. Y., on the use of electricity from a floating central station for the purpose of marine transportation and the propulsion of vessels. As described by Mr. Donnelly, the proposition is that in the majority of cases marine transportation of freight can be more economically accomplished in barges, lighters, canal boats and similar vessels by motor-driven propellers supplied with current from a floating central power station than by towing.

It was argued that the same amount of power distributed to several boats by means of electric cables with proper connection around tunnels transports more freight a given distance than if all expended by a single towboat.

The Detroit Return Trap

An improved and modified form of the tilting return trap is illustrated herewith. It is known as the Detroit trap, and consists of a galvanized-steel tank, held in a horizontal position by a weighted arm, as shown in Fig. 1, and supported in two stuffing-box bearings located in lugs in the cast-iron base of the trap.

Both steam and water connections are situated in the base, where expansion and contraction of the pipes cannot in any way distort the adjustment of the trap and render it inoperative.

Condensed steam enters by pressure or gravity at *A*, Fig. 1, and fills the tank through the bottom connection at the left. The vent valve *B* communicates with the top of the tank inside and has a flexible connection, as shown, leading to the sewer. This valve remains open as long as the tank is in a horizontal position and serves to let out the air as the tank fills.

When enough condensation has been collected to disturb the equilibrium, the trap tilts over on the buffer spring *C*, closing the vent valve and opening the steam connection at *D*. This puts boiler pressure on top of the contents of the tank and, by means of suitable check valves in the intake pipe, allows the trap to deliver to the heater, receiver, or wherever required.

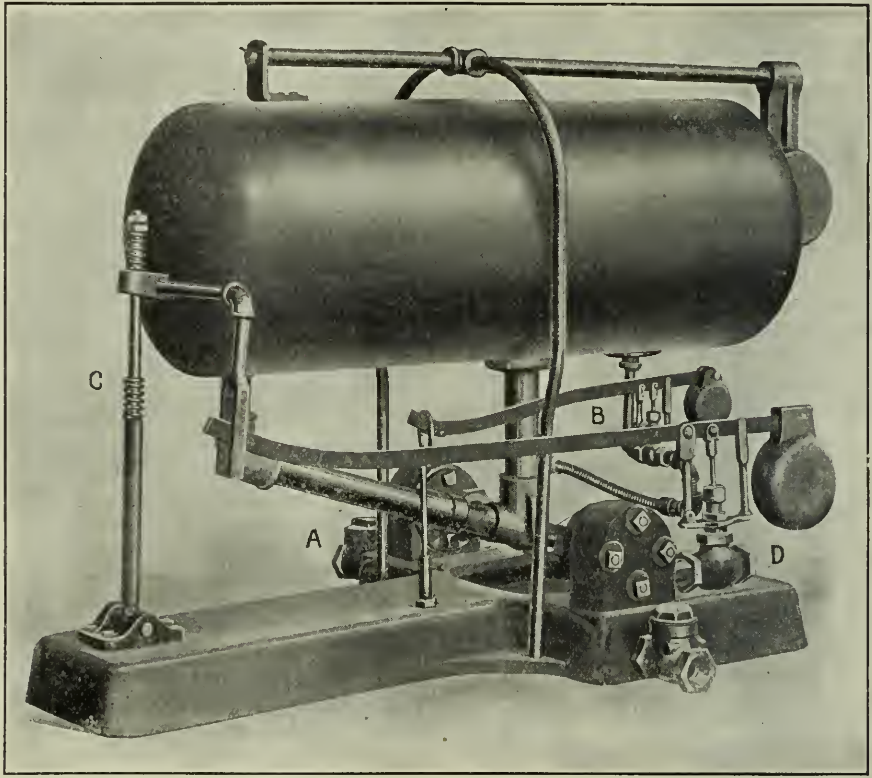

FIG. 1. THE DETROIT RETURN TRAP

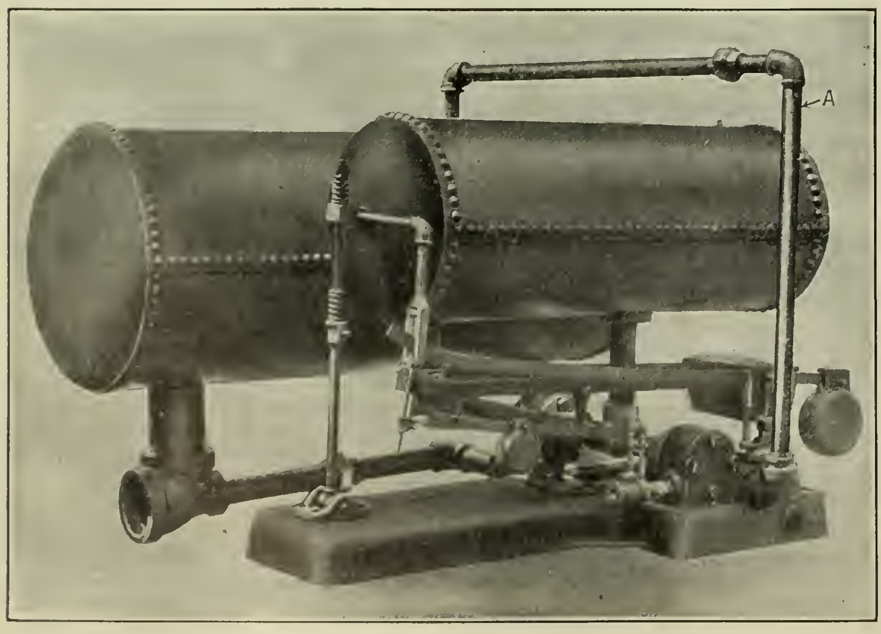

FIG. 2. SPECIAL APPLICATION OF THE DETROIT RETURN TRAP

To use as a boiler feeder, it is only necessary to place the trap at a convenient point above the water level so that, when discharging, the contents will flow to the boiler by gravity. With condensation at a very low pressure, another trap is used to deliver to the one feeding the boiler, in which case the installation is known as a double-trap system. Properly modified, these traps are successful in draining systems in which a vacuum is carried.

A special application of this trap is shown in Fig. 2. This consists of an auxiliary tank arrangement for use in places where large quantities of condensation must be taken care of.

The illustration shows an outfit designed to handle 50 gallons of condensation per minute. The trap itself has a volume of 8 gallons, and the auxiliary tank 50 gallons. A 4-inch connection leads to the large tank, the connection to the trap proper being of such size that both will

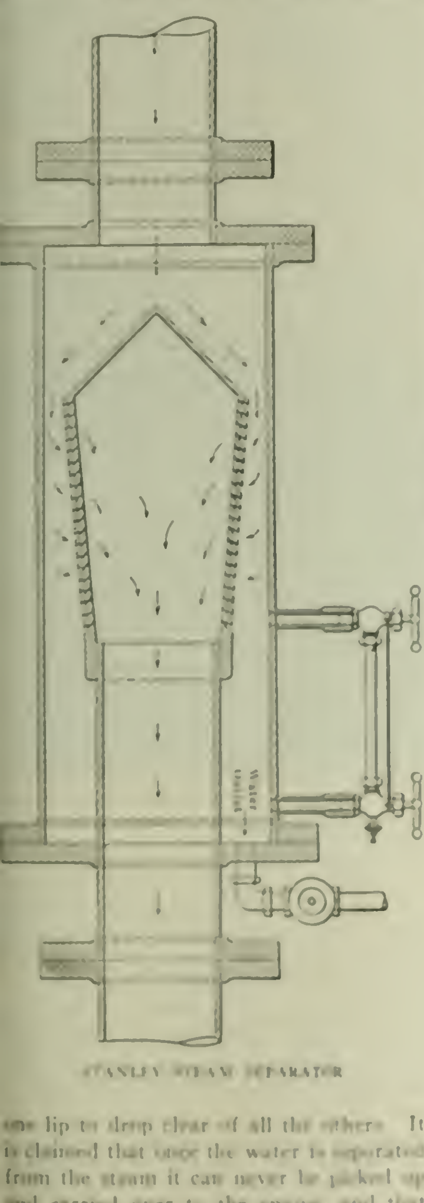
ill at the same rate. When full, the tilting of the trap turns steam at boiler pressure into both tanks, using the auxiliary connection *A* for the larger one, and the discharge in each takes place at the same time.

With this arrangement, a relatively small trap can take care of large volumes of water, it being only necessary to proportion the areas of the two water-supply pipes so the tanks will fill and empty at the same rate, the trap acting merely as a pilot valve on the system.

These traps are manufactured by the American Blower Company, Detroit, Mich.

Stanley Steam Separator

One of the advantages of this separator is the conical taper-shaped head, which is grooved or lipped so that the lips overhang each other, as shown in the illustration. This permits the water from any



STANLEY STEAM SEPARATOR

one lip to drop clear of all the others. It is claimed that once the water is separated from the steam it can never be picked up and carried over to the engine, and that the water, after being separated from the steam, does not come in contact with any metal surface that surrounds the dry steam, thus preventing condensation in the dry-steam chamber after separation.

The design is such that the large volume of steam passing through the separator is broken up into many small volumes by changing the direction of flow into an acute angle, thus permitting the water to drop freely to the bottom of the receiving chamber, whence it is immediately removed.

This separator has no baffles, funnels, pockets, troughs or vertical surface for water to lie in or cling to, and it is designed for a separator and receiver. It is manufactured by W. E. Stanley, Louisville, Ky.

"Union-Cinch" Pipe Fittings

The "Union-Cinch" pipe fittings, a type of which is shown in Fig. 1, are made in sizes corresponding to standard iron pipe up to 1 inch, and are especially designed for use in connection with oil pumps and oilers. They are manufactured by the Sight Feed Oil Pump Company, Milwaukee, Wis.

It is possible to use ordinary rough pipe with these fittings, if care is exercised in filing the ends of the pipe round and

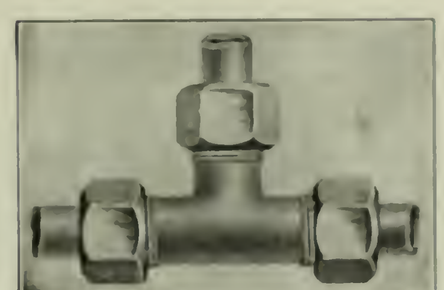


FIG. 1. "UNION-CINCH" PIPE FITTING

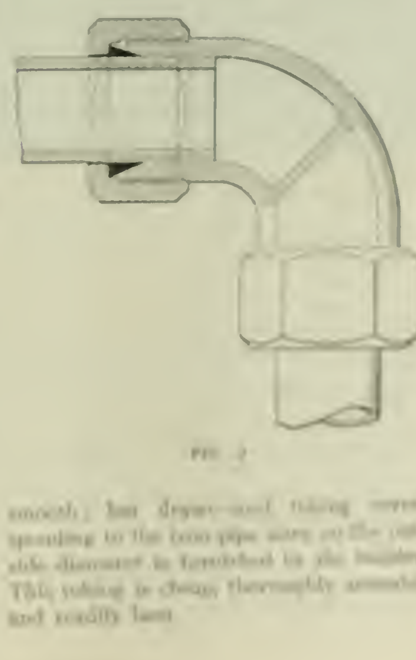

FIG. 2

smooth; but drawn-steel tubing corresponding to the iron pipe sizes in the outside diameter is furnished by the builder. This tubing is cheap, thoroughly annealed and readily bent.

Each fitting is a union, and the piping may be taken down at any point where a fitting is inserted. The joint is made by screwing down the outside nut, which presses a thin, tapered shell into the annular cavity around the pipe, between it and the fitting, as shown in Fig. 2. These nuts may be pulled up hard and the soft cone shell will make a tight joint around the tubing, which, it is stated, is good for [illegible] pounds pressure per square inch; or, in fact, is absolutely tight under any pressure that the tubing will stand. This type of joint may be taken down and made up again any number of times without trouble.

"Standard" Independent Steam Gage Movement

The accompanying illustration shows a gage movement that is distinctive in character in that a liberal air space separates the movement from the back of the case, preventing unequal thermal expansion of metal in movement and case. Considerable advantage is also gained by supporting the movement by the [illegible], as twisting of the case cannot change the relative position of the working parts, which would happen if fastened to the back and the case was accidentally strained out of position. [illegible] not affect its accuracy [illegible]. The pinion and segments are made of special [illegible], a composition selected for its perfect adaptability to conditions of wear and exposure to which it is subjected; [illegible] and others are of german silver.

"STANDARD" GAGE MOVEMENT

The gage movement is manufactured by the Standard Gauge Manufacturing Company, Foxboro, Mass.

Presentation to an Engineer

Arthur S. Vincent, for more than twenty-one years in the employ of the *New York Tribune*, first as machinists' helper and latterly mechanical superintendent of the Tribune building, recently resigned to go with the Belnord Construction Company, of New York, as mechanical superintendent. In view of his pending change, a number of friends assembled at the Tribune building Saturday afternoon, January 2, to give him a "send-off," and at the same time to present him a silver tea service. There were present the members of the engineers' and building departments of the *Tribune* and a number of invited guests, including James P. Holland, business agent of Eccentric Firemen's local union No. 56, who made the presentation, and D. A. Mason, who will succeed Mr. Vincent. The committee in charge of the occasion, which was most felicitous, comprised John Smith, Christopher Hatfield, William Funk, "Gus" Hedin and John Healy.

Business Items

F. E. Myers & Brother, of Ashland, Ohio, are distributing their annual calendar poster for 1909.

The Ashton Valve Company, 271 Franklin street, Boston, Mass., is sending out an attractive calendar for the new year.

The Minneapolis Steel and Machinery Company will remove its Dallas (Texas) office to the Praetorian building. J. P. Greenwood is the company's representative in that section.

The Ohio Blower Company, Cleveland, Ohio, reports recent sales of eight steam separators, one oil separator, eleven cast-iron exhaust heads and twenty-one gravity-closing ventilators.

R. A. Zoeller, manufacturers' agent of Tarboro, N. C., would like to hear from manufacturers of steam specialties, with a view of handling their goods in his section of the country.

The American Steam Gauge and Valve Manufacturing Company announces that after January 1, John B. Guthrie will be its sole representative in the Pittsburg district, with offices in the Columbia Bank building, corner of Fourth avenue and Wood street, Pittsburg, Penn.

The Nelson Valve Company, of Philadelphia, recently established two branch offices in the middle West to keep pace with its rapidly expanding business, one in Detroit, in the Penobscot building, the other in Cleveland, in the Perry Payne building. John M. Bulkley has been appointed sales manager for the territory of Ohio and Michigan.

D. D. Pendleton, who was connected with the Westinghouse Electric and Manufacturing Company, of Pittsburg, for some 15 years, recently opened an office as district sales manager of the American Boiler Economy Company, manufacturer of the Copes feed-water regulator, and the Copes pump governor. Mr. Pendleton's offices are located in the Frick building annex, Pittsburg, Penn.

The Commercial Testing and Engineering Company, recently opened offices and laboratories in the Old Colony building, Chicago, where it will specialize along the lines of boiler-room economies, coal analysis, heat-value method of purchasing fuel and coal washing and preparation for operators. The officers are: Edward H. Taylor, president; Harry W. Weeks, vice-president; W. D. Stuckenberg, treasurer; B. J. Maynes, secretary.

The Buffalo Steam Pump Company, of Buffalo, N. Y., has contracted with the city of Grand Rapids, Mich., to furnish ten sewage pumps having a total capacity under maximum conditions of over 250,000 gallons per minute. The pumps are to be placed in four stations, one station to contain two 18-inch pumps, one to contain two 24-inch pumps, one to contain two 24-inch pumps, and the fourth station four 40-inch pumps. The ten pumps together, without motors, will weigh approximately 200,000 pounds. Westinghouse electric motors will be used to operate them.

The Buckeye Boiler Skimmer Company, South End, Toledo, Ohio, is in receipt of a communication from the general foreman of the El Paso-Northeastern System, Alamogerdo, N. M., in which he says: "The skimmer arrived O.K. and we at once applied it to our No. 2 boiler. We were eight hours putting it on, and that same night we began operating it. To our surprise the boiler doesn't prime over any more. Fifty gallons of lime and magnesia have been skimmed off in sixty days, and we have also experienced a decided saving in fuel. After the second week we cleaned the boiler and found at least half a wagon load of old scale, which I consider very fine. We wash our boiler only once in two weeks now, where previously we washed it twice in one week. Mr. Martin, general manager of the E. P. & N. E. railroad system, who is authority in this section on bad water and treating appliances, claims this device the best he ever saw, and has ordered three more to be put on as soon as we can conveniently get to it."

New Equipment

Dr. J. I. Coleman, Hurdle Mills, N. C., is in the market for a 100-light dynamo.

The Escondido (Cal.) Mutual Water Company will install an electric lighting and power plant to cost $30,000.

It is reported that about $10,000 will be spent in improving water-works and electric-light plant at Marlow, Okla.

The Portland (Ore.) Railway Light and Power Company has had plans prepared for a new power station.

The Waurika (Okla.) Ice and Electric Company will build a 30-ton ice plant in connection with electric-light plant.

It is said that plans are being prepared for a power station at Garden City, Kans., for the Kansas-Colorado Railroad.

The City Council, Waukegan, Ill., is said to be considering the purchase of a 5,000,000-gallon water-works pump.

The citizens of Cherokee, Okla., are said to have voted to issue $65,000 bonds for watreworks and sewerage system.

The city of Thomaston, Ga., voted $10,000 bonds for the purpose of enlarging and improving electric-light plant.

The City Council, Wooster, Ohio, is said to be considering the question of establishng a municipal electric-light plant.

The city of Thomaston, Ga., contemplates doubling the municipal electric-light plant. W. C. Hartman, superintendent.

The Union Central Light and Ice Company, Hubbard City, Texas, will make additions and improvements to cost about $10,000.

Bids will be received until 11 a.m. December 22 by Capt. O. W. Bell, Jefferson Barracks, Mo., for a complete electric-lighting system.

The question of constructing an electric light plant at Bellefonte, Penn., is said to be under consideration. W. Kelly, borough clerk.

The citizens of North Arlington, N. J., have voted to issue $25,000 bonds to install water-supply system. H. C. Bayliss, borough clerk.

The Rochester (N. Y.) Railway and Light Company is having plans prepared for a vertical retort gas plant, which will cost about $150,000.

The Waurika (Okla.) Ice and Electric Company has been incorporated. Capital, $50,000. Incorporators, T. B. Martin, E. W. Gautt and others.

The Las Cruces (N. M.) Electric Light and Ice Company has applied for franchise to construct electric-light plant and water works.

Church E. Gates & Co., Fourth avenue and 138th street, New York, have filed plans for the construction of a power house to cost about $50,000.

The City Council, Linton, Ind., will enlarge and re-equip the municipal electric-light plant. It is said about $15,000 will be spent on new equipment.

The Brattleboro & Vernon Railroad Co. has been incorporated to construct an electric railway. Incorporators, C. R. Crosby, G. L. Dunham, of Brattleboro, and others.

The city of Marlow, Okla., will make improvements to electric-light plant and water works to cost about $10,000. T. T. Eason, chairman, purchasing committee.

Bids will be received about December 20 for construction of water-works at Hays, Kan. Cost, about $18,000. Orr Engineering Company, Kansas City, Mo., engineers.

The Lake Superior Power Company, Sault Ste. Marie, Ont., is said to be making plans for a new hydroelectric plant to cost about $110,000. L. H. Davis, chief engineer.

The Booneville (Ark.) Light and Power Company has been incorporated to construct and operate electric-light and power plant and water-works system. J. T. Thayer, president.

The Freeport (Ill.) Interurban Railway Company has been incorporated to construct an interurban electric railway. Owen T. Smith, W. A. Hance and Edward Courtney, incorporators.

Plans are being made for additions and improvements to the municipal electric-light plant and water works at Macon, Mo., to cost about $18,000. E. S. Bennett, superintendent.

The Acme Hosiery Mills, Asheboro, N. C., recently incorporated with $100,000 capital, is ready to buy equipment including 40-horsepower engine and 70-horsepower boiler. O. R. Cox, secretary.

The Grand Junction (Colo.) Electric Railway Company has completed plans for construction of new electric railway, which is to cost over $2,000,000. A power plant will be constructed at Debeque.

The Vernon Light and Power Company, Vernon, Texas, will buy in the next thirty days, 150-horsepower engine, 100 kilowatt alternator, boiler feed pumps, lubricators, etc. About $5000 will be expended.

The De Kalb (Ill.) Midland Railway Company has been incorporated to construct an electric railway from DeKalb to Sandwich. Capital, $150,000. Incorporators, J. W. McQueen, W. G. Wilcox, Elgin, Ill., and others.

L. W. Trumbull, Van Vleck, Texas, is interested in an electric and refrigerating plant to supply a town of about five thousand and would like to hear from manufacturers of electrical equipment and refrigerating machinery.

Hampton Power Plant of the D., L. & W. R. R.

The Largest of Its Kind in the Anthracite Region, Employing Both Steam and Electric Apparatus of the Most Modern Type

BY WARREN O. ROGERS

A central power station at the mines, the ideal condition to which mechanical engineers have given more or less attention, is found in the Hampton power plant of the Delaware, Lackawanna & Western Railroad Company, Scranton, Penn.

In the mining of coal, three kinds of power are available: steam, compressed air and electricity. These mediums are utilized in operating all kinds of mine hoisting, pumping, ventilating, drilling and machine operation. The mining of coal is, therefore, to a large extent, a mechanical proposition, and the best means which will not only insure reliable operation but the cheapest power, all things considered, should be selected.

The central station idea has proved economical in other phases of power transmission, and recent installations of electrically driven machinery at mines have demonstrated that the central power plant at the mines is productive of economy and efficiency. In the instance of large coal-producing companies this idea is all the more feasible because they operate numerous collieries which permit of distributing a large amount of current to them at minimum cost. Under the modern methods of wiring mines from a central station, the transmission losses which enter into the question of economies are very low. Where steam is used, the loss from condensation due to long steam pipes is considerable; the pipes in some instances being more than 3000 feet long.

Among the first to experiment with electrically operated breakers was the Lackawanna company, which has been experimenting for several years, with most favorable results. This was also one of the first of the anthracite companies to adopt the electric locomotive for mine haulage, thus doing away with steam and compressed-air locomotives.

Owing to the successful outcome of these and other electrical experiments, the Hampton power plant, the largest of its kind in the anthracite region, was installed. This station, which has a boiler capacity of more than 8500 normal horsepower, and an electrical output of 4500 kilowatts, supplies steam to five collieries and electricity to 18 additional mines. The nearest mine is only 1200 feet distant from the station; the farthest three miles away.

FIG. 1. GENERAL VIEW OF THE SITE OF THE HAMPTON POWER STATION

The power plant is situated in a basin formed by ranges of hills, a general view of the site being shown in Fig. 1. This location has several advantages. It is centrally located, is near its source of coal supply and obtains its boiler-feed water from the West hill section nearby. The water flows by gravity from a 700,000-gallon reservoir, shown at the left of Fig. 1, and is of excellent quality.

The buildings are constructed of brick, concrete, iron and steel. The roofs are of concrete, and no wood, with the exception of window casings and doors, is used in their construction. This feature is also observed in the construction of the oil house and work house, in which are shower baths, tubs and lockers.

Boilers

The original boiler plant consisted of fifteen 313-horsepower Babcock & Wilcox water-tube boilers, shown in Fig. 4, which are equipped with McClave stokers. A number of changes have been made in the arrangement of the furnaces, however, due to the fact that barley anthracite is used as fuel. Three factors were found of paramount importance in the plant for the successful burning of barley fuel; sufficient grate area, furnace arches, necessary to maintain a high furnace temperature, and a combination of forced draft and superheated steam.

The present arrangement of the furnaces of these boilers is shown in Fig. [illegible]. A steam conduit runs under the boilers, with branches extending to each furnace. The steam is superheated in order to reduce the moisture. Steam and air enter the furnace above the grates through a number of ... pipes set in the back wall, the supply being regulated by hand from the front of the boiler. This method, when properly handled, reduces the CO from about [illegible] per cent. to a trace and increases the CO_2 to about [illegible] per cent. As a result of this increase-ment, the fuel consumption has been reduced about 20 tons per day, with the same load.

The changes made in the stoker to meet the conditions of burning a very fine fuel, were to prevent the movement of the grate bars more than necessary to produce the proper amount of feed. The bottom end of the grate on each boiler has been equipped with a cleaning plate to facilitate dumping the ashes. The grates have an air space of 20 per cent.

Forced and induced drafts are used in all the boiler installations, the pressure in the furnace being almost balanced with a slight vacuum. The blowers were furnished by the American Blower Company and are driven by engines of suitable size built by the same company. The blower system is in duplicate, there being two 12-foot induced-draft fans, and two 10-foot forced-draft fans. The speed of the engines and fans is regulated, as the steam pressure raises or falls, by a Foster reducing valve.

The stacks are simply for the purpose

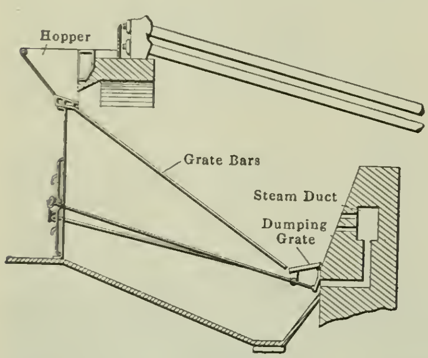

FIG. 2. ARRANGEMENT OF AIR AND STEAM DUCTS

of carrying away the gases, and are not depended on to create a draft. They are of iron, the tops being 60 feet above the surface of the grates. Two Green economizers are used with the old boilers, the gases passing through them to the induced-draft fans. The stack temperature averages 550 degrees after leaving the economizers.

The new section of the boiler room consists of six 2-drum Stirling boilers, each of 625 horsepower, the ratio of heating surface to grate area being 30 to 1. The new boilers are equipped with the Parsons system of forced draft without economizers. They are hand-fired, and the furnaces are equipped with stationary grates having an air space of 10 per cent. These furnaces are constructed with arches to assist the furnace temperature, also doors at both ends of the grates. Ash-dumping plates are also arranged to facilitate cleaning the fires.

The boilers are equipped with Murray, Williams and Vigilant boiler feed-water regulators.

As shown in Fig. 4, the coal is de-

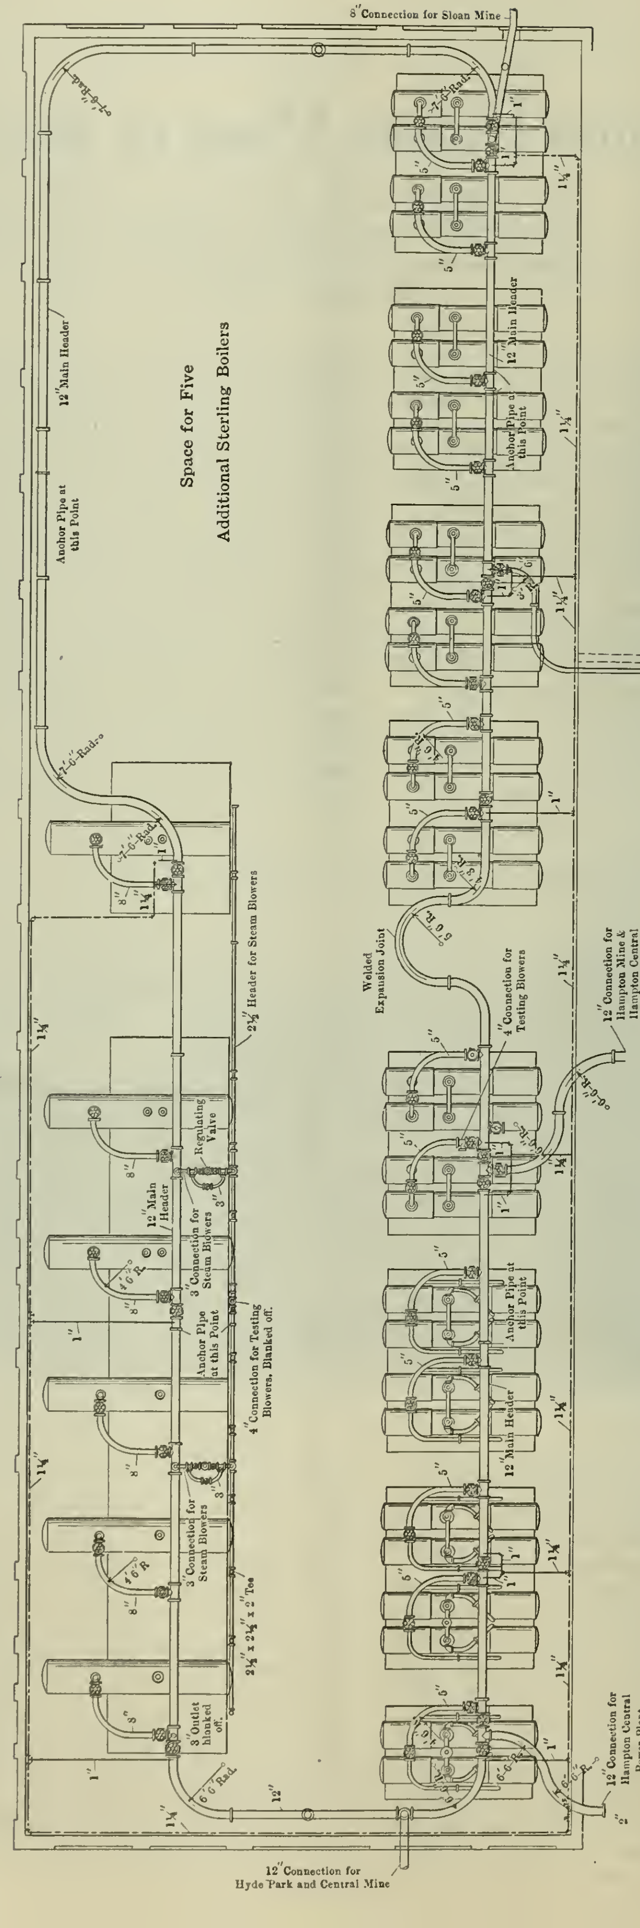

FIG. 3. PLAN OF THE BOILER-ROOM LAYOUT AT THE HAMPTON PLANT

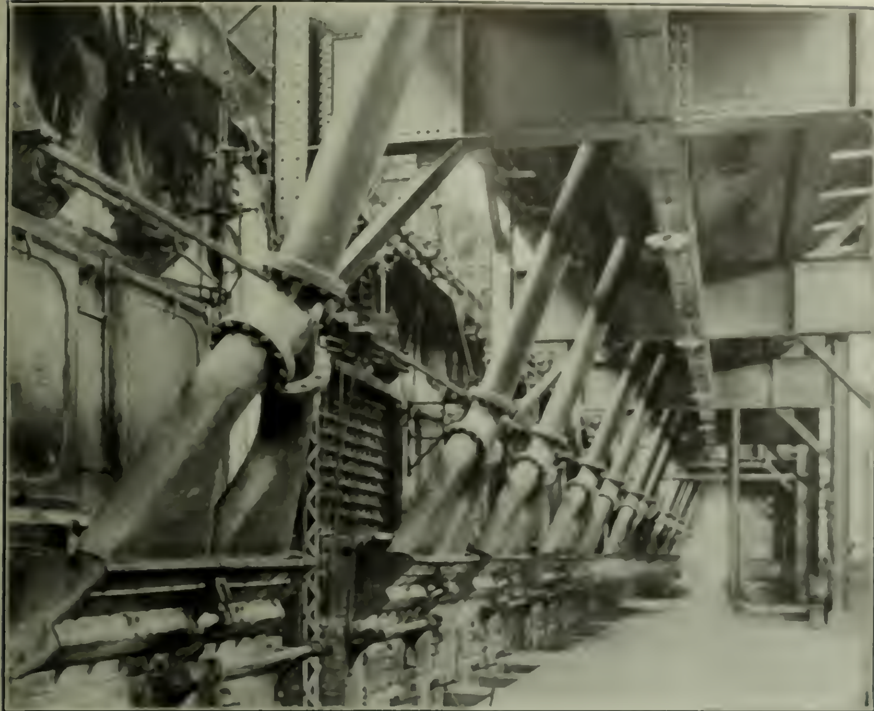

FIG. 4. VIEW IN THE BOILER ROOM

livered to the hopper in the case of the Babcock & Wilcox boilers by means of chutes from the storage bin located above and between the two rows of boilers. In the case of the new installation, the fuel is delivered on the floor in front of the boiler.

In Figs. 3 and 5 are shown a plan and elevation of the boiler-room layout. As will be seen, the Babcock & Wilcox boilers are arranged in seven batteries of two boilers and one of one boiler. The Stirling boilers are arranged in one battery of five boilers, the sixth boiler being set so that it will be the first of a second battery of six boilers, space being provided for five additional boilers, as shown. Each boiler is equipped with a superheater which superheats the steam 150 degrees. The boiler pressure carried is 150 pounds per square inch.

Piping and Valves

Each boiler is connected to a 12-inch main header of the loop construction. By this method, if one of the boilers should suffer a severe accident or a section of the header become defective, the remaining boilers and section of uninjured steam main may be operated, thus preventing the suspension of the mines depending on the station for steam and power.

The connection between each boiler and header is of 5-inch pipe, made with bends, having a radius of 4 feet 6 inches in the case of the Babcock & Wilcox boilers, and 8-inch pipes bent at the same radius in the Stirling boiler connection. The 12-inch header is bent at a radius of 6 feet 6 inches at one end of the plant and 7 feet 6 inches at the other.

From the 12-inch header the various pipe lines extend to the central power station, and to the various mines. These pipes vary in size and length, the pipes running to the turbine station being 12 inches in diameter. The steam mains leading to the mines are as follows: One 8-inch line, 1450 feet long; one 8-inch line, 1700 feet long; one 8-inch line, 1900 feet long; one 8-inch line, 3450 feet long; one 12-inch line, 1200 feet long.

Special steel piping with flanged ends and the improved Van Stone joints is used. This joint forms an ideal method of joining high-pressure steam pipes.

The advantages of doing away with as many joints as possible on the high-pressure steam mains was the reason for the use of welded pipes where possible. This has resulted in a saving in maintenance, there being fewer joints, and a saving in first cost because there are fewer flanges to make and cover. The advantage of welded mains is self-evident. In such instances of expansion bends or where the large high-pressure pipes make a bend of such magnitude that more than

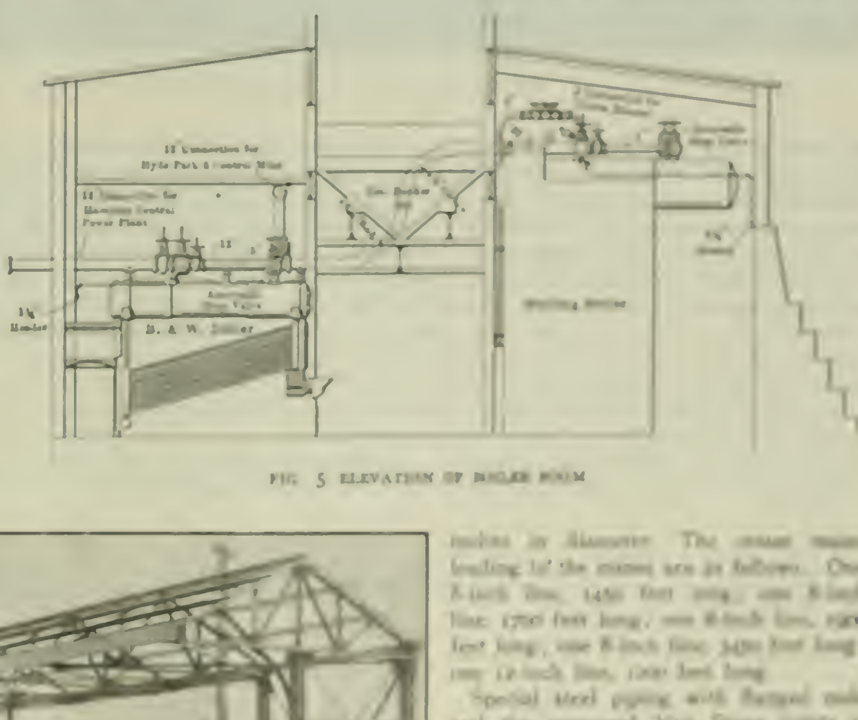

FIG. 5 ELEVATION OF BOILER ROOM

FIG. 6 SHOWING THE COAL CONVEYER INSTALLATION

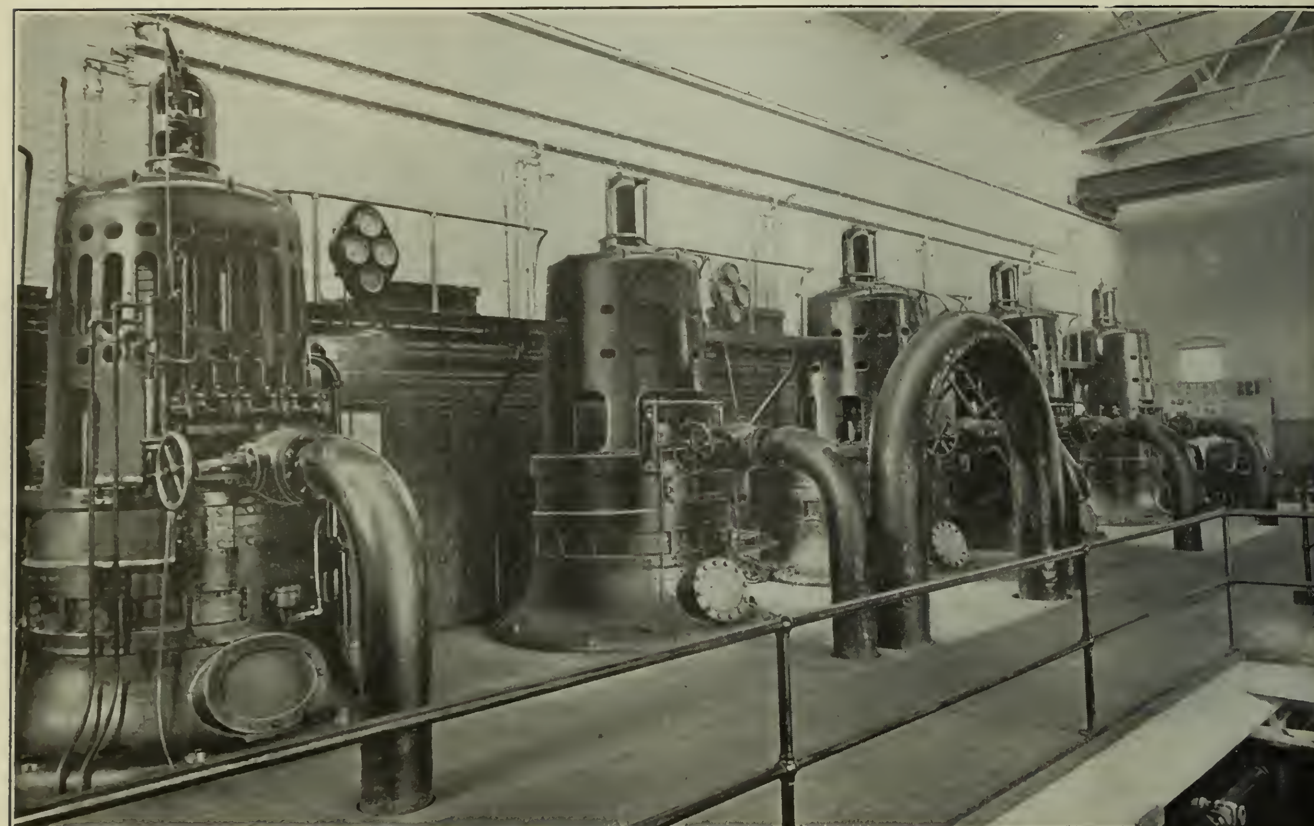

FIG. 7. VIEW IN THE TURBINE ROOM OF THE HAMPTON PLANT

one ordinary length of pipe is required. Other applications of the welded pipe are in the pipe connection between the boiler and the main steam header and the header and the prime mover. The piping system was furnished by the M. W. Kellogg Company, which also makes the improved Van Stone joint.

Another feature in the welding art is that of the welded separator placed in the 12-inch steam line leading to the turbine house. This separator is located on the outside of the building, but is protected by suitable covering, as are also the various steam pipes. It is constructed of open-hearth steel and has no joints whatever, with the exception of the inlet and outlet flanges and, in addition, even the supporting lugs at the bottom are welded to the cylinder of the separator. The body of the separator is welded together, and also to the top and bottom heads. The flanges, which are made of rolled steel, are also welded on. This separator was also furnished by the Kellogg company.

The valves throughout the plant are the product of the New Bedford Boiler and Machine Company. The globe valves are of the extra-heavy type for high-pressure service. They are designed for a working pressure of 300 pounds. The seats and disks are constructed of nickel bronze which, having the same coefficient of expansion as cast iron, makes a serviceable combination.

Disposal of Ash

A most unique method of disposing of the ash has been adopted, which not only eliminates all expense in the matter of cartage, but is turned to practical use.

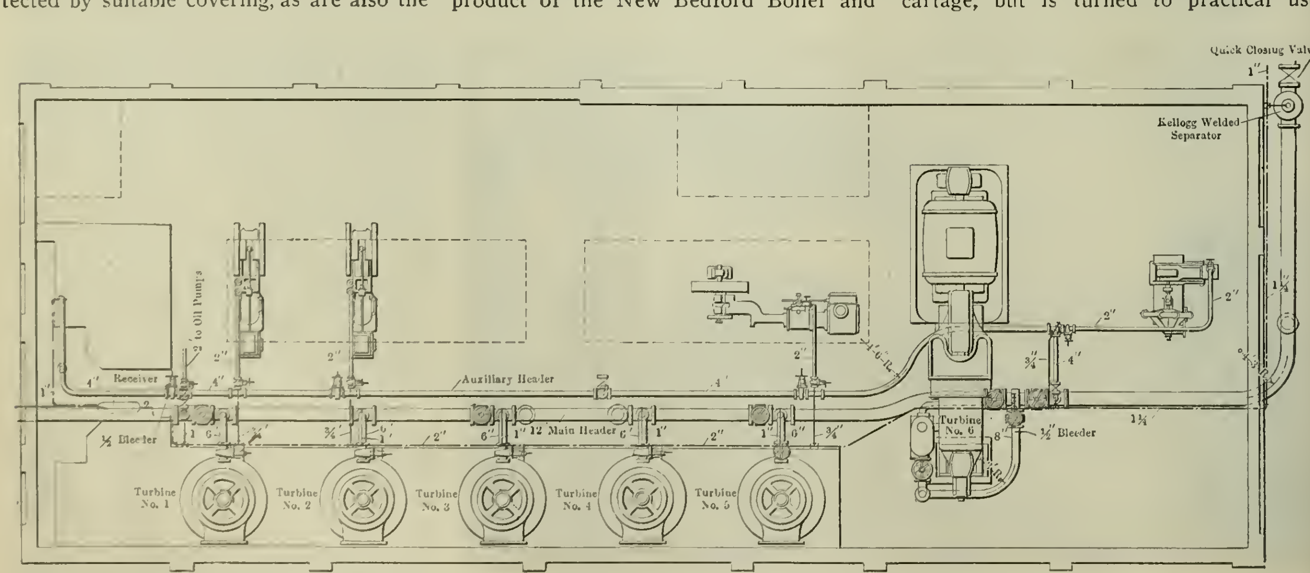

FIG. 8. SHOWING THE TURBINE LAYOUT AND DRY-VACUUM PUMPS

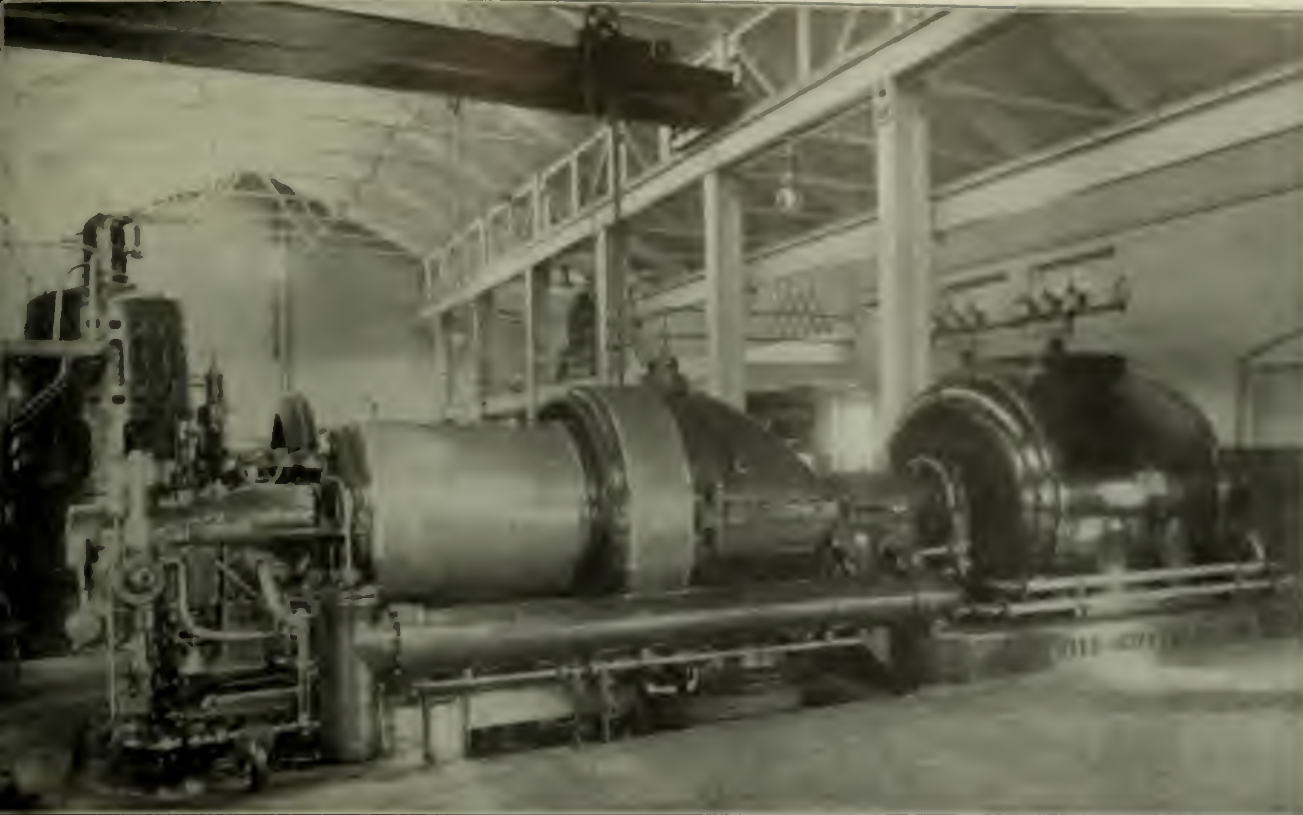

FIG. 9. ALLIS CHALMERS TURBINE AND BULLOCK ALTERNATOR

Under the ashpits of the Babcock & Wilcox boilers a tunnel has been constructed, and beneath the furnace doors of the new boiler another set of tunnels has been built. The ashes fall from the grate in the first instance, and pass into a tunnel which has a slope of ⅜ inch to the foot. In the case of the Stirling boilers the ashes are pulled out into the conveyer lines from both the furnace and the ashpits, the latter being cleaned but once a week. Pin hole grates are used; consequently, very little ash falls through into the ashpit. Water from the mines flushes the ash into a bore hole leading to abandoned mine chambers. It is estimated that about 50 tons of ash is flushed into these chambers from under the boilers each day. As the ashes in time harden sufficiently to support the roof of the mine, the solid-coal columns, which were left in place for this purpose can be removed.

Coal Conveyer

The barley-coal supply comes from the washeries in ordinary railroad cars. From these cars it is dumped into a concrete pit having a capacity of [illegible] tons, from which it passes onto an endless conveyer belt and is then conveyed up an incline and along an upper floor in the boiler house, Fig. 6. Along the path of the belt is an arrangement known as the tripper, which causes the coal to be emptied into a chute, through which it is carried down into the bunkers. The tripper moves slowly along the track made for it at just the proper speed to load the bunkers, and when it gets to the end starts back again.

The conveyer belt is [illegible] feet long and extends the entire length of the boiler room over the coal bunkers, from which the supply is delivered to the respective boilers. The coal bunker extends the entire length of the boiler room and has a capacity of [illegible] tons. It is covered with concrete on which the conveyer operates. The conveyer handles an average of [illegible] tons an hour and is in duplicate, as shown in Fig. 6, though when the photograph was taken the second belt was not in position. It will be seen that the building over the car, the concrete coal pit and the conveyer were unfinished at the time of photographing. The incline has the return-belt conveyer in support by concrete columns.

The conveyer, which was furnished by the [illegible] Works is operated by a [illegible]-horsepower Westinghouse [illegible] induction motor, running at [illegible] revolutions per minute.

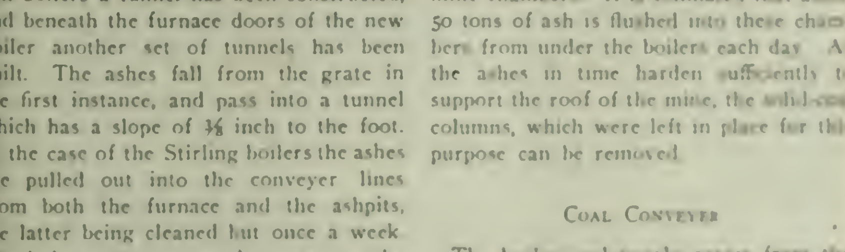

FIG. 10. ELEVATION OF CURTIS TURBINE SET, DRY-VACUUM PUMP AND ENGINE

Pumps

The pump room contains two of the Scranton Pump Company's 22 and 12 by 24-inch pumps of the outside-packed type, each equipped with a counter which acts as a check on the amount of water pumped. There is also one tandem duplex Epping-Carpenter pump, which is held as a reserve. In the pump room is also a Westinghouse air pump which compresses air for cleaning the tubes of the boilers.

The feed water for the boiler is taken from the reservoir already mentioned and is passed through a 6000-horsepower Cochrane feed-water heater.

Turbines

A section of the turbine room, which is about 25 feet from the boiler room, is shown in Fig. 7. The five Curtis turbines are located on one side of the room. They are of 500 kilowatts capacity and are direct-connected to alternators, generating a current of 2300 volts at a speed of 1800 revolutions per minute. In the right-hand corner is shown part of the air-pump pit.

The 12-inch steam header enters the basement and is tapped for a 6-inch pipe leading to each Curtis turbine. The arrangement of the piping is shown in Figs. 8 and 10, the former being a plan view of the turbine layout and dry-vacuum pumps.

In Fig. 9 is shown an Allis-Chalmers turbine direct-connected to a 2000-kilowatt Bullock three-phase 60-cycle alternator. It runs at a speed of 1800 revolutions per minute and generates a current of 2300 volts. This turbine has only been in operation a few months and represents the latest turbine design. Incidentally, it may be said that the Curtis turbine shown at the extreme end of the turbine room, Fig. 7, is one of the first, if not the first, turbines of 500 kilowatts manufactured by the General Electric Company, thus making the Delaware, Lackawanna & Western Railroad Company a pioneer in turbine practice.

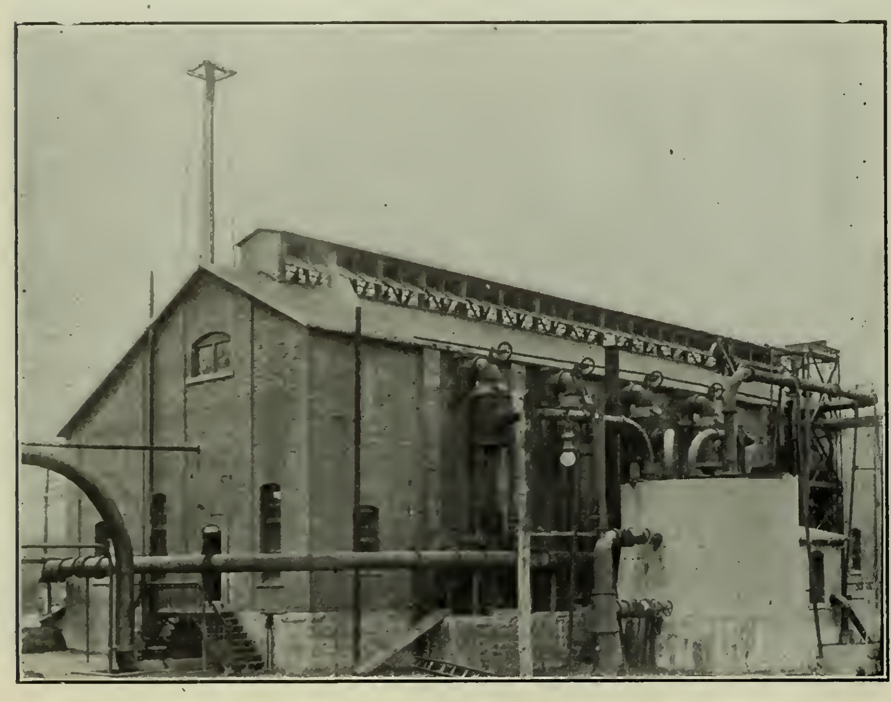

FIG. 11. SHOWING THE BAROMETRIC CONDENSERS

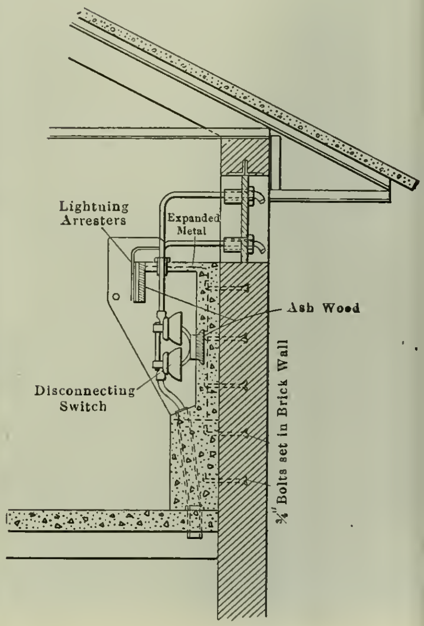

FIG. 15. ELEVATION OF LIGHTNING-ARRESTER ARRANGEMENT

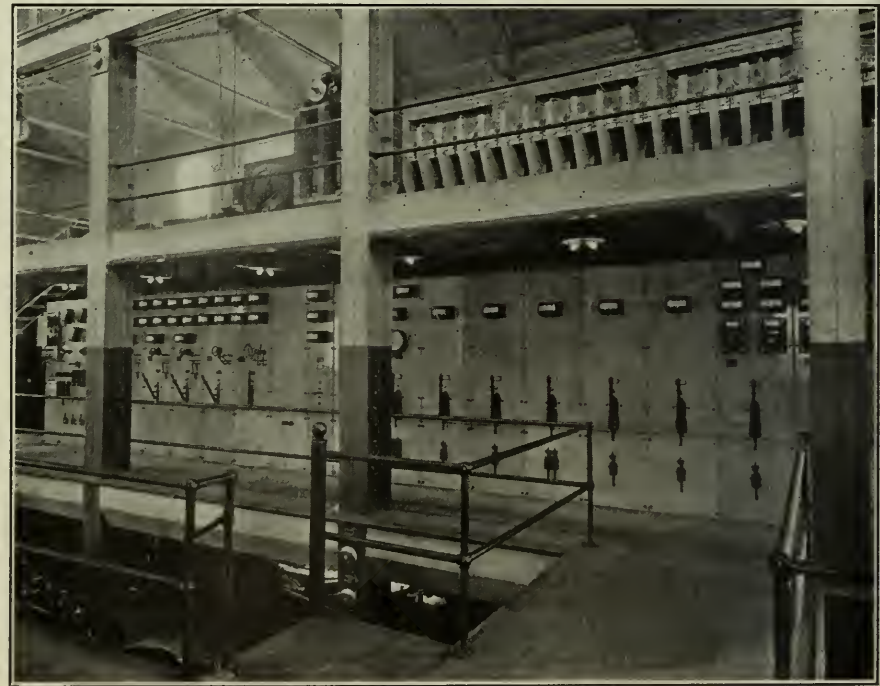

FIG. 13. GENERAL VIEW OF THE SWITCHBOARD

In the rear portion of Fig. 9 is shown the Curtis turbine, switchboard and one of the 10-ton cranes, the other being over the Allis-Chalmers turbine and used for handling the outer bearing, if necessary.

An elevation showing the arrangement and steam pipes of one of the Curtis turbine sets, dry-vacuum pump and exciter units is shown in Fig. 10.

Condensers

Four of the Curtis turbines are connected to Worthington barometric jet condensers and one is connected to a Worthington surface condenser. The Allis-Chalmers turbine is connected to a Tomlinson barometric jet condenser. The barometric condensers are placed on the outside of the turbine building, as shown in Fig. 11.

As is well known, mine water contains more or less sulphuric acid; therefore, considerable trouble has been encountered with the condensers, as mine water is used for condensing purposes in the jet condensers. In this case the water contains 39 grains of free sulphuric acid per gallon of water.

FIG. 12. THE EXCITER UNITS

The condenser heads were attacked as a matter of course, and to obviate this they were lined with lead as a protection. Here a difficulty was encountered, as air would get between the lining and the shell when the condensers were not in use, consequently, when a vacuum was again formed the air, due to expansion, would push the lead lining inward, reducing the area of the condenser heads and requiring more water to produce the same vacuum. Wood linings were next tried and have given fair satisfaction, and if the condensers could be operated continuously there would be but little, if any, trouble encountered. The alternate wetting and drying, however, tend to loosen the wood casing. Water-supply pipes lead the condenser heads from the concrete tank shown in Fig. 11. The water flows to the tank by gravity through concrete pipe.

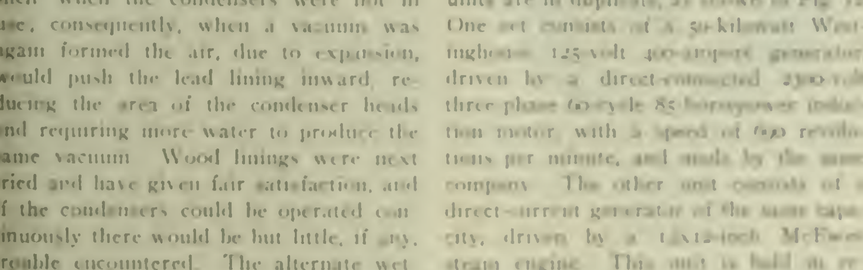

FIG. 14. PLAN OF LIGHTNING-ARRESTER LAYOUT

The surface condenser obtains its water from the reservoir containing the feed water. The course of the water is through the condenser to the circulating pump, and then through the heater, the surplus, if any, returning to the reservoir.

The vacuum is handled by two Worthington vacuum pumps which care for the Curtis turbines, one being a reserve. There is also a Union Steam Pump Company's vacuum pump for the new turbine. The layout of these units is shown in Fig. 8.

EXCITER SETS

As in all other apparatus, the exciter units are in duplicate, as shown in Fig. 12. One set consists of a 50-kilowatt Westinghouse 125-volt 400-ampere generator, driven by a direct-connected 2300-volt three-phase 60-cycle 85-horsepower induction motor, with a speed of 690 revolutions per minute, and made by the same company. The other unit consists of a direct-current generator of the same capacity, driven by a 12x12-inch McEwen steam engine. This unit is held in reserve and used in starting up in case the entire plant should be closed down for any cause. This unit runs at 280 revolutions per minute.

SWITCHBOARD

A general view of the switchboard is shown in Fig. 13. It consists of 12 panels of Vermont marble divided into six generator panels, the remainder being utilized for instruments and distributing panels, which are equipped with the necessary switches, recording instruments, etc. It is regrettable that a photograph of the rear of the switchboard could not be obtained, as it presents one of the most compact and yet systematic arrangements of switchboard wiring and feed-line distribution the writer has seen. All cables and wiring are incased in iron pipe and fiber conduits which are arranged in a systematic manner. The feed lines, incased in the fiber conduit, pass to the lightning arresters, which are arranged in a group on a platform above and back of the switchboard, as shown in Fig. 13. A plan and elevation of the lightning-arrester arrangement and wiring are shown in Figs. 14 and 15. The arresters are attached to a concrete backing secured to the brick sidewall of the station. Between each pair of arresters is a concrete slab 3 feet 2 inches high, 3 inches thick and 12 inches wide between the arresters. These slabs, which prevent arcing in case of lightning discharge, are removable. They are placed 9½ inches apart and are 24 in number. The outer feed lines pass out through the wall as shown.

The current generated by this plant is sent through overhead wires and lights the mines and breakers and operates the electric locomotives in the various mines. It also lights the passenger station and the railroad shops in Scranton. An arrangement is also made for switching current to the local electric company, if desired, and vice versa.

The writer is indebted to H. M. Warren, electrical engineer of the company, and Christopher Schillinger, engineer of the Hampton boiler plant, for data pertaining to this installation.

Effect of Superheated Steam on Mineral Cylinder Oils

According to G. W. Worrall and J. E. Southcombe, in a recent issue of the Journal of the Society of Chemical Industry, (1) no chemical change of a hydrocarbon cylinder oil takes place in a cylinder using steam which is not heated up to 700 degrees Fahrenheit; (2) the deposits consist chiefly of oxide of iron, which is formed independently of the oil; (3) the adherence of the iron-producing deposits depends upon the [illegible] constituent in the oil and the completeness of distillation; (4) the oil is carbonized by the steam, the shape of the cylinder and adjacent parts and the temperature influencing the quantity of sooty matter resulting hereby.—The London Practical Engineer.

A correspondent recommends the application of equal parts of lard, graphite and tallow oil, in equal parts, to the hot box of a journal, to reduce the heat.

Development of the High Speed Steam Engine

Why the Compound Single Valve Engine Is Preferable Where High Efficiency Is Necessary; the Angle Compound Engine; Inertia Thrusts

Tuesday evening, December 15, Frank H. Ball lectured before the Modern Science Club, of Brooklyn, N. Y., on "The Development of the High-speed Engine." Lantern-slide illustrations were freely used. The lecture hall was filled and the discussion which followed the lecture was pertinent and interesting. What Mr. Ball said was, in part, as follows:

It has been said that Charles T. Porter is the father of this type of engine, and it is true that he built and sent to the Paris Exposition of 1875 a remarkable engine which attracted great attention because it ran at much higher speed than was customary at that time; and it ran very smoothly and quietly. The performance of this engine was partly due to the design, which made it extremely rigid, and partly to the liberal size of the bearings and the perfect workmanship.

Mr. Porter embodied in this engine a pet theory of his regarding the use of heavy reciprocating parts for the purpose of absorbing the shock of the impact of steam on the piston during admission and giving off the stored-up energy to the crank pin during the latter part of the stroke, when these parts are being brought to rest. In other words, these heavy parts were to act as a flywheel in equalizing the effort on the crank pin throughout the stroke.

Those who have seen Mr. Porter's book on the Richards indicator will remember the elaborate tables given for calculating the effort on the crank pin as modified by the inertia of the reciprocating parts. These calculations are all very correct, and are theoretically beautiful, but experience has shown that this refinement is unnecessary and that heavy reciprocating parts are very difficult to counterbalance, and are, therefore, very destructive to foundations, so that extreme lightness of these parts is now considered desirable for high speed.

The Porter engine, although it ran at a high speed, did not belong to the class since called high-speed engines, because its valve gear was entirely different, and it did not use a shaft governor.

The chief characteristics of the modern high-speed engine are the shaft governor and generally a single valve. The first engines that came into general use with these distinguishing features were built by the Armington & Sims Company, of Providence, R. I.

Then followed the familiar straight-line engine of Professor Sweet, and another that will be called to your attention soon, and as the electrical business grew, the number of builders of these engines increased greatly.

At first the electric generators were all belt-driven machines of small capacity, and the engines were therefore small. Later the generators grew in size, and as the horsepower of the engines increased to correspond, the question of efficiency became more important. The Corliss engine was then, as it is now, the standard of efficiency, but the regulation was less satisfactory than with the shaft-governor engines, and it was inconvenient and cumbersome to belt from the slow-speed engine to the high-speed generator. Therefore it became a choice of evils between the inconvenience of the slow-speed engine and the less efficient performance of the high-speed engine, with the advantage clearly on the side of the shaft-governor engines for small powers, and the Corliss engine for large powers, but with the

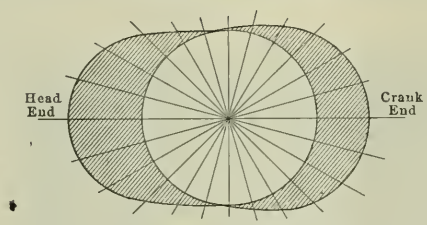

FIG. I. 160-HORSEPOWER SIMPLE ENGINE. UNBALANCED RADIAL FORCES WITH RECIPROCATING PARTS COUNTERBALANCED

boundary line of good practice not clearly defined. The tendency seemed to be to increase the field of the Corliss engine, and to limit the use of high-speed engines to still smaller powers, when it was found that single-valve engines were peculiarly adapted to compounding, and unlike the Corliss engine, these compound engines were very desirable for noncondensing service.

This changed the situation materially, for it was found that the high-speed compound engine was appreciably more efficient than the simple Corliss engine, so that the boundary line of good practice was moved up a long way into the field of larger powers, which had been held by the Corliss engine.

These compound engines first appeared as tandem engines, or as cross-compounds, but always with a shaft governor, and for many years the single valve was universally used. During all these years there was great similarity between the engines produced by the large number of builders of this class of machinery, but presently there began to be a divergence in the ideas of designers. Some sought to improve the efficiency of the single-valve engines by the use of complicated valve gears and an increased number of valves, while others claimed that the small gain in efficiency to be obtained by a multiplication of the valves and parts is more than offset by the increased cost of maintenance, and the greater liability of interrupted service, and that where high efficiency is desired a better plan is to use a compound engine of simple design and few parts.

The advocates of the multiple-valve high-speed engine answered this argument by proposing to compound the four-valve engine, while the opponents of the plan condemned it severely as being a wholly impracticable arrangement, because of the greatly increased number of parts and the rather appalling complication, which was held to be very objectionable for high speed.

Those who advocated the simpler valve gear for high-speed engines sought to realize the extreme of simplicity and fewness of parts. An illustration of the development in this line is found in the type known as duplex-compound. Comparing this with the compound engine just considered the difference in the valve gear is rather startling to the man who is expected to maintain these mechanisms.

Bear in mind that both these engines are compound engines. The engine wtih complicated valve gear gives slightly better efficiency, but the saving is unimportant. The following table of the number of parts in the valve gear of both engines makes an interesting showing:

	Eight-valve Compound.	Duplex Compound.
Number of eccentrics	2	0
Number of eccentric crank-pins	0	1
Number of eccentric rods	2	1
Number of connecting links	12	0
Number of rock arms	19	2
Number of rock-arm pins	26	2
Number of valves	8	1
Number of valve stems	8	1
Number of stuffing boxes	8	1
	85	9
Total number of working bearings	42	5
Total	127	14

The question naturally arises, what is the increased efficiency to be obtained by all this complication? The relative performance of the three classes of engine, the Corliss, the four-valve high-speed engine and the single-valve engine, may be best illustrated by comparing simple engines of these types. The Corliss engine has been so long known and so fully tested that its performance is well established as approximately 26 pounds of steam per horsepower per hour under usual conditions. The single-valve engine has been very definitely located at about 30 pounds per horsepower per hour, but the four-valve high-speed engine is newer and its efficiency is not so well known. Without regard to what may be finally considered a fair representation of the average performance of this engine, it must be evident that because it does not use the releasing valve gear, and because its clearance is necessarily greater than the Corliss engine, its efficiency must fall short of the standard efficiency of the releasing-gear engine, and its performance must therefore be between the Corliss and the single-valve types.

It has been abundantly demonstrated that the single-valve compound engine develops power on a consumption of from 22 to 24 pounds of water per horsepower per hour and therefore it is a more efficient engine than any type of simple engine.

It becomes, then, a question of the practicability of compounding the four-valve high-speed engine. Here again an interesting comparison may be made between the two types of valve gear, as follows:

NUMBER OF MOVING PARTS AND WORKING BEARINGS IN VALVE GEAR.

	Simple Engine	Compound Engine
Four-valve type	71	127
Single-valve type	14	14

From this table it appears that the single-valve engine may be compounded without increasing the number of parts of the valve gear, whereas the compounding of the four-valve engine increases the number of these parts 60 per cent.

The matter is summed up by the advocates of simplicity in high-speed engines as follows: Where the efficiency is not important the simple single-valve engine is desirable because it represents the smallest initial investment and the least cost of maintenance.

If high efficiency is necessary, then the compound single-valve engine is better than the simple four-valve engine, because it does not increase the number of parts of the valve gear and it is appreciably more efficient than any form of simple engine.

Leaving these comparisons and going back to the early days of the high-speed engine, you will remember the pioneer engine with shaft governor, known as the Armington & Sims engine. Then followed the straight-line engine of Professor Sweet and about the same time the engine which is to be followed in its development through all these intervening years.

The distinctive features of the high-speed engine are the shaft governor and the single valve, but we will not undertake to follow the development of these governors. A description of one of the latest designs may be interesting. The features of this construction are the gravity balance and the arrangement of the springs. During the whole period of the development of the engine the same form of the valve has been used continuously in the simple engine.

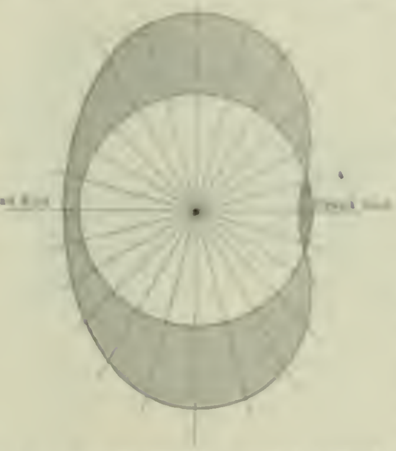

FIG. 2. 160-HORSEPOWER SIMPLE ENGINE. UNBALANCED RADIAL FORCES WITH RECIPROCATING PARTS COUNTER-BALANCED

Going on now to the compound engines as the next stage of development, the duplex-compound will be investigated as being along the line of extreme simplicity. The latest development along the line followed is a new type of compound engine that many of you have not seen.

FIG. 3. 160-HORSEPOWER ANGLE-COMPOUND ENGINE. UNBALANCED RADIAL FORCES WITH RECIPROCATING PARTS COUNTERBALANCED

This engine is called the "angle-compound" because the high-pressure and low-pressure elements are placed at an angle of 90 degrees in the plane of the crank's rotation, and both connecting rods engage the same crank pin, being placed side by side on a pin of double the usual length. This general arrangement is not new. It is the general plan of the mammoth engines installed in one of the large traction power houses in New York City, and has been very successful there and elsewhere.

Engineers do not seem to have realized, however, the peculiar advantages of this form of construction for small high-speed engines, where the counterbalance problem makes smooth running and freedom from vibration increasingly difficult as the speed is increased.

With even moderately high speed it has been found wholly impracticable to depend on ordinary foundations to resist the unbalanced inertia thrust of the reciprocating parts of horizontal engines, so a certain amount of counterbalance is therefore placed opposite the crank to neutralize these inertia thrusts.

The difficulty here encountered is that while it neutralizes horizontal thrusts, it also develops an unbalanced thrust in a vertical plane, so that, contrary to a very prevalent idea, the reciprocating parts of an engine cannot be counterbalanced by a rotating counterweight, and it becomes a matter of choice as to what part of this thrust shall be transferred from the plane of the engine to a plane at right angles to it. With horizontal engines it is common practice to use a counterweight to the extent of transferring the larger part of the inertia thrust to a vertical plane, because ordinary foundations resist vertical thrusts more successfully than horizontal thrusts. The magnitude of these thrusts increases as the square of the speed of rotation, so that at very high speeds they become very serious.

It has been positively demonstrated that the counterbalance in the driving wheel of a locomotive, necessary to prevent the engine from "nosing" badly at high speed, develops so much vertical thrust that the wheels, with the weight of the locomotive on them, actually lift clear of the rail at each revolution.

Keeping this all in mind it is evident that with the angle-compound engine the counterweight necessary fully to neutralize the inertia thrusts of the horizontal engine is just what is required to neutralize the inertia thrusts of the vertical reciprocating parts when the crank passes the line of centers. A practically perfect balance may therefore be obtained if both sets of reciprocating parts are made to weigh the same, and the counterbalance be made sufficient entirely to neutralize the inertia thrusts as the crank passes each of the four centers.

This is just what has been done in the angle-compound engine, with the result that remarkable smoothness of running is obtained even at very high speeds and the foundation problem becomes a very simple one. There are four small impulses on the crank pin of this engine at each revolution, instead of the two large ones ordinarily delivered to the crank pin of an engine. This is a more desirable condition for uniform rate of rotation without heavy flywheels and, because the shocks of impact are small on all these bearings, the wear is proportionately slight and the tendency to heat is reduced.

Among the many views shown on the screen were three showing the inertia thrusts of the reciprocating parts on the crank pin. These were graphic illustrations of the extent and direction of the force developed. Fig. 1 shows the direction and extent of the inertia force in an engine with unbalanced reciprocating parts; Fig. 2 shows the transference of force from the horizontal to the vertical plane when the reciprocating parts of the engine are as nearly balanced as may be by revolving weights; and in Fig. 3 is shown the inertia stress exerted in the angle-compound engine with the weight of both sets of reciprocating parts made to weigh the same, with the counterbalance sufficient to neutralize the inertia thrust at each center. There are thus four small inertia impulses at each revolution instead of the ordinary two large ones of the single engine.

Reserve Power for Auxiliaries

By W. H. Wakeman

There are many large and medium-sized plants in which the operation of the main engine depends on the action of auxiliary apparatus which is not equipped with reserve power of any kind for driving it, in case the regular means fails on account of an accident or the wearing out of some essential part.

For illustration, a certain mill that is run twenty-four hours per day is lighted by electricity supplied by a generator driven by a simple high-speed engine. If this engine is disabled by an accident the generator must stop, because no other method of driving it has been provided. This would leave the rooms in darkness, as the local electric-lighting company declined to supply current in case of such an emergency, and would not run wires into the plant for this purpose, as they wanted all of the job or none of it.

Again, a large power pump draws water for a certain manufacturing process. It must deliver water nearly every hour that the plant is in operation, or else the supply does not equal the demand; consequently, if it stops for any cause, the main engine must be shut down until the damage is repaired.

A certain plant which develops about 1000 horsepower is equipped with a stack sufficient for about 200. A fan is located between the boilers and this stack, and it is large enough to send the products of combustion to the low stack at a very rapid rate; but if the single engine which drives it is temporarily disabled no other means can be used to make it revolve, because none has been provided.

These illustrations show the advisability of providing more than one way to drive these important auxiliaries, especially when the comparatively small expense involved is considered.

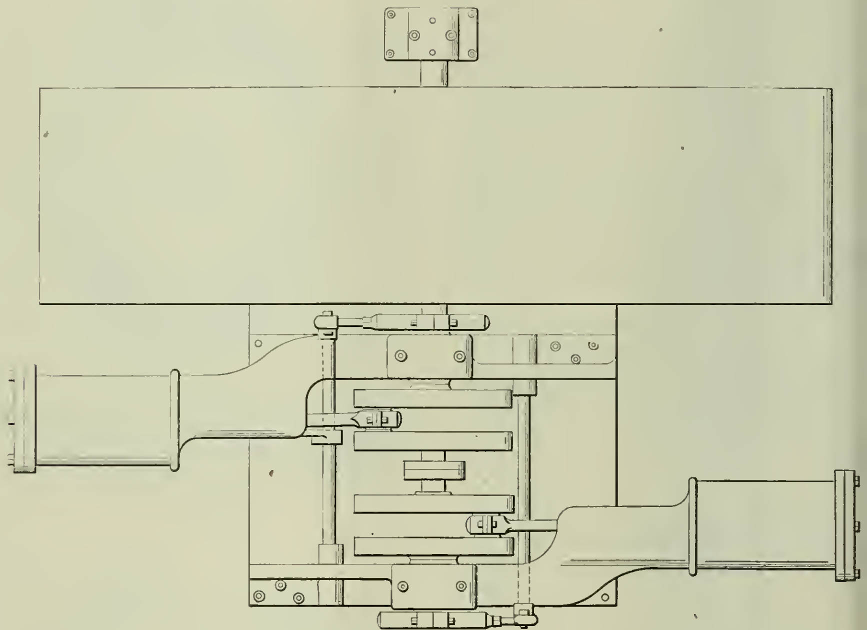

FIG. 1

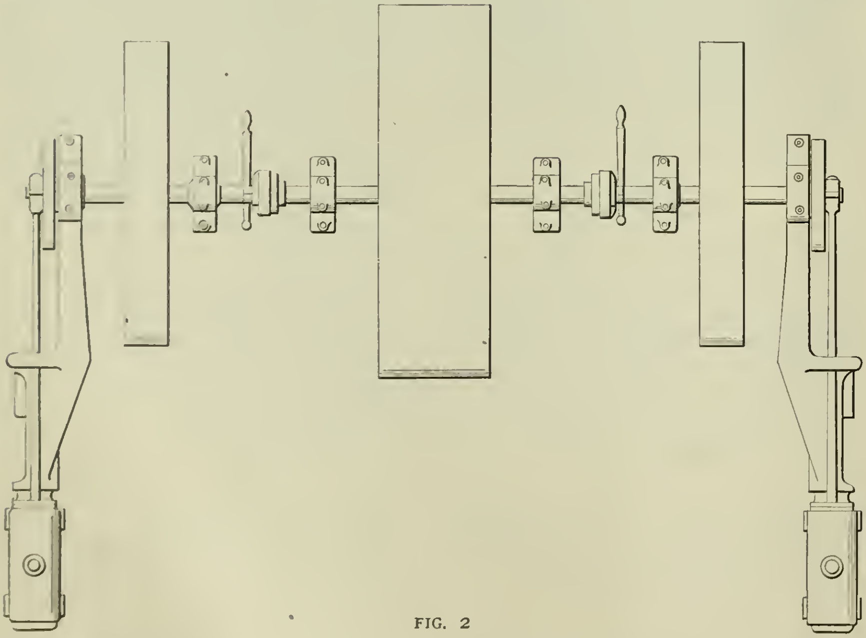

FIG. 2

Fig. 1 is a compact double engine which can be used as shown, or if one piston, cylinder, crosshead or connecting rod must be repaired, that part can be disconnected and the other used to drive part of the load, or carry the whole of it, if possible. Such an engine ought to be designed so that one cylinder will be large enough to do nearly all of the work; then, if both are used the liability of accident will be made less and the parts will prove durable. The engine as a whole will not show its greatest possible efficiency, but inasmuch as it develops only a small part of the power used this is of little consequence.

Fig. 2 occupies more space, but the design is excellent for several reasons. This shows two separate engines, with one flywheel that is common to both. It is not necessary to run one "over" and the other "under," as both must revolve in the same direction.

A substantial cutoff coupling is provided for each, with a suitable lever to operate it, by means of which either one or both of the engines can be disconnected with no delay whatever. They also make it practical to set the cranks in any desired position in relation to each other at pleasure as it is only necessary to shut off steam from both cylinders and set one crank on either center. Release the other coupling set this crank with the other, directly opposite to it, or at any point between these extremes. Throw in the lever and the cranks must remain in the given position.

A heavy balance wheel is provided for each engine for the following reason: The turning effect on the crank shaft in each case is not constant, but varies with the position of the crank pin, therefore the resulting strain on the cutoff coupling would be severe if it was not counteracted by the steady motion of the balance wheel. On this account a throttling, slide-valve engine, with a valve designed to cut off at seven-eighths stroke, is better than one of the automatic type, because its action is more nearly uniform in this respect.

Catechism of Electricity

914. If the sparking is due to the brushes, how should it be remedied?

If the brushes do not conform to the curvature of the commutator, or are not smooth, a strip of coarse sandpaper should be wrapped face upward once around the commutator, allowing it to lap a couple of inches over the first turn. By slowly turning the armature while the brushes are thus pressing on the sandpaper around the commutator, the contact surfaces of the brushes will be given the desired curvature. Then remove the coarse sandpaper and give each brush the necessary smoothness by drawing back and forth under it a short strip of fine sandpaper, keeping the back of the sandpaper throughout its length close against the surface of the commutator. Use a bellows to blow out the carbon dust from the commutator, brushes and brush holders and adjust the tension spring of the brush holders so the brushes are given the proper pressure upon the commutator as explained in 890.

Oil is sometimes applied to the commutator for the purpose of reducing the noise or chattering of the brushes and when much of it has been applied the brushes become sticky and readily collect dirt on their contact surfaces, producing sparking. They should then be cleaned by a cloth moistened in oil or benzine.

915. Is there any simple way of ascertaining whether sparking is caused by brushes of too high resistance?

Yes, this may be detected by the abnormally high temperature of the brushes. Such brushes should be replaced by others having a lower resistance.

916. How is one to know if the brushes are at the neutral points?

If there is sparking, and by shifting the brushes slightly around the commutator by means of the rocker arm the sparking is decreased, it proves that the brushes were not at the neutral points. In case, however, the brushes are not spaced as explained in 892, no amount of shifting will place them at the neutral points. They must then be readjusted before satisfactory results can be secured.

917. What causes the commutator to become rough or worn?

Unless there is some end play in the armature shaft, allowing it to move backward and forward in accordance with the motion imparted to it by the belt, the

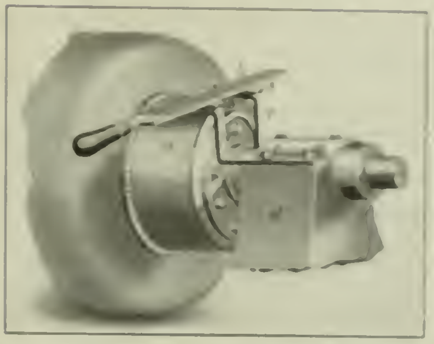

FIG. 285. A CONVENIENT FORM OF FILE REST FOR SMOOTHING THE COMMUTATOR

brushes will bear continuously on the same portion of the commutator and will in time cause it to become grooved and roughened. Hard particles in the carbon brushes will scratch the commutator. And it may be that the commutator has been turned out of the shop in a rough state.

Sometimes a bar in the commutator is of softer metal than the others and, by wearing, more rapidly causes the commutator to become flattened or eccentric. There will then be a gap between the brushes and the commutator at this point, resulting in sparking.

A high bar in the commutator, or a projecting strip of mica between the bars, which on account of its hardness does not wear down as quickly as the bars, will throw the brushes off the surface of the commutator during the rotation of the latter, and this will cause sparking.

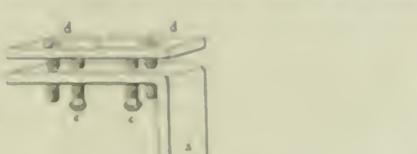

FIG. 286. DETAIL OF THE FILE REST SHOWN IN FIG. 285

918. What is the best guide with reference to the condition of the commutator and brushes?

The appearance of the commutator. If there is perfect contact between the brushes and commutator, the surface of the latter will take on a glossy brown or bronze appearance. A rough commutator, however, will generally overcome itself by lowering the brushes so make a chattering noise; this is particularly the case in high-speed motors. With an uneven commutator there will be a considerable rising and falling of the brushes when the armature is rotating slowly.

919. What precautions should be observed to keep the commutator in good condition?

Wipe its surface occasionally with a soft cloth or piece of waste to remove accumulations of dust. Dust is a direct cause of poor contact between brushes and commutator; it is therefore responsible for much of the sparking, roughness and heating of a commutator. After removing the dust from the commutator, it is advisable to place a few drops of good machine oil or vaseline on a clean portion of the wiping cloth, and while the commutator is in motion, move the cloth slowly across it so the oil will spread lightly over its entire surface.

920. If the commutator is rough, how should it be smoothed?

Place a piece of fine sandpaper on a block of wood which has been hollowed out to fit the curvature of the commutator and press it against the commutator while the armature is in motion. If the commutator is very rough or unevenly worn, sandpaper does very little good. It is then necessary to use a file.

921. Explain how to use a file in smoothing the commutator.

The grade of the file used should depend on the work to be done, but it must be one that is least liable to be clogged by the copper. Oil must be used freely to avoid heating and clogging, and to make the file cut well. The commutator must not revolve too rapidly and the file must be held properly. The hand which holds the file from slipping should be in a position where the commutator tends to pull rather than push the file. Failure to observe this rule may result in serious injury to the hand, or in a piece gouged out of the commutator.

To make a file safer and more serviceable for this work, a file rest should be provided. Without a file rest it is impossible to file the commutator surface level from end to end, and the flat places will not be taken out but made larger. There is also danger and difficulty in doing the work. Where there are several motors (one size), one file rest may be used for all of them.

922. What kind of a file rest should be used and how should it be fastened in place?

A convenient form of a file rest, bolted in place, is shown in Fig. 285. It consists of two pieces of iron, a and b, each provided at one end with an adjustable point c. Each of the pieces a and b is attached to one side of the bearing d, and is held in position by the cap bolts e and c. A bar f is laid across the pieces a and b, which are so adjusted that the file will just touch the commutator *a*.

The separate parts of the file rest are more clearly illustrated in Fig. 281, where *a* represents one of the pieces of iron, provided with slots *b*, etc., for the reception of the cap bolts. The other end is made adjustable by being provided with an extra piece *c*, whose hight is regulated by the screws *e*, etc. The piece *c* after having thus been raised to the proper hight is held in position by the screws *d*, etc. The part *c*, consequently, rests on the screws *e* and *e* and is held on them by the screws *d* and *d*. The latter screws are countersunk so that they will not be in the way of the file. The bar *a* should be of such dimensions that the pressure on the file will not cause it to move.

Driving up Bags in Steam Boilers

By M. Kennett

Among the many defects to which steam boilers are subject, there is none more common than that which is usually called a bag. These are sometimes called blisters, although a blister, or lamination, which is the correct name, is an entirely different phenomenon. In the days of iron boiler plates, laminations were quite common, but they are seldom found in modern steel plates, although occasionally met with, and the writer has noticed that they appear to be more common in the heavy plates which have recently been coming into more general use, than in the lighter ones.

A bag is caused by the sheet becoming overheated from some cause and forced out by the pressure. This overheating is usually caused by an accumulation of scale or sediment on the fire sheet, or it sometimes occurs around the blowoff at the rear. There are two methods of repairing a bag: one is to drive the metal back to its original position, and the other is to cut out the affected portion and put on a patch. Generally speaking, it is a great mistake to patch a boiler on this account unless the bag is unusually deep or very large. A patch is objectionable for several reasons. If it is of considerable size it weakens the shell, unless provided with the same design of riveted seam with which the longitudinal joints are provided, and this is usually impractical unless a half sheet or two-thirds sheet is put in. Owing to the difficulty of doing the work under unfavorable circumstances, the rivet holes often do not come fair when the patch is to be riveted-up, and the drift pin is resorted to, with the result that the rivet holes soon crack out, forming what are known as fire cracks and causing a great deal of annoyance from the resulting leakage and corrosion of the sheets. Furthermore, it is much more expensive to put on a patch than it is to drive up a bag, even of considerable size.

The process of driving up a bag is so simple that there is little excuse for an engineer calling in a boilermaker to do it, yet frequently bags are allowed to remain in boilers for months at a time because the engineer dislikes to call in the boilermaker. It is not good practice to allow a bag to remain in a boiler, as it forms a pocket which is apt to collect more sediment and serious results are liable to follow.

To drive up a bag, the plate must be heated to a dull cherry red, and with a short-handled sledge hammer light enough to be handled easily and quickly it should be driven back. Care must be exercised to start around the outer edge and gradually work in toward the center, for if the work is started in the center, the plate is certain to be buckled and cannot be straightened without probably removing some of the tubes and driving it back from the inside. When a bag forms in a boiler, the metal is stretched and, of course, is reduced somewhat in thickness, and in driving it back the metal must be made to flow back to its original position. In order to do this it is plain that work must be started on the outer edge, gradually proceeding in toward the center as the metal is forced in ahead of the hammer. In the case of a very deep bag it is sometimes impossible to cause the metal to flow back sufficiently to prevent buckling and in this case it is a good plan to drill about a 1-inch hole in the center of the bag, so that the surplus metal will flow into this space, almost completely closing it by the time the sheet is straightened, after which it should be reamed out and fitted with a rivet.

The essential apparatus is a forge of some kind for heating the plate and a hammer. This forge must be such that it may be easily pushed aside out of the way when the required heat has been reached, for the thin sheet will cool quickly and no time can be lost. A style of forge which the writer has used to good advantage is made of a common galvanized-iron water pail as follows: About 3 or 4 inches from the bottom a number of holes are cut and into these pieces of 3/8- or 1/2-inch pipe are slipped to serve as grate bars. Below the grates another hole is cut and a short piece of 1/2-inch pipe inserted, to which a hose leading to a small bellows is attached for the blast. This will be found to be an excellent forge for the purpose, being inexpensive and so light that it is easily removed.

When ready to proceed with the work, remove the boiler grate bars, with the exception of one on either side, and lay a couple of boards across these to set the forge on. Fill the forge with charcoal and set it on the boards close up against the boiler shell and directly under the bag, and by means of the blast from the bellows bring the metal to a dull red heat. A small pile of charcoal placed in the bag inside the boiler will assist in this somewhat. Do not hurry the heating, and when the desired temperature is reached, remove the forge as quickly as possible and with the hammer begin driving up the sheet, working around the outer edge. Work until the metal is almost black and then heat it again, working in toward the center all the time and taking care not to drive the sheet up too far. It is better, if anything, not to drive it up quite far enough rather than too far, as the finishing may be done with a flatter as a final touch, using a straight edge to make sure there is no depression remaining in the plate. Of course this cannot all be done in one heat, and if the bag is very deep or large, a great many may be required. In one case a large bag required 80 heats, although not all in one spot.

Some engineers are of the opinion that if a sheet has once bagged and been driven back, it is apt to bag again. There is no good reason to suppose that this is the case, however, and the experience of a good many years in this line of work does not justify it. The metal is practically the original thickness, and unless scale or sediment of some kind is allowed to accumulate, there is no reason why the sheet should come down again.

A small amount of oil or grease will produce a serious bag and one difficult to repair, because it extends over a great area, and for this reason, as a rule, cannot be driven back. Furthermore, the patch required is so large that the usual single-riveted seam would seriously weaken the shell, and a joint similar to that in the longitudinal seams must be used. These are not practical where exposed to the fire, and the consequence is that half or two-thirds of a sheet must be put in to bring these joints above the fire line.

Dimensions of Valve Parts

By O. James

The table on the opposite page gives values which will facilitate the design of composition valves for pressures up to 200 pounds per square inch and for sizes from 1-inch to 9 1/2-inch, with additional 11 1/2-inch and 13-inch heavy sizes.

This table is excellent for those who have to design valves, as each figure or size has been carefully checked by drawing the valve either to full or half scale.

The angle, cross and globe valves, with the different combinations of stop and check valves, for both light and heavy pressure, have been carefully treated, as will be seen from the different sketches above the table. Provision has also been made for loose seats in all the valves above 5 inches in diameter.

DIMENSIONS OF VALVE PARTS—SEE PAGE 152

The Plunger Hydraulic Elevator

Different Designs of the Lower Casting in "Standard" Plunger Elevators Described, with Illustrations of Piping Connections

BY WILLIAM BAXTER, JR.

Construction of Plunger Lower Casting

The lower casting *F* of the plunger is arranged to carry the guide brushes *H* that hold the plunger in the center of the cylinder. The construction of this casting and the way in which the brushes are held in place may be fully understood by the aid of the two horizontal sections, Figs. 295 and 296, taken on lines *N N* and *M M*, Fig. 291, and the vertical elevation, Fig. 297. The two sectional views also show a section of the cylinder *C*, to present more clearly the relative positions of the several parts. In Fig. 295 it will be seen that the brushes are held in grooves cast lengthwise of the casting *F*, and that these grooves are provided with flanges *a* along their inner edges, to prevent forcing the brushes too far in toward the center, and other short flanges *F′* to lock them in position. The brush back is made with short flanges *H′* that slide in back of the flanges *F′*. In putting the brush in position it is raised to the top of the groove and then pressed in until the flanges *H′* can be forced down back of the flanges *F′*, then the brush is driven down and a key *I*, Fig. 291, is put in above the brush to prevent it from jumping up. The brush is forced down until the back rests hard against the bottom *F″* of the side grooves in casting *F*. The keys *I* are not driven in endwise but sidewise, that is, toward the center of the casting

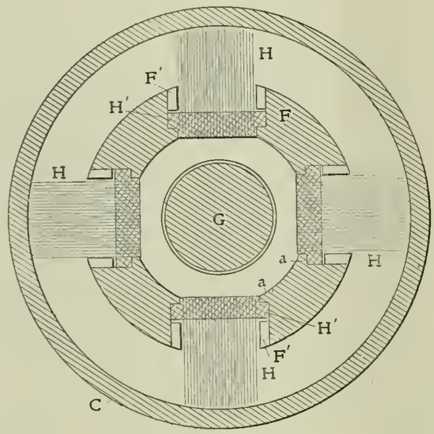

FIG. 295

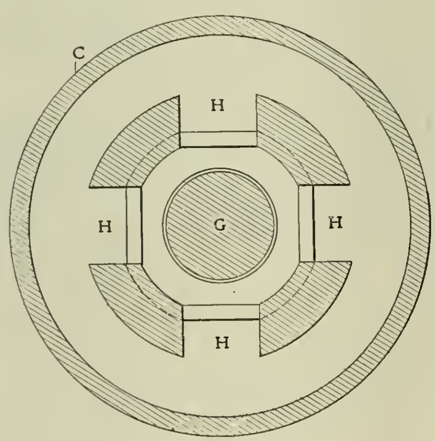

FIG. 296

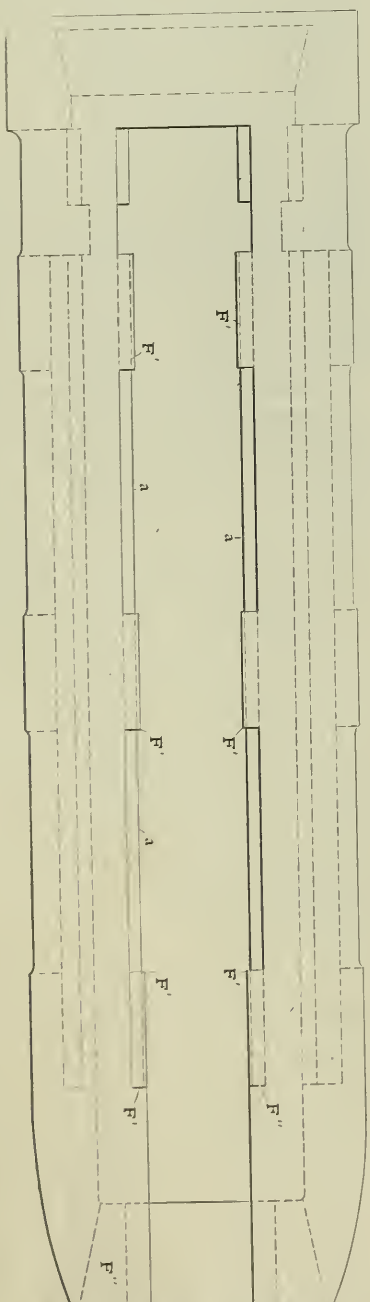

FIG. 297

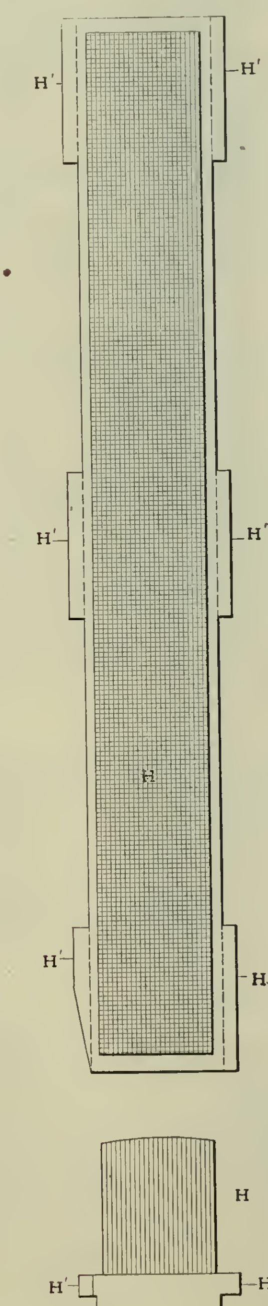

FIG. 298

and, when in position, are clinched so they cannot work out.

The shape of the brush is more fully shown by the aid of Fig. 298, which is a view looking at the face of the brush. The positions of the short flanges H' are clearly shown, there being six of them arranged in pairs. At the lower end the brush back is tapered off so as to facilitate getting it in the groove back of the flanges F' of the casting F. The space above the flanges F' is greater than the length of the brush flanges H', so there may be no difficulty in pushing the brush into the proper position. The brushes are made of hard spring-brass wire, about No. 22 gage. The back is of babbitt metal and is cast around the wires to hold them firmly in position. The grooves in the casting F, into which the brush backs fit, are not machined, but are simply carefully cast, and the burs well cleaned off. As the brush back is soft, there is no difficulty in forcing it into place. If it should fit too tightly, it can be easily shaved off where it binds. When the brushes are in place in the casting F the water in the cylinder can reach the central space through the openings above and below the brushes and also through the joints between the brush back and the casting, as these are not tight fits.

Another Design of Plunger End

Another design of plunger end made by the Standard company is shown in Fig. 299, which is a vertical elevation in section, showing the plunger at its highest position, that is, in the position it reaches when the car is even with the upper floor of the building. The brushes in this case are held by the bolts B. A horizontal section through the lower end of the casting F is shown in Fig. 300, from which it will be seen that there are only three brushes. The design, Fig. 291, can also be made with three brushes, but Fig. 299 cannot be made with four, unless they are made considerably narrower and the bolts B are set farther away from the center. This design is simpler than that of Fig. 291, but it is not as perfect. In the latter if the car overruns the upper limit of travel the holes B' in the piece B will pass above the stuffing box and let the water in the cylinder flow out before the brushes reach the packing, but in Fig. 299 it can be seen that for the water to escape the plunger must run up until the part F of the casting passes above the gland E, and this will carry the upper end of the brushes up into the stuffing. If the latter is of the cup type it may not be damaged to any extent, but if it is hemp it is liable to be pulled out of place. This plunger end cannot be used with the cylinder top shown in Fig. 289, unless there is so much head room above the elevator car, when even with the top floor, as to permit running it several feet higher before the casting F is high enough to permit the water to escape.

If with this cylinder top the plunger should run normally as high as it is drawn in Fig. 299, the brushes would be carried up into the brass lining D and, by being bent back and forth at every trip, would soon become useless. The cylinder top in Fig. 299 is very much shorter, so the plunger can run just as high as the plunger in Fig. 299 can run in the top in Fig. 289, without running the brushes up into the bore of the casting.

FIG. 299

FIG. 300

Piping Connections

The pipe connections between the pump, tanks and lifting cylinder of a plunger-elevator system are generally very simple, but in some of the higher-grade passenger-elevator installations they are very elaborate. The arrangement most commonly used is shown in Fig. 301. In this diagram A represents the lower portion of the elevator car, B the plunger, C the cylinder and D D spring buffers provided for the car to rest on when at the lower floor. The main valve is shown at F, and is represented as of the simple rack-and-single-gear type. The discharge tank is at G, and H is the pressure tank. The water in the lifting cylinder C is discharged into the tank G through the pipe L, and from this tank the pump draws its supply through the suction pipe M. The discharge pipe N of the pump leads to the pressure tank H, and from the latter the water is carried to the lifting cylinder through the pipe O. In order to keep the necessary quantity of air in the pressure tank H means must be provided for forcing air into it from time to time, to replenish that which will inevitably escape in one way or another. In large installations, where several pumps and possibly tanks are provided, a small air pump is installed to furnish the compressed-air supply, but in smaller plants the pump K is arranged so as to be [illegible] necessary. The pressure tank H is provided with a glass water gage to show the height of water in it and also with a pressure gage. In addition, a pressure regulator is used to stop the pump when the pressure in H rises to the maximum, and to start it when the pressure falls below the minimum.

Fig. 301 shows a system provided with a full complement of hand valves, three of these being marked I, I' and I''. There are two more, one in the pump suction and one in the pump-delivery pipe N. When all these valves are placed in the pipe lines the inspection of the several parts of the apparatus may be done with very little trouble. If it is desired to examine or renew the cylinder packing, all that is necessary is to run the car down to the lower floor and then close valve I'. If the main valve is to be taken apart, the valves I, I' and I'' are closed. To inspect the pressure tank H, the valve I'' and the one in pipe N are closed. If repairs or inspection of the pump are required the valves in pipes M and N are closed. Thus with all the valves closed it is not necessary to drain water from any part of the system, as has been found in previous accidents in which it was assumed that a [illegible]. If the discharge tank is at a lower level than the cylinder pipe O the valve I' may be [illegible] pensed with without impairing the system, and we may also add that the balanced main valve *F* can be replaced by one of the unbalanced type, such as shown in Fig. 287. The valve in the suction pipe *M* may also be discarded.

The Nature of the Volatile Matter of Coal*

By Horace C. Porter and F. K. Ovitz

In connection with the fuel investigations being conducted by the Technologic Branch of the United States Geological Survey, a special effort is being made to determine the chemical and physical structure of coal. The chemical investigation is being pursued along three special lines: (1) The chemistry of combustion in the furnace, that is, determining the chemical composition of the hydrocarbons given off during the process of combustion; (2) the hydrocarbons which are given off at different temperatures, starting with a normal temperature and determining the nature of the hydrocarbons given off at each of a series of successively higher temperatures from the normal to the temperature of the ordinary furnace, and (3) the hydrocarbons existing in the coal at normal temperatures to be determined by solution and subsequent analytical methods.

A paper presented by Dr. Horace C. Porter at the June meeting of the American Chemical Society, of which the present statement is an abstract, relates to the second of these three lines of investigation. Dr. Porter is in charge of the chemistry of the distillates of coal under the United States Geological Survey. The statement is in part as follows:

It is a familiar fact to retort-coke-oven and gas-works operators that the volatile products of coal are largely affected, both in quantity and character, by the conditions of temperature and rapidity of the rise of temperature in the coal, and by the conditions to which the products are subjected after leaving the coal. The usual laboratory determination of volatile matter serves almost universally as a more or less valuable indication of the coal's adaptability to industrial uses either for combustion, destructive distillation or gasification. The method for this determination is, however, an arbitrary one and does not duplicate closely that of any industrial operation, nor is the character of the volatile matter produced by the laboratory method known with any degree of certainty. Furthermore, the results by the laboratory method are very sensitive to varying conditions, and the influence of such variation on the character of the volatile products has not heretofore been the subject of extended study.

The importance of the role played by the volatile matter in all industrial applications of fuel is generally recognized. There are more heat units in the volatile matter in proportion to its weight than in the fixed residue. Pittsburg coal, of 30 per cent. volatile matter and 7 per cent. ash, has 36 per cent. of its heat value in its volatile matter, as shown by comparing the heat values of coal and coke. When coal is fired under a boiler, either by hand or mechanically, it first undergoes a process of distillation, and both the quantity and quality of the volatile products and the relative ease of their liberation are concerned very largely in the boiler efficiency and the production of smoke. It is reasonable to suppose that coals of different origin may yield volatile gases carrying different percentages of tarry vapors and heavy hydrocarbons and may on that account differ in smoke-producing tendencies. A knowledge of the chemical reasons why coals smoke in varying degrees, and why high volatile coals are hard to burn with maximum efficiency, is a necessary preliminary to the taking of intelligent steps toward improvement in these respects.

The gas producer for bituminous and low-grade fuels is coming more and more into favor. Here also the volatile matter in the fuel plays a very important role, since at the top of the fuel bed a process of distillation is continually going on. A certain proposed new type of producer will utilize high volatile fuels, such as bituminous coal, lignite, peat and wood, by passing the hot gases from the producer through the raw fuel in a series of preliminary chambers, thus distilling the valuable hydrocarbon gases, as well as ammonia, out of the fuel before it is charged into the producer itself.

Attention need hardly be called to the preëminent importance of the volatile matter of coal in the illuminating-gas and by-product coke-oven industries. It is of interest to note, however, the increasing favor accorded by the gas industry to the

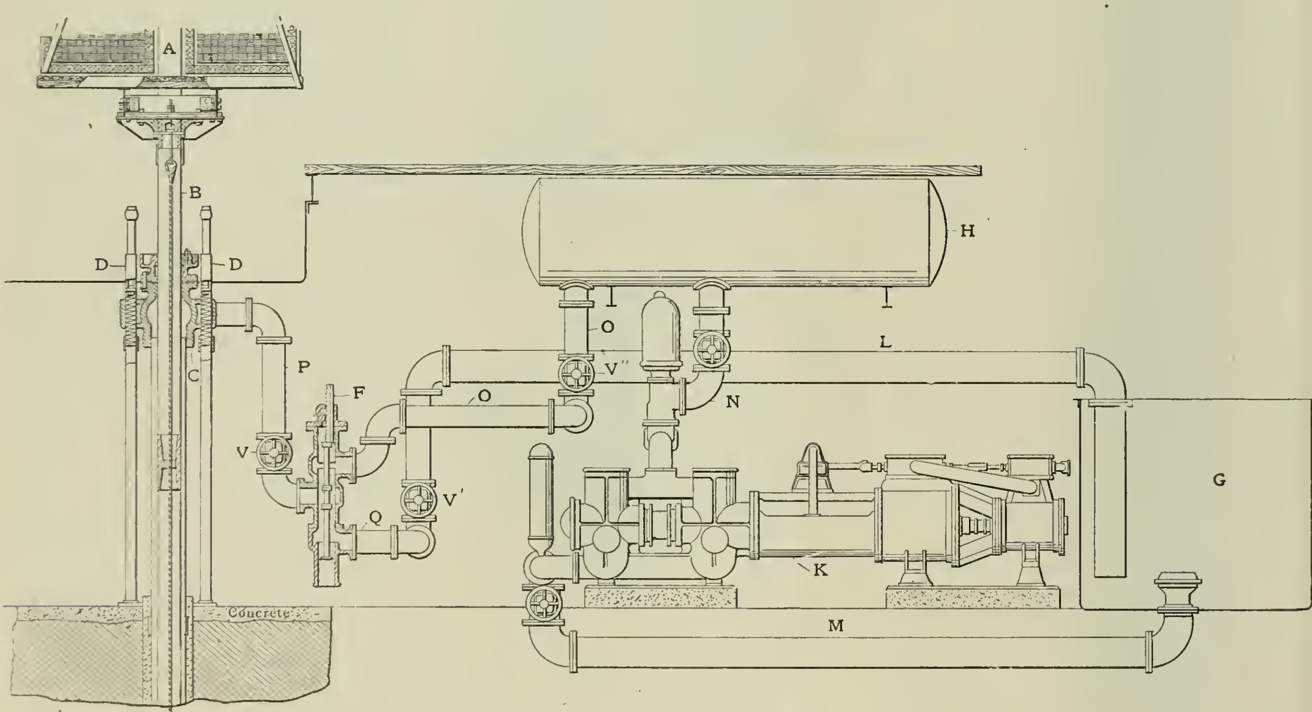

FIG. 301

vertical gas retort, as most successfully operated by the Bueb system at Dessau, Germany, and to explain that one advantage of this process lies in avoiding decomposition of certain valuable gases in passing over heated surface, as occurs in the ordinary processes, although at the same time a higher gas yield is obtained by using higher temperatures in the retort itself

Purpose of the Investigation

The purpose of the investigation described in this paper has been: (1) To throw light on the nature of the volatile products from coal, and on the manner in which they are affected by the conditions prevailing during their formation, or to which they are subjected after formation; (2) to contribute, in the interests of smoke abatement, some data on the comparative amount and character of the gases and vapors distilled from different coals at low temperatures, a subject intimately concerned in the production of smoke; (3) to prove experimentally that the volatile product of coal is to some extent incombustible, and that the proportion of inert volatile varies in different coals; and, finally, (4) to show that the oxygen of coal is in many cases evolved in the volatile matter very largely in combination with carbon as CO and CO_2 as well as with hydrogen as water, thereby explaining in great degree the discrepancy found in these cases between the determined calorific value and that calculated by Du Long's formula

Deterioration in Heating Value at Ordinary Temperatures

In connection with a series of experiments not yet completed, on the deterioration in heat value of various coals during storage under different conditions, a liberation of gas in remarkably large quantities was found in certain cases. About 25 pounds of bituminous coal of nut-wheat size was stored in a 5-gallon glass bottle closed with a rubber stopper, which was provided with glass tubes for removing gas samples. The bottles stood in the laboratory at a temperature ranging from 20 to 25 degrees. In some of the bottles the coal was immersed in distilled water and the interstices well filled with water by attaching a partial vacuum for about one hour. About 400 cubic centimeters of air remained above the surface of the water.

The gas liberated during these experiments consisted almost entirely of methane, with a very slight amount of CO_2 and no more than doubtful traces of CO and heavy hydrocarbons. No hydrogen could be detected by the palladium fractional combustion method. Whether this gas may properly be considered as volatile matter due to decomposition of the coal, or whether it is held in the coal as such by occlusion or absorption, cannot be decided without further study. The fact that the oxygen of the air surrounding the coal was rapidly absorbed without forming CO_2 indicates a change of composition in the coal. It is reasonable to suppose that a larger quantity of gas escaped between the mining of the coal and the starting of the experiments than was measured during the experiments. The measurement of quantity of gas formed is therefore of little value. The gas pressure in the case of one coal measured, reached at one time 7 inches of mercury.

*10 grams of coal.

Volatile Matter at 105 Degrees Centigrade

A series of experiments, conducted primarily for direct weighing of moisture driven off from coal at 105 degrees, yielded results incidentally which showed the amount of the loss of substances other than moisture, generally CO_2 in small percentages.

Volatile Matter at 500 to 1100 Degrees Centigrade

In studying the nature of the volatile matter at the medium and higher temperatures, 500 to 1100 degrees Centigrade, two sets of experiments were run, using a different apparatus in each. In one a 10-gram sample was heated in a platinum retort suspended in an electric resistance furnace maintained constant at the desired temperature, the gases evolved being collected by displacement of water in a bottle. No attempt was made in this set of experiments to duplicate the methods of industrial practice. The apparatus was designed with the idea of maintaining definite and controllable conditions which would yield results comparable with each other in experiments on different scale. The other set of experiments was run on a somewhat larger scale, heating 400 grams of coal in a cast-iron retort resting in a cylindrical electric resistance furnace, the tar, water, ammonia, CO_2, H_2S, and gas being collected in appropriate absorption apparatus and measured. Owing to the heavy nature of the retort and the large sample of coal the temperature in the coal could not be varied as easily in these experiments as in those using the platinum retort. Accordingly one set of conditions was adopted approximating as nearly as possible those of industrial by-product coke-oven practice, and a number of typical coals compared under these conditions. The object was rather to compare the different coals with each other under this set of conditions, than to determine absolutely the industrial by-product yields; and further, to determine the composition of the volatile matter from different coals under these conditions.

Series of Tests of 10 Grams of Coal

The series of tests on 10 grams of coal in a platinum retort, at various temperatures, is not yet completed, but has yielded sufficient results to show their approximate agreement with those obtained on 400 grams of coal, and also to indicate the composition of the gas produced from different coals in the early stages of heating at low temperatures. A thermocouple was inserted in the retort to determine the temperature under the surface of the coal itself. The tests were run in an atmosphere of nitrogen, which was passed through the retort until the exit gases contained less than 1 per cent. oxygen. The tar was collected in two 6-inch tubes of absorbent cotton heated to 100 degrees Centigrade and also weighed on the neck of the retort. The water was collected in a 5-inch $CaCl_2$ U-tube, and always contained a slight amount of light oil, driven over from the tar, causing an error of 1 per cent., or less.

Smoke Formation and the Composition of Low Temperature Gases

From the results given in Table 2 and in different form in Table 3, it may be seen that the low-temperature gases are high in illuminants and the higher homologues of methane, and low in hydrogen. Comparing the four coals at 700 degrees, where the gas begins to be formed in considerable amount, the Connellsville is the richest of the four coals in illuminants and heavy hydrocarbons and the Pocahontas the highest in hydrogen. The high CO_2 and CO from the Illinois and Wyoming coals accords with other experiments on these coals. The tar at 700 degrees is greater also in the Connellsville coal. The smokeless character of the Pocahontas coal may be connected more or less with the presence of considerable hydrogen in its gas at low temperatures, since the low-ignition point of hydrogen tends to assist in the burning of other gases present.

From the tables the bearing of these results on smoke formation may be seen. The smoke-producing constituents of the volatile matter are here considered as including tar, and the heavier hydrocarbon gases: benzine, ethylene and homologues of methune, calculated as C_2H_6. While at 440 degrees, in the coal, the Illinois coal, and probably also the Wyoming, has produced more smoky gases than the Eastern coals; at 565 degrees and higher the Connellsville produces much more. This accords with the finding in practice of greater difficulty in burning coals of the Connellsville type without smoke.

Conclusions Drawn from Experiments Made

1. Some coals liberate gas during storage, of a composition similar to that of natural gas, and some coals rapidly absorb oxygen from the air during storage without forming CO_2.

2. During drying in air at 105 degrees Centigrade, some coals lose appreciable amounts of CO_2, and most coals take up oxygen to a considerable extent, but none of those tested showed any considerable formation of combustible gases.

3. The nature of the volatile products, distilled from several coals at low temperatures in the early stages of heating, vary in different coals in accordance with their smoke-producing tendencies.

4. The volatile matter of coal comprises a considerable proportion of noncombustible matter, varying with the typ of coal.

5. A modification is suggested of Du long's heat-value calculation for coal based on experimental results showing th distribution of oxygen between hydrogen and carbon.

Steel Belts for Power Transmission*

Steel belts, or metal belts, are by no means unknown, yet they are not generally used and are considered as particularly unadapted for heavy duty. Thus the development of steel belts for heavy power-transmission service in Germany is of more than passing interest. The subject of this article is the steel-belt development of the Eloesser-Kraftband-Gesellschaft, of Berlin.

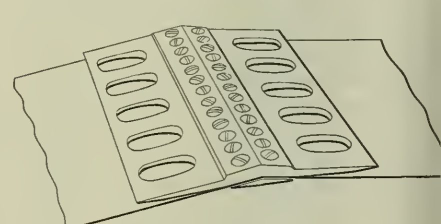

FIG. 1. JOINT OF A GERMAN STEEL BELT

As would naturally be expected, the joint or splice of a steel belt is one of the critical features. The joint construction used by this German firm is illustrated by Fig. 1. It consists of two steel plates, an under and an upper, between which the ends of the belts are joined. These plates taper from a thickened section at the center to comparatively thin edges. In the size illustrated, the upper plate is made with a series of holes in order to lighten it. Each of these plates is shaped to a circular arc, whose radius is equal to the radius of the smallest pulley on which the joint is to be used. Thus, for a given joint there is a minimum limiting diameter of pulley on which it can run, but no similar maximum limiting diameter; for a given joint can be used on pulleys of any diameter larger than the one to which the plates are particularly fitted.

COMPARISON OF ROPE, LEATHER-BELT AND STEEL-BELT DRIVE.

Item.	Rope Drive.	Leather-belt Drive.	Steel-belt Drive.
Breadth of belt space	6 ropes 45 mm. in diameter	500 m.	100 mm.
Breadth of pulley	380 mm.	500 mm.	110 mm.
Weight of pulley	1000 kg.	520 kg.	270 kg.
Weight of rope or belt	240 kg.	140 kg.	13 kg.
Total weight of drive	1240 kg.	660 kg.	283 kg.
Cost of pulleys	720 marks	400 marks	250 marks
Cost of ropes or belts	600 marks	1300 marks	750 marks
Total cost	1340 marks	1700 marks	1000 marks
Power lost in per cent	13 %	6 %	0.5%
Power lost in horsepower	13 h.p.	6 h.p.	0.5 h.p.

*Condensed translation.

The belt itself is made of a uniform quality of steel of an even thickness and is tempered. The ends are carefully brought together, fitted and soldered with a special solder that flows at a comparatively low temperature. This joining is then placed between the two plates that we have described, and these plates are fastened together by means of screws, as shown in the illustration, Fig. 1.

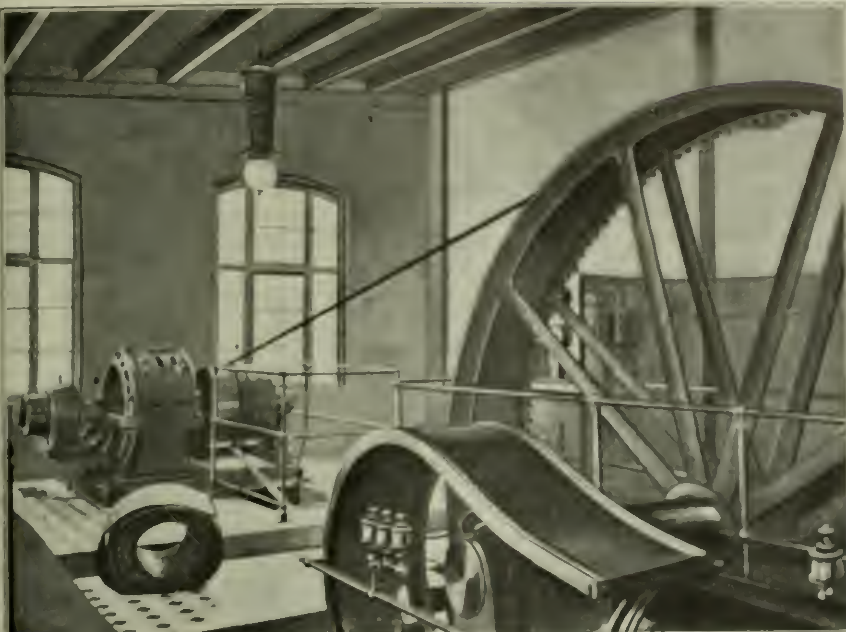

FIG. 2. A 250-HORSEPOWER STEEL-BELT DRIVE

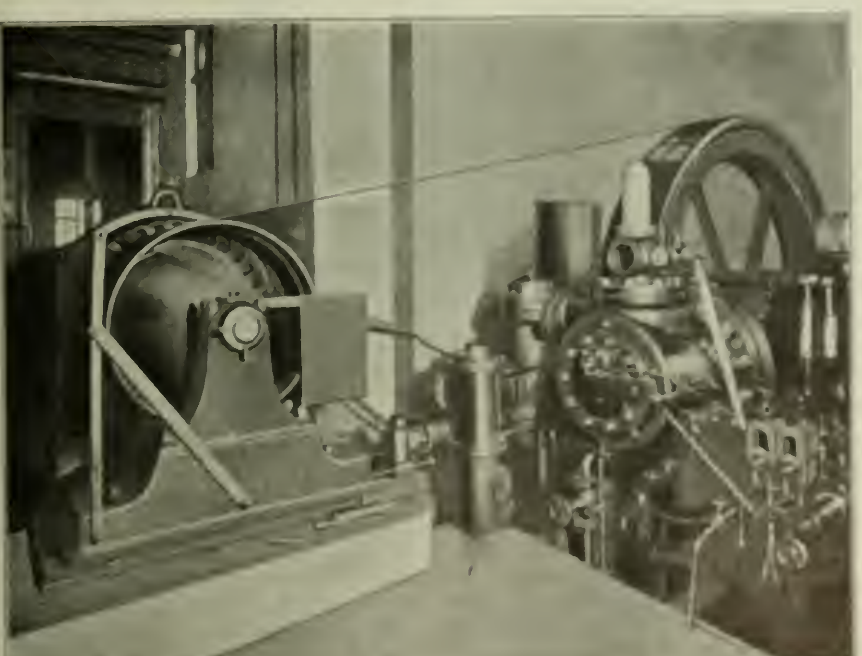

FIG. 3. A 160-HORSEPOWER STEEL-BELT DRIVE

ADVANTAGES

A number of interesting claims are made for these belts. Three of the most striking are: The small amount of slipping of the belt on the pulley, given in figures as less than 1/10 of one per cent.; the narrow width of the belt compared with leather belts, the proportion being about 1 to 5; and the great speed at which these belts can be run, given as 100 meters per second, or say 19,000 feet per minute. This latter figure is striking if we compare it with the figure usually given for leather belting at 5000 feet per minute. It is very common to run these steel belts at a speed of 50 meters per second or, roughly, 10,000 feet per minute.

Other minor advantages which are really dependent upon the three major ones that we have pointed out are: A narrower and lighter pulley for given service, a lighter and smaller shaft, a reduction of the strains upon bearings (thereby a reduction of the size of bearings and in many cases—especially on electrical machinery—the elimination of outboard bearings), a saving of room through a reduction of the general dimensions of machinery, avoidance of temperature and humidity effects (thereby a lessening of the required attendance) and, in case the belt is applied to existing pulleys, the possibility of using the pulley face for other belts. This last feature is particularly true of portable engines.

Because of the high permissible speed these belts have been adapted in many cases to electrical machinery, both generators and motors, and to gas engines. They have also been used for driving belts in machine shops and other manufacturing establishments. The table gives comparative data between a rope drive, a leather-belt drive and steel-belt drive for 100 horsepower, transmitted by pulleys 10 meters, 30 feet apart, at a speed of 200 revolutions per minute and a diameter of 1 meter, 3 feet. The metric measurements in the table are not translated into English measurements because the table is of comparative interest only.

REPRESENTATIVE INSTALLATIONS

Referring to the half-tone illustrations, Fig. 2 shows a drive on a steam engine at the plant of Ludwig Stollwerk & Company, Berlin, from a 250-horsepower steam engine to an electric generator. The width of the steel belt is 100 millimeters, or say 4 inches; the width of the leather belt which was removed, and which is seen lying on the floor, is 600 millimeters, or say 24 inches. The striking feature of this illustration is the narrowness of the belt.

Fig. 3 shows a drive in the plant of the Berliner Elektricitäts-Lieferungs-Gesellschaft, Berlin. It transmits 160 horsepower, and the breadth of the belt is 100 millimeters, or say 4 inches. The leather belt that it replaced was 480 millimeters wide, or about 19 inches.

The American consul at Naples states that steam engines and boilers are being built in Italy, and the demand for the latter from abroad has almost disappeared. Steam engines are still imported from Switzerland and Great Britain. The introduction of suction-gas engines has of late diminished the use of steam engines and locomobiles in industrial enterprises. Centrifugal engines are built by a few large firms in Italy, but they are also imported from Great Britain, Switzerland and Germany. Dynamos and electric motors are imported from Great Britain, United States, Germany, but only in small quantities as yet, the demand being, however, increased as a result of the reduction of duty on petroleum. Steam pumps are imported from Great Britain and Germany.

Extraneous Supervision of Power Plants

I trust that you will give me space for a self-discussion of your editorial on "Extraneous Supervision of Power Plants":

First—Let me state that I recognize the fairness of your presentation of the subject, but I do not agree with your conclusions.

Second—I wish to call attention to the fact that I purposely modified, in the same paper in which the original matter was published, viz., the *Record and Guide*, my remarks about graft in the engine room. By this I mean that I publicly stated that there were a great many high-class engineers who recognized the evils of the graft system and the system of receiving commissions on supplies and repairs as fully as I did, and they further recognized the fact that an honest engineer who would not take graft was placed at a serious disadvantage when applying for a position, because other engineers who were not honest and who expected to take graft and commissions were able to offer to take the position at a very much less salary.

It is, of course, a matter of common knowledge and of individual knowledge that in a great many plants in this city, the purchasing agents, whether they be engineers or others, exact commissions on purchases. It is not the amount of these commissions that is the serious drawback, but it is the fact that a fair judgment as to quality of the supplies is absolutely precluded. It is also a fact that in many instances repairs are undertaken, which would not otherwise be necessary, merely for the purpose of obtaining commissions; and in such cases the employer not only pays the commission made by the repairman to the engineer, but he spends probably nine times the amount of this commission in an unnecessary repair. How can an honest engineer, expecting to receive nothing more than his salary, compete with an engineer who counts on these commissions and graft as part of his salary; and is it any wonder that where such conditions do exist the Edison company is able to come in and shut down a plant?

It is my honest opinion that with a properly and honestly managed plant, whether operated under engineering supervision or not, there is no chance at all of shutting the plant down after it is once installed, but with dishonest or incompetent management the shutting down of a plant is a foregone conclusion.

Now as to your conclusion; your idea is that the engineer of the plant becomes an automaton, a mechanical automaton you say, whose strings are pulled by the engineering supervision office. *This conception of the relations between the supervision company and the operating or chief engineer is entirely erroneous.* It must be evident to anyone who is familiar with the operation of the modern complex plant that any attempt to operate this plant without a high-grade trained engineer on the premises would be disastrous. It is the writer's opinion, and one that he has stated frequently, that unless the chief engineer worked in sympathy with the supervising engineer, no good results can be accomplished; and the chief engineer of the plant is, in my estimation, one of the most important members of the organization of the supervision company, and I see no reason why there should be any more conflict between the chief operating engineer and the advisory consulting operating engineer than there is between the architect of a building and the builder. The supervising advisory engineering office has functions to perform requiring a whole office staff consisting of draftsmen, engineers, stenographers, auditors, etc., which cannot be properly performed by a single chief engineer no matter how good; and on the other hand, a chief engineer has duties to perform which could not be performed by any organization unless located directly on the premises operated.

A large plant has its advisory consulting engineer, and if the small plant is to compete with service from the central station, it must have at its disposal engineering services and purchasing services equal to those available to the central stations.

You speak of contracting engineering companies; the supervision company is not a contracting company. I have always objected to a contracting engineering company, as I think it essential that the interests of the employer and of the advisory engineer be identical and not opposed, as they are to a certain extent where a contract for operation is entered into. That is, the supervising engineering company should be paid for its services the same as the architect is paid, and the plant should be operated to the best interests of all concerned.

Another point of importance in connection with the relations between a supervision company and the operating engineer is that efforts to effect improvements are noted, and the capable, honest engineer is sure of advancement as well as steady employment. As examples of this, may be noted the chief engineer of the Langham, who started as assistant engineer; the chief of the Weil & Mayer buildings, who has been promoted from one plant to another paying better, inside of one year; the chiefs of Reisenweber's, Acker, Merrall & Condit's, Langsdorf's, Saks & Co., all promoted from assistant engineers to their present positions; in fact nine-tenths of our chief engineers have graduated from assistants.

P. R. Moses.

Engineering Supervision Company. New York City.

Multiple Feed Lubricator

Several months ago I constructed a lubricator, a sketch and description of which are herewith submitted.

The reservoir, Fig. 1, is made of 5-inch iron pipe, 15 inches long, capped at both ends. The sight feed is attached directly on the pipe. There are two sight feeds for lubricating two different steam cylinders, but any number of sight feeds may be attached. There is a gage glass to denote the hight of oil; *C* is a ¾-inch cross valve connecting the bottom of the reservoir with the pressure pipe *M*, which can be connected to any steam pipe; it is preferable, however, to connect this pipe direct from the main steam pipe so that pressure is always available. The valves *D D* are for feed regulation. The valves *E E* must be kept closed at all times while in operation, as they are ordinary gage valves. At *F F* are oil-feed pipes leading to the cylinders; at *G* is a ½-inch filling valve, on top of which is a funnel *H* containing a brass-wire screen for a strainer; the top of this funnel is closed with a leather cup to keep out dust and dirt. At *I* is a ¼-inch air vent to be opened when filling and also when draining out the water. Valves *J* and *K K* are to drain the body and sight feeds; all drains are piped together. At *L L* are sight-feed glasses. The part *M* acts as a ¾-inch condenser and pressure pipe. The highest point is 6 feet above the top of the oil reservoir. At $N N$ are ⅛-inch pipes on the inside of the reservoir, which extend to the top of the body of the lubricator; they connect to the feed-regulating valves D, the shanks of which are tapped out, and a short nipple and elbow screwed in and the long vertical pipe screwed into the elbow. To fill, after once in operation, it is only necessary to close the valve C and the feed valves D. The valves $E E$ serve another purpose beside holding the gage glass and, as mentioned, must be kept closed, as the pressure would immediately force the oil through them to the oil-feed pipes and empty the lubricator.

Where the steam cylinders are quite a distance from the lubricator, it would be better to run the oil-feed pipe from the top of the reservoir directly to the cylinder and place the regulating valve as in Fig. 2. It is also well to have the oil-feed pipes covered, especially if exposed to a cold draft, or where the pipe is rather long, as it may cause trouble by clogging with cold oil. When placing the independent sight feed, Fig. 2, directly on the cylinder or steam pipe, the same advantage of forcing any amount of oil directly into the cylinder in case of necessity is had but in a different way.

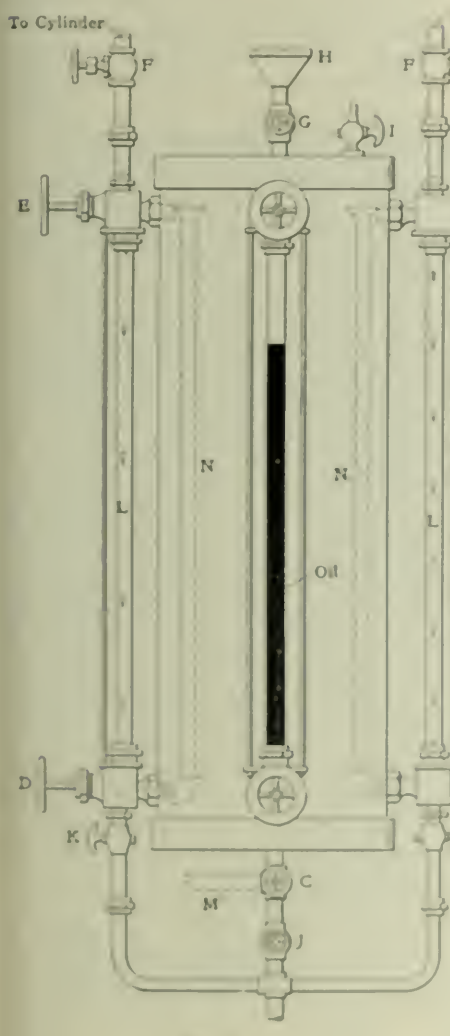

FIG. 1

FIG. 2

MULTIPLE-FEED LUBRICATOR

This action, however, is taken advantage of when first starting the engine or pump; or, in case a cylinder becomes dry for want of oil, any amount of oil can immediately be forced to any cylinder by opening the valve E for a few moments and then closing it again.

Another advantage of this lubricator is that any pipe, glass or drain can be blown out without interfering with any other part, as long as there is steam pressure.

In Fig. 2, is seen a steam pipe leading to the engine or pump; B is a valve placed in the oil-pipe line F, and is of any convenient size.

To operate, close the valve B and slowly open the top valve so as to fill the glass with water and leave it open. Then open the regulating valve D and adjust the oil feed. To flood the cylinder with oil, open the valve B for a moment.

A. J. Stone.

Cincinnati, O.

Mr. Sheehan's Motor Trouble

The cause of the trouble reported by Thomas Sheehan on page 1013 of the December 15 number may be readily explained by the fact that the motor in question had a compound winding on its field magnet. Such a motor has two field windings, one a shunt winding connected across the line, and the other a series winding which carries the entire armature current. It is customary to connect these two field windings so that they assist each other in building up the magnetic field. In this case, however, the series winding must be connected so as to oppose the shunt winding.

What happened was this: When the workman started the beater the clutch on the shaft was not thrown out quickly enough to prevent the motor from shutting down. It stopped, as stated by Mr. Sheehan, while still connected to the line. That would cause the motor to take a very heavy current through the armature and the series field winding, and the result would be that the voltage of the generator would drop off to a very low value. The motor at a standstill put almost a short circuit on the generator, and under these conditions the generator could not hold its voltage. The low voltage greatly decreased the strength of the current in the shunt field winding of the motor, while the current in the series winding was much stronger than normal; consequently, the series field winding was the stronger and reversed the polarity of the field magnet, causing the motor to run backward as soon as the clutch on the shaft was thrown out. The reversed direction and the heavy current would cause the motor to spark violently. The current would very speedily drop off as the motor gained speed, but the reversed direction of rotation would still account for the sparking, as the brushes were undoubtedly shifted backward somewhat for the correct direction of rotation.

The high speed was due to the fact that the motor was running as a series motor without load. It is to be further noted that the shunt field winding of the motor would gradually build up and as it opposed the series winding would still further weaken the magnetism of the poles. The voltage of the generator did not rise at once when the motor became unloaded because the field strength could not build up instantaneously.

If the attendant had allowed the motor to run a little longer it is possible that the voltage would have risen sufficiently for the shunt field winding to overpower the series field winding and cause the motor to stop and reverse again. But before doing so it would undoubtedly have reached a dangerous speed, so that the operator did the correct thing in opening the switches.

It is to be noted that this does not

count for the reversal of the meters, inasmuch as the large current would still flow in the usual direction as there was no action to reverse the generator. In fact, there seems to be no reason why the polarity of the meters should have been changed, unless the ammeter was of such a design as to become reversed by a large current. It is in fact very questionable whether the meters actually did reverse, for it is frequently reported that meters have become reversed when as a matter of fact the pointers are only stuck at one end or the other of the scale. I am not casting any reflection on the accuracy of Mr. Sheehan's statements, but merely suggest that an instrument may appear to be reversed when a more careful investigation will show that this has not happened. In the instance under discussion the voltmeter pointer would drop back practically to zero and might easily become caught at the lower end of the scale, due to the sudden swing, while the ammeter pointer would go off the scale at the upper end, and might stick there.

It might be of interest to Mr. Sheehan and the motor attendant to note that the connection of the series field winding as it now stands is not usually employed except where it is desired to maintain a very close speed regulation through all changes of load. The opposing influence of the series field winding causes decreased ability of the motor to carry a heavy load, and, just as has happened in this case, when the load becomes too heavy the motor will stop. By reversing the connections of the series field winding and making it assist the shunt winding the motor will be better able to stand up under severe load conditions and will also have better starting torque. The drop in speed from no load to full load will be greater than it now is, but in all probability this will not be objectionable.

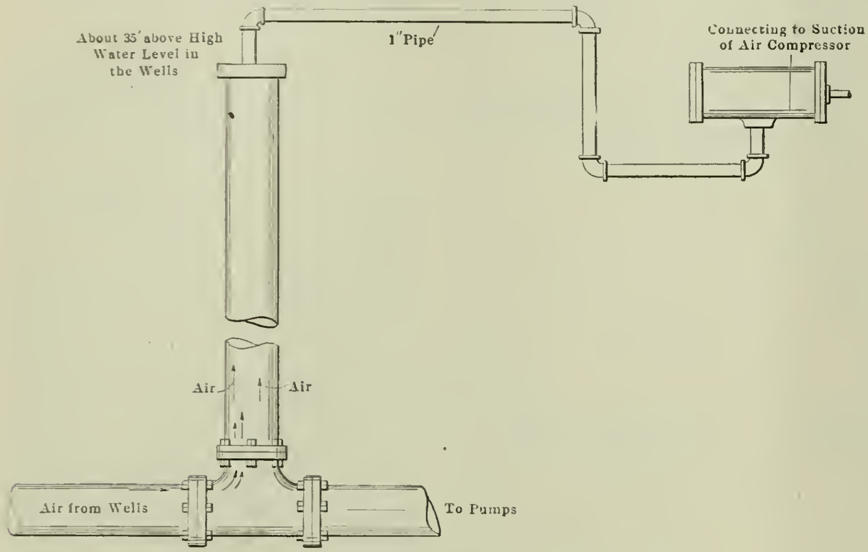
Air Pump Arrangement in a Pumping Station

While visiting a large pumping station recently, my attention was called to the arrangement shown herewith. The main suction line connects to 115 driven wells,



AIR-PUMP ARRANGEMENT IN A PUMPING STATION

the water level of which is ordinarily from 10 to 12 feet below the pumps, which are located in a circular pit about 25 feet below the level of the engine-room floor.

During the dry weather of last year the water level fell to such an extent that, on account of so many wells being connected, considerable air was drawn into the suction, causing the pumps to pound badly when any attempt was made to run them above half-speed.

Just outside the pump connections on the suction line was a tee having a vertical pipe 10 feet long capped on the end, which acted as an air chamber. This pipe was extended up level with the engine-room floor, making about 35 feet above the highest water level in the wells. The top cap was drilled for a 1-inch pipe to connect to the intake of a small steam-driven air compressor, which was not being used at the time. By running the compressor (or vacuum pump, as it was in this case) at a moderate speed, a 26-inch vacuum was maintained on the 1-inch line.

As all air coming from the well connections would naturally follow along the top of the suction line, it would pass up into the vacuum chamber and be removed through the compressor, leaving a solid body of water entering the pumps. Since making this arrangement no trouble has been experienced in operating the pumps at their full capacity.

How to Set Brushes

There has been a discussion for some time relative to the proper way to set brushes on motors and generators. There seems to be a wide difference of opinion regarding this matter, which is probably due to the fact that each person in relating his experience has reference to the type of brush holder with which he is familiar, and as different types of holder require different treatment, there arises an apparent contradiction of one writer by another.

Some brush holders require brushes set *with* the direction of rotation of the commutator, and others require brushes set *against* the direction of rotation. In Fig. 1 is shown a brush holder of the first class, which must always be set as indicated by the arrow. If set in the opposite direction trouble will surely ensue, as an inspection of the figure will show, because the surface of the commutator and the brush would form a toggle joint, and the brush would tend to dig into the commutator and either break itself or bend the brush rigging.

In Fig. 2 is shown a brush holder of the other type which is used by one of the large manufacturing companies. This brush is set against the direction of rotation but an inspection of the cut will show that there is, in this case, no tendency for the brush to dig into the commutator surface.

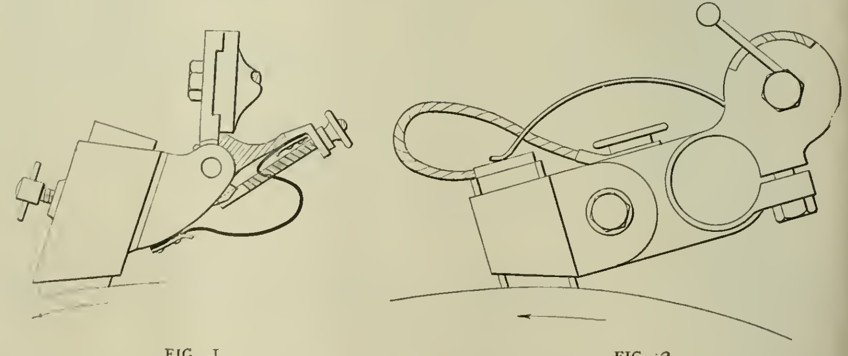

FIG. 1 FIG. 2

From the foregoing it is seen that no hard and fast rule for brush setting can be made, but each type of holder must be treated as recommended by the manufacturer of that particular type.

San Francisco, Cal.

Capacity of Rectangular Tanks

By the use of the accompanying diagram the capacity of rectangular tanks may be found. Tables giving the cubic contents of this style of tank for 1 foot of depth will be found in many handbooks, but it is necessary to multiply this value by the hight of the tank to find the total capacity. The diagram also serves as a ready means for securing the dimensions of tanks of equal capacity.

The lines running upward from the lower left-hand corner to the right represent the width of the tank, and are so labeled. The lines running upward from right to left represent the hight of the tank. The lower margin gives the length of the tank in feet. The left-hand margin gives the capacity of the tank for 1 foot in depth, while the upper margin gives the total capacity.

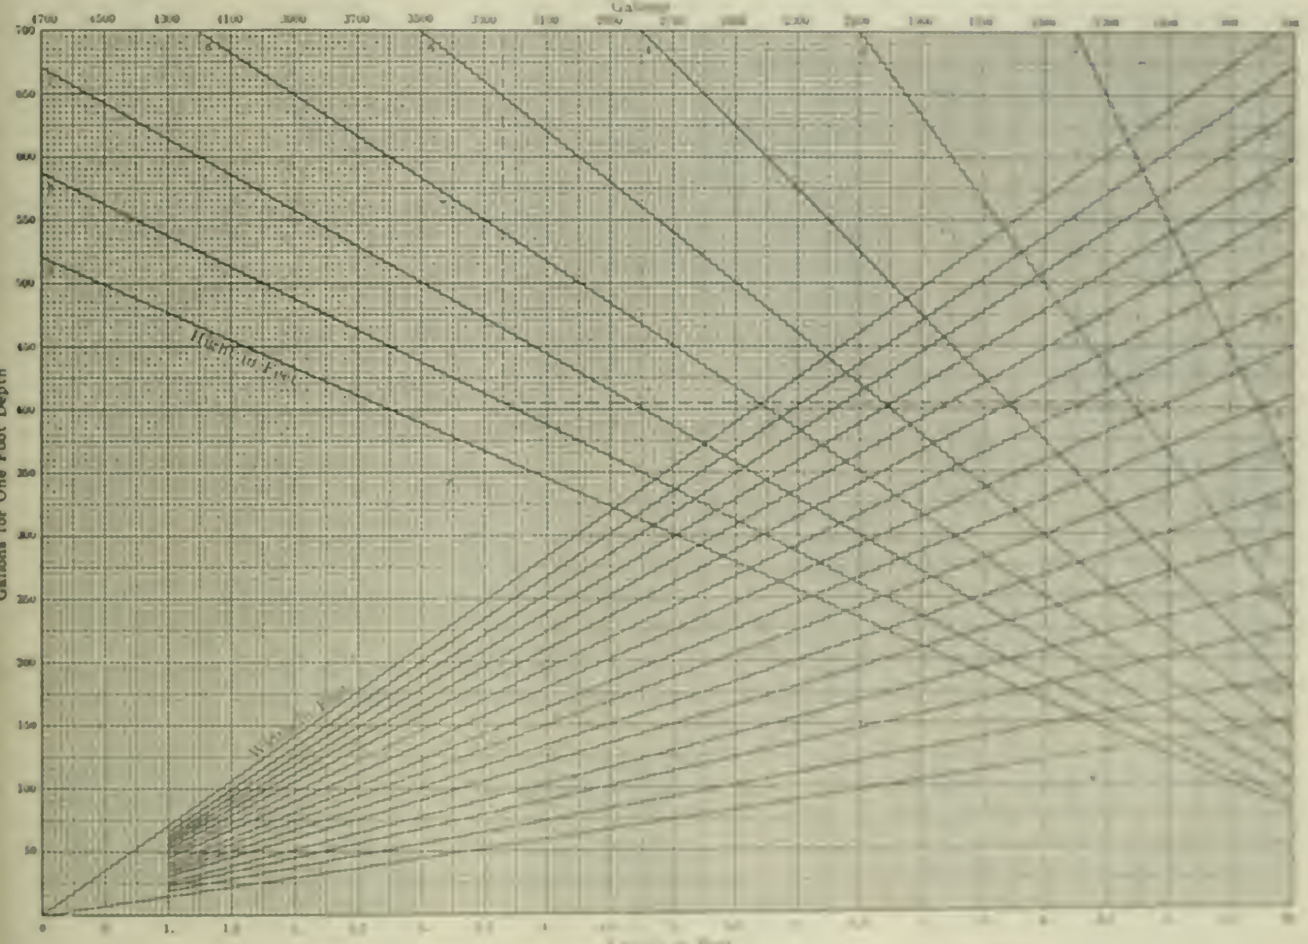

DIAGRAM GIVING THE NUMBER OF U. S. GALLONS IN RECTANGULAR TANKS

As an example, suppose the capacity of a 6x9x8-foot rectangular tank is required. The method of solving this problem is shown in dotted lines on the diagram. Starting with the length, 9 feet, project upward to the 6-foot line, across to the 8-foot line, then upward to the top margin, where the answer is found to be 3240 gallons.

The given capacity of a tank equals 3500 gallons, its hight is 7 feet and the width 7 feet; find the other dimension: Project down from 3500 on the top margin to the hight line, marked 7, across to the width line 7, and then downward to the lower margin, where the length is found to be 9.55 feet.

Suppose the capacity of a tank equals 3000 gallons, then the dimensions of tanks of this capacity are found by the chart to be 5x9.5x8.45 feet, 6x8x8.35 feet, etc.

Cast Iron Crosshead Pins

F. L. Johnson stated, in an article in the December 8 issue, that "somehow it looks as if the whole family of engine makers has gone steel crazy and are using steel for everything under the sun, even where a moment's thought would show that for some purposes steel is the worst possible material that could be selected, and crosshead pins is one of these."

As the best engine builders use cast steel for pins, and steel pins can be worked at nearly double the pressure permissible with iron running at the same speed (Kent, page 801), I should like to ask Mr. Johnson to give his reasons for his statement, as I believe the same will be of interest to many engineers.

G. Hecklinger.

Portland, Ore.

[Mr. Hecklinger's letter was sent by Mr. Johnson to Mr. Sawyer, whose remarks were quoted in the article in question, and he commented as follows: "What I said about the use of steel referred entirely to crosshead pins, and my critic turns to Kent on crank pins, an entirely different matter, and the comparisons made there is between steel and wrought iron, and not between steel and cast iron. What I had in mind for crosshead pins was cast iron, which is not considered at all by the 'best engine builders' referred to by Mr. Hecklinger. These same engine builders make steel pins and bronze boxes for the crossheads, but in this [illegible] heavy [illegible]. These heavy pressures and the slow movements of the surfaces in the crosshead bearings. Lubrication is difficult and dangerous, and unless made of proper materials the wear is rapid. The coefficient of friction is greater between brass and steel than between any two metals used in machine construction, while with one of the [illegible] the coefficient of friction is low. Cast iron is more easily lubricated than any other metal, hence its amount of lubrication [illegible] is ample for a cast-iron pin may be, and usually is, insufficient for a steel pin. Not long ago I saw a cast-iron crosshead pin that had been in daily use for more than 25 years and the most careful measurements failed to detect any wear. I have never known of a hot or cut pin where cast iron was used, but have personally had several cut steel pins. I would use cast iron for crosshead pins because they run with less friction, are more easily lubricated, wear better and give less trouble than steel pins."—EDITORS.]

Engine Wreck Prevented by Quick Action

At our street-railway power station two cross-compound vertical engines are

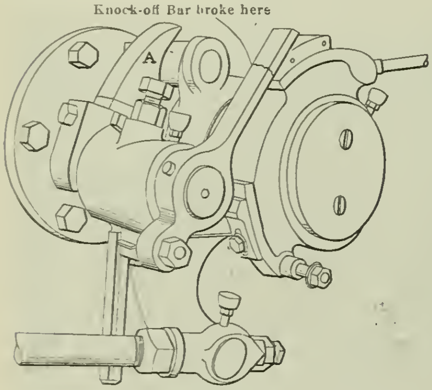

FIG. 1

equipped with the type of releasing gear shown in Fig. 1. Not long ago the knockoff bar broke, as shown in Fig. 1, and, dropping down, became wedged against the knockoff lever, as shown in Fig. 2, forcing the governor down to its lowest running position, when the engine would take steam at seven-eighths stroke.

The governor belt being intact, the idler pulley kept the lugs in contact with the

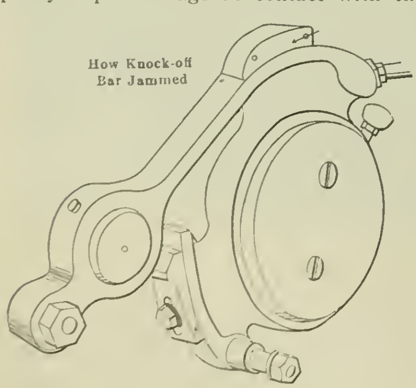

FIG. 2

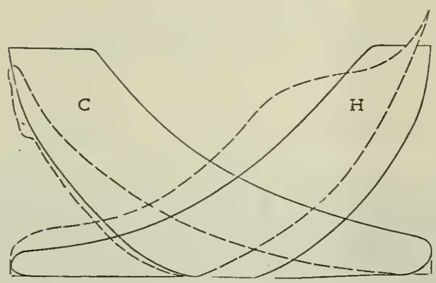
governor collar and prevented the governor from assuming its lowest position and bringing the safety cams into action. Of course, the engine started to race and only quick action prevented a wreck. The throttle-valve wheel is handled from the floor and the engineer was on the valve deck. Knowing that there was no time to come down in the ordinary way, he jumped from the upper deck to the floor and shut the throttle.

THOMAS SHEEHAN.

Pittsfield, Mass.

Faulty Indicator Diagrams

In a recent number, under the heading "Faulty Indicator Diagrams," a contributor asked what could be done to benefit the engine. The trouble is due to incorrect valve setting, and the only thing to do is to set the valves correctly.



CORRECT AND INCORRECT DIAGRAMS

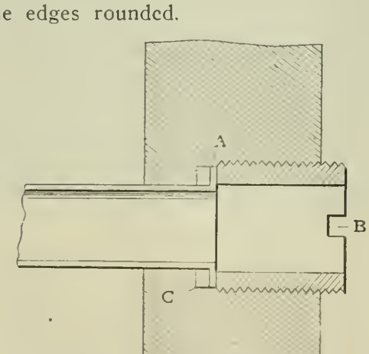
I believe the problem can be solved by plotting correct diagrams on the faulty ones to compare them. The illustration shows the full lines indicating the correct diagrams; the dotted lines the faulty ones.

E. J. FARKAS.

Detroit, Mich.

Condenser Tube Packing

The tubes of a surface condenser began to leak badly, and were repaired in the following manner: The tubes were annealed on one end and flanged over leaving a collar *A*. (See sketch.) The holes in the condenser head were bored and tapped with a radial drill press. Brass glands were made in the usual manner by the aid of an adjustable box tool, and the edges rounded.



REPAIR OF CONDENSER TUBE

One end of each condenser tube was packed by placing a rubber gasket *C* underneath the collar of the tube, and the gland screwed down against the face of this collar. The other end of the tube was packed in the same manner as water-glass tubes, allowing the tube to pass through the gland, squeezing the rubber against the outside of the tube. This made an excellent job and for six years the condensers have not leaked.

SAMUEL KINSEY, JR.

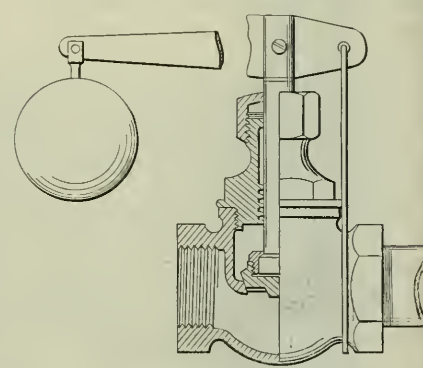
A Homemade Relief Valve

Herewith is described the way I made a relief valve to put between a pump and a water motor. I got an old globe valve and, removing the stem, filed the threads off to make a smooth surface. A slot for the lever arm was then cut, and a hole drilled and tapped to receive a 5/32-inch button-head machine screw, as shown in the illustration. The lever was cut from a piece of 3/32-inch band iron and the



A HOMEMADE RELIEF VALVE

necessary holes drilled in it. The fulcrum was made from a piece of No. 8 wire, bending it in the middle where it passes through the lever, and securing it around the valve body, as shown.

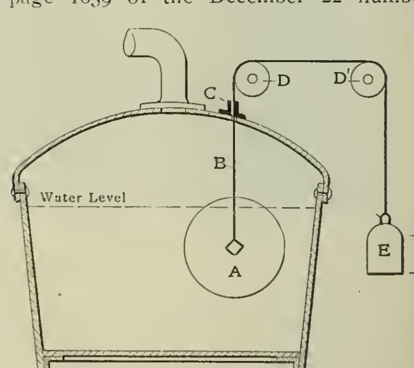
Middlefield, O.

An Old Haystack Boiler

The article on the above subject on page 1039 of the December 22 number



A FLOAT-STONE WATER GAGE

interested me greatly. It seems a pity to let those old fellows rust but, of course, it is impossible to preserve all of them. The method of running the vertical seams straight instead of staggering each tier seems to me to be wrong. Mr. Maplethorpe says:

"There is no sign of gage cocks or water gage."

It is peculiar, for the only part of the half-tone which stands out by itself is probably all that is left, *outside* the boiler, of the water gage.

On top of the haystack boiler is an upright which supports a sheave. If this is what I take it to be then it is part of a water gage much used in the early days.

When Puffing Billy was used at Killingworth colliery in England, that is subsequent to 1813, these haystack boilers were used for raising steam for the winding engines. There was as a general thing either a platform or the brickwork built up around the boiler to near the hight of the water level. The engineer with his wooden-soled clogs would ascertain the level of the water by kicking the plate. The sound would tell him whether there was water or steam behind the part of the plate where he was tapping it with his foot. This was much the same as we tap a plastered ceiling or wall to find where the joists or studding are.

A later invention in the way of a water gage was evidently used on the haystack boiler referred to. It consisted of a piece of stone somewhat like a grindstone. Grindstones when worn small were often used for this purpose. These were called "float stones" and their application is shown in the accompanying cut in which *A* is the float stone and *B* is a copper wire, one end of which is secured to the float stone and the other end to the iron weight *E*. The wire passes up through the stuffing box *C* and over the two sheaves *D D*, *D* being the sheave shown in the half-tone. As the water "boiled down" the heavy float stone would lift the weight *F*. The relation of the weight *E* to the marks *X Y* showed the engineer where his water was.

If Mr. Maplethorpe will crawl inside that old boiler he will probably find an old float stone.

It is merely a question of specific gravity. In air the stone weighed more than the iron weight *F* but with the stone partly immersed in water the stone would balance the weight *F* in air.

C. A. Dunn.

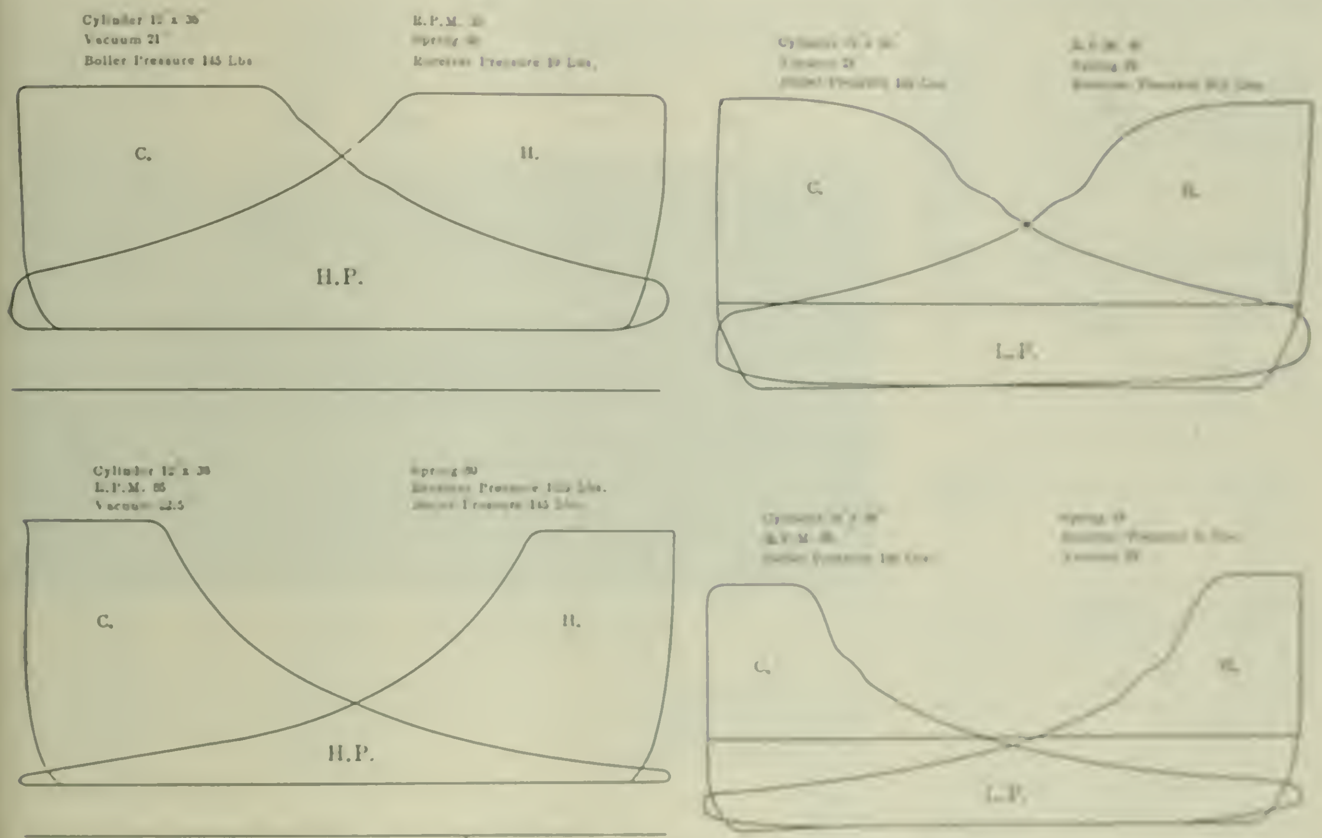
New York City.

that it can be done. I do hope Mr. Hall will not disregard such a question. I submit the accompanying diagrams from a Corliss 12 and 24 by 36-inch cross-compound condensing engine. While these diagrams do not figure quite the same horsepower on each side, I have taken diagrams where there was only a slight difference in the work done in both cylinders.

I should like to know the theory in putting a larger cylinder on an old engine frame when, by compounding, the steam is not only saved but the extra work is gratuitously done by the low-pressure cylinder for the same coal. It is true that by putting a larger cylinder on an old engine frame more power is obtained, but it will require more steam to do the extra work.

George W. Hanson.

Lexington, Neb.



DIAGRAMS FROM A 12 AND 24 BY 36-INCH CROSS-COMPOUND CONDENSING ENGINE

Compounding Engines

Recently in a letter entitled "Horsepower of Compound Engines," W. H. Wakeman says that some steam users think a compound engine develops twice the horsepower that a simple engine does, and that somebody ought to show them their mistake.

If it is not to increase the horsepower, why are engines compounded so as to do more work by using again the steam that has done work in the high-pressure cylinder?

Mr. Wakeman also challenges Mr. Hall to produce indicator diagrams to show

Gas and Boiler Explosions

Charcoal can absorb about forty times its own volume of "marsh damp gas" (the deadly agent in explosions). How can H. R. Cobb reconcile this fact with his theory for the explosion of his boiler, which was made of charcoal iron, as noted on page 1058 of the December 22 number?

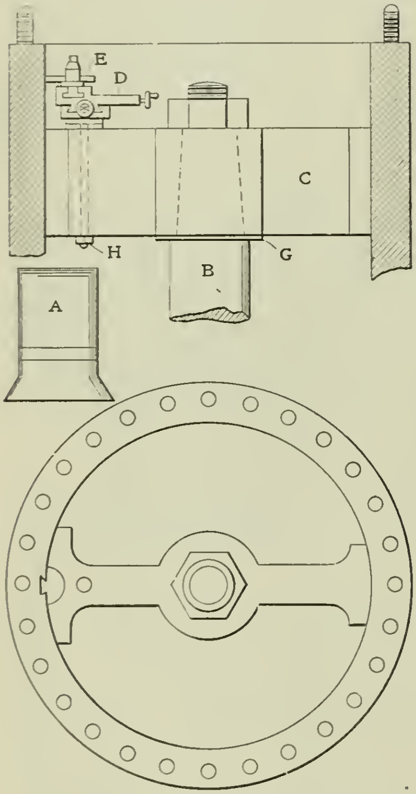
[illegible] "laughing gas" [illegible]

Pump Cylinder Repair

An accident happened to one of the high-pressure cylinders of a pumping engine, and as the pump was needed almost any moment, the owners looked for the quickest way to repair it.

The trouble was due to one of the sections of packing ring breaking and cutting a score the full length of the cylinder about ¾ inch wide and 5/16 inch deep.

Several machine-shop superintendents wanted to rebore the cylinder, but as this would necessitate a new piston, and



ILLUSTRATING A PUMP-CYLINDER REPAIR

considerable time, we gave up this idea and resorted to the following method:

An iron casting *C* was bored to fit the piston rod *B*, and turned to a nice sliding fit in the cylinder. A slide rest *D* was fitted to the top of this casting and held with the bolt *H*.

With this arrangement we planed a dovetailed slot in the cylinder, the full length, raising the piston rod by water pressure and lowering it by allowing the water to escape from the lower cylinder. The slot was planed as far down as could be with the slide rest on the top of the casting, and then we finished by placing the slide rest on the under side. Next a bronze strip was prepared the exact size of the slot and driven to the bottom of the cylinder. As this strip was rather slender and long it was soldered on a reinforcement at *A*. A washer *G* was placed under the casting *C*, so we could loosen the nut holding it, allowing it to turn without binding on the taper end of the rod.

By swinging this casting in a circular motion it was possible to plane off the excess metal to the same arc as the cylinder. This made an excellent job, and took but a short time to finish.

There was quite a discussion as to whether to cut the bronze strip off flush with the end of the cylinder or cut it off a little short, to allow for expansion, but finally it was decided that the best plan was to cut it off the same length as the cylinder and let the metal take up itself. This cylinder was opened again after running about one year and if the exact place where the strip was had not been known, it could not have been detected.

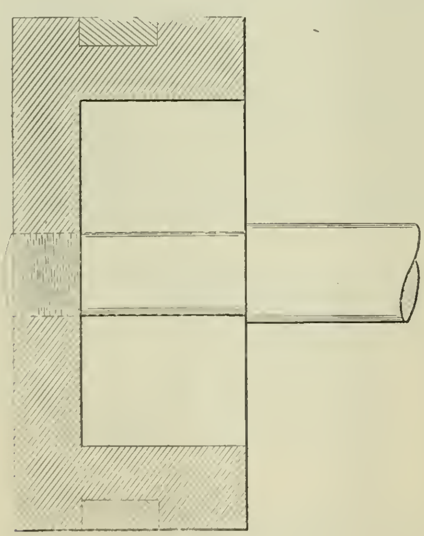
Samuel Kinsey, Jr.

Peoria, Ill.

What a Substitute Piston Did

A very dangerously designed piston rod which came to my notice recently partly wrecked a 26x51-inch Corliss engine, running 56 revoluions per minute.

The piston was 6 inches thick. The end of the piston rod was threaded for 1½ inches and engaged with a corresponding thread in the 1½-inch cast-iron follower plate, there being no thread in the piston spider. Instead of securing the rod with a nut, it was left flush with the follower plate. The strain on the cast-iron thread caused it to strip, allowing the piston to deliver a blow against the head, cracking it in several places, and as the momentum in the wheel forced the rod back it caught on the piston, breaking the



HOW THE PISTON ROD WAS PUT IN

crank. The cylinder was cracked by one of the thin steel packing springs being jarred out of place and wedging under the piston. A piece was broken out of the back side of the piston and was afterward found in one of the exhaust ports.

It may be said in favor of the engine builders that this piston and rod were not of their design. The original piston and rod having been put out of business by a dose of water, this freak piston was put in without the builders' knowledge.

R. F. Blanchard.

Fitchburg, Mass.

Indicator Stop Device

This device for taking indicator diagrams is somewhat unusual. It consists of a ½-inch board, 42 inches long and 6 inches wide. The upper end swings on a

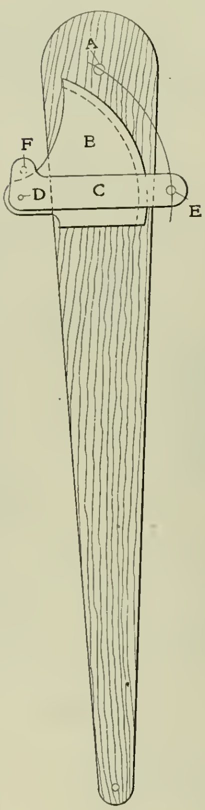


FIG. 1

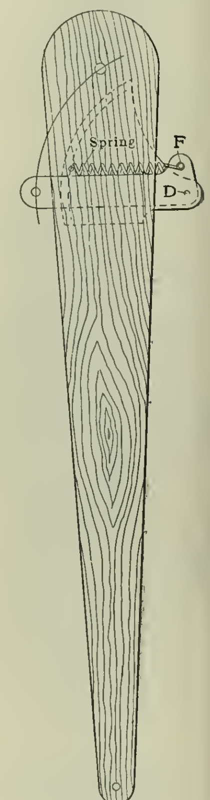

FIG. 2

pivot at *A*, Fig. 1; the lower end has a projection which swings in a block, sliding on a spindle fastened to the crosshead. A piece of iron *B* is placed over a ½-inch board of the same shape, but does not come quite to the edge at the curved part. Both are fastened to the main board. A lever *C* is attached at *D* with a joined spring at *F*, as shown in Fig. 2.

The indicator cord is attached to a projection at *E*.

When desiring to put a new cord on the indicator diagram, a string running to another projection back of *E* may be pulled through the groove left between the main board and the iron *B*, which will bring *E* in line with *A*, and all motion of the indicator will cease.

In making this device it is necessary to locate the point *E* down from *A* according to the length of diagram desired and to place *D* so that when *E* is pulled up it will come exactly over *A*.

Bert E. Evans.

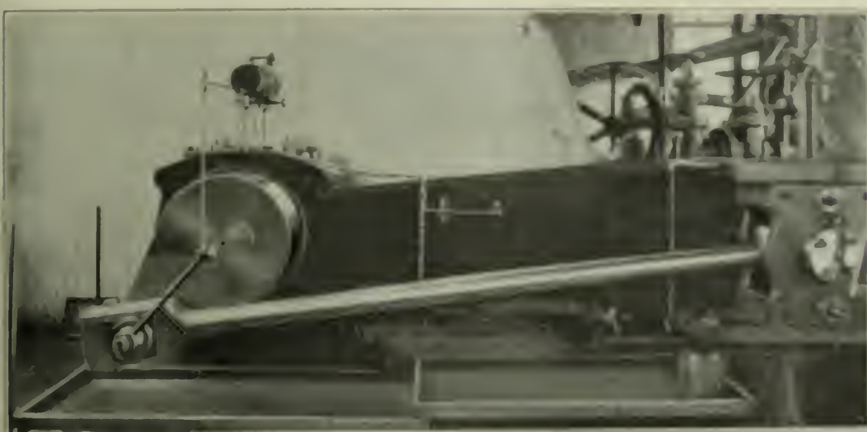
Springfield, Mass.

An Oiling Device

The accompanying photograph is of an oiling device attached to the frame of our engine. The oil tank above the main pillow block was originally a piece of 6-inch iron pipe. It has a head welded in at either end. A gage glass is attached to show the amount of oil in the tank. The front oil guard of the engine has been removed so as to give a better view of the arrangement.

The pump is fastened directly to the front side of the engine frame and connected to the rocker arm from which it derives its motion.

After the oil has lubricated the various bearings and drops into pans, as shown,



THE OILING DEVICE ATTACHED TO ENGINE FRAME

it runs into the filtering tank just below the pans, where all sediment is removed and the oil used over and over again.

F. H. JANNEY.

Minneapolis, Minn.

Calculation of Cooling Surface for Surface Condenser

The article by C. L. Hubbard, on condensers, in the December 22 issue, attracted my attention, and I wish to offer some comments on the calculation of cooling surfaces. Attention should be directed to the analysis of the formula

$$S = \frac{W\ L}{180\ (T - t)},$$

where L is the latent heat of the steam at condenser pressure. This, at the outset, assumes that the steam is saturated at the condenser pressure but, as will be shown, this is not so.

Assume an engine exhausting to the atmosphere against a back pressure of 2.3 pounds, gage, and also an engine using 30 pounds of steam per indicated horsepower at a pressure of 80.3 pounds, gage. The total heat for 30 pounds is, therefore,

$$30 \times 1180.7 = 35,421$$

B.t.u. One horsepower corresponds to 33,000 foot-pounds per minute, or

$$\frac{33,000 \times 60}{778} = 2542$$

B.t.u. per hour.

The heat in the exhaust equals the total heat taken in minus the heat transformed into work. Using the above figures, these

$$35,421 - 2542 = 32,879$$

B.t.u. above 32 degrees.

Looking in the steam table, it is seen that the total heat in the steam at 2.3 pounds gage pressure is 1148.9 B.t.u., and

$$1148.9 \times 30 = 34,467$$

B.t.u. The error is, therefore,

$$\frac{34,467 - 32,879}{34,467} = 0.046$$

or 4.6 per cent; and radiation would tend to increase it.

Taking the case of a high-economy engine using 11 pounds of steam per indicated horsepower at 175.1 pounds gage pressure and exhausting into a condenser at 28 inches vacuum, and applying the same method as before, the total heat equals

$$11 \times 1197 = 13,167$$

B.t.u. The heat left in the exhaust equals

$$13,167 - 2542 = 10,625$$

B.t.u. The heat corresponding to saturated steam at condenser pressure equals

$$11 \times 1114.4 = 12,258$$

B.t.u. The error amounts to

$$\frac{12,258 - 10,625}{12,258} = 0.133$$

or 13.3 per cent.

By using higher economy and lower condenser pressures the figure reaches above 15 per cent, as can be seen by working out the necessary example. This error is too large to be neglected in scientific investigation, and a rational formula should take this into account.

I also take a different view as to assuming the ratio of heating surface of the boiler to the cooling surface of the condenser. I think Professor Thurston was the first to express this ratio, but the idea is entirely too crude and inaccurate to be propagated.

The methods of computing the total heat as illustrated may be objectionable to some, on account of the uncertainty in the data on the transmission of heat through the plates. The experiments usually quoted are those of Joule and Isherwood. However, they are far from the actual conditions that exist in a condenser. The rapidity of the cooling water passing through the tubes affects the rate of absorption; the higher the velocity the higher the absorption.

To my mind the rational formula should be based on actual conditions, theoretically correct, and then multiplied by a factor expressing the efficiency as a cooler.

ALPHONSE A. ADLER.

Brooklyn, N. Y.

Method of Setting Gas Engine Valves

Nearly all directions for setting valves give certain crank angles at which the valves should open or close. The cams having fixed contours allows of adjustment only by varying the relative lead or lag and the amount of clearance or lost motion in the connections. It follows, then, that with a certain clearance the closing of a valve becomes fixed as soon as the opening is fixed, or vice versa. Too much clearance not being desirable, it is limited to a small amount, and the smaller the error limited in the adjustment.

The placing of the flywheel at definite crank angles requires measuring of angles, or the use of trams, which should have already been marked on the wheel. Why not give definite piston positions, and set the valves when the piston is at those positions? Marks may be made on the guides at the right places, or measurements may be taken from the piston to some fixed point. Then the inlet should close when the piston has moved back a certain distance, and the exhaust should open when the piston is at a certain distance from the end of its stroke. With the piston placed at a given position the inlet valve is set to close. It will open at the right time if the clearance is set right. With the piston in another position, at the proper stroke, the exhaust valve is set to open and will close at the correct time with the clearance set right.

R. W. [illegible]

Baltimore, Md.

What Knocked the Cylinder Head Out?

Some time ago both cylinder heads of an Atlas automatic cutoff engine were knocked out, the wrist strap pulled apart and the connecting rod badly bent.

The piston was fitted with rings, made in three sections with a lap joint and a brass bushing and a coiled spring under each joint. One of the sections began to rattle one day and an examination showed that the rivets had worked loose. We repaired them and replaced the rings.

As the engineer was putting the piston in place the "boss" came around and, noticing the way he was placing the rings, told him they were wrong, stating that the bushings and springs should be in the center of each section instead of at the joint. As one-half of the outer rings travel over the counterbore in this type of engine, it may account for the trouble.

The bushing being in the center of each section may have allowed the sections to rock, thus letting one end of a section extend out far enough to catch in the counterbore, when the velocity of the flywheel pulled the wrist strap apart, carrying the crank and connecting rod around, the connecting rod striking the crosshead, knocking it through the crank-end cylinder head and the piston out through the head-end cylinder head.

W. A. Hamlin.

Paola, Kan.

Firemen's Conditions Should Be Improved

While the many developments in boilers, engines and their accessories have placed greater responsibility on engineers, there has been, to a great extent, corresponding improvement in the status of the engineers themselves.

Passing over the question of salaries, the average engineer nowadays has privileges, and his comfort and convenience are consulted to an extent unthought of in the old times. These things had to come and will continue to come in the natural evolution of events.

But what of the fireman? Happening in a boiler room recently, just as watches were being changed, the engineer made the remark to me that "there are two dandy firemen." Yet as we talked these firemen were washing in a greasy pail, and their street clothes hung, exposed to ashes and dirt, on the bare wall.

In another plant, wagons deliver fuel directly from a driveway, along the whole front of the boiler room, which is practically wide open all the time. The fuel is dumped on the floor along the boiler fronts, leaving but a small space for the firemen to stand in while at work.

What, then, of the average stationary fireman? Is his life made any easier, does he get any more thought from employers than he did twenty years ago?

W. Auld.

Milwaukee, Wis.

An Unusual Crank Shaft Repair

The engine on which the herein described repair was made is a 600-horsepower, 18 and 36 by 36-inch, cross-compound condensing engine, side crank on the high-pressure side and center crank on the low-pressure side, direct-connected to an 8-inch line shaft on the low-pressure side. The rather unusual design of this engine, the first of its type put out by the builders, made it a subject of much interest and attention. It was prophesied that it would run warm on the low-pressure side, but the engine was on duty 150 continuous hours per week for more than a year, and after the first night evidenced no cause for uneasiness, running but a trifle warm after this hard service.

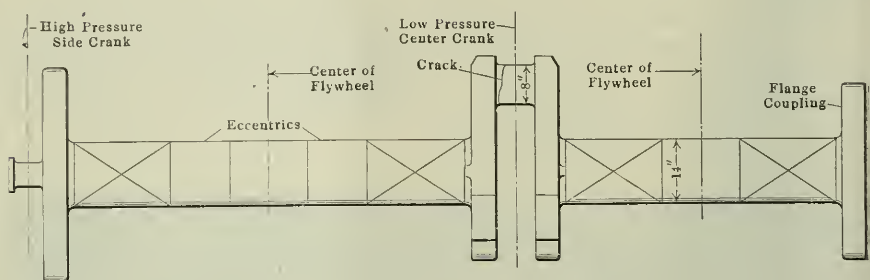


FIG. 1. SHOWING THE LOCATION OF THE CRACK

Needless to say, then, that after a little over a year's time the superintendent was astonished to find, upon taking out the center-crank connecting-rod brasses for examination, a small and almost imperceptible crack on the surface of the center-crank pin, running about ⅝ of the way around the pin, as shown in Fig. 1. The extent of this crack, after being drilled in for ½ inch or so, and examined by representatives of both the builders and the plant, was still only a matter of conjecture. The question to be solved was how to make the repair with the least possible interruption to service, and at the same time at a cost which should not be prohibitive. A new crank shaft being out of the question, and those in charge not knowing sufficiently well the staying qualities of thermit welding, it was decided to adopt the following method, which proved entirely satisfactory:

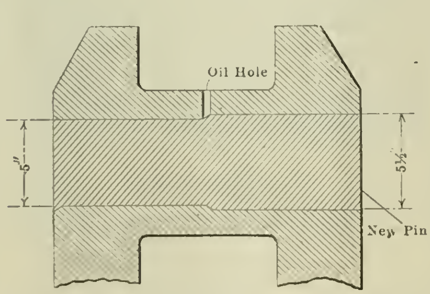

FIG. 2

The pin was drilled through as shown by Fig. 2, leaving the original pin as a shell. The bore was made 5½ inches on one end and 5 inches on the other, thus leaving a ¼-inch shoulder, so that when the pin was drawn in against the shoulder, the small end could be riveted into the countersink, flush with the cheek of the crank, thus preventing side motion on the part of the pin, and at the same time serving to draw the crack together. The shoulder was made to come midway the length of the pin, so that the confined air would not cushion against the shoulder, but would escape through the original oil hole. It was a drive fit, the crank cheeks being warmed and the pin pulled in with a stud at the small end and driven in at the large end at the same time.

The method of boring out is also of interest. A timber superstructure was built up above the crank shaft, the ends being supported by the flywheel on either side and an old lathe head, rigged up with a self-feed, was inverted and bolted to the timber work. The distance between the crank cheek and flywheel did not permit the headstock being set upright in the usual position, as the feed works interfered with the hub of the flywheel, hence the necessity of inverting it.

The first drill was made with an 1¼-inch twist drill and after being redrilled to 2½ inches a regular boring bar was used in the usual manner. A small 1½-horsepower vertical engine was used to drive the lathe head. More than six months have passed and everything seems to indicate the entire success of the repair.

L. C. Blake.

St. Louis, Mo.

The fourteenth entertainment and ball of the Eccentric Firemen's local union No. 56, I. B. of S. F., of New York City, will be held at the Grand Central Palace, Saturday evening, January 23. Aside from the entertainment program, as usually provided by the best professional talent, there will be a special four-hand reel exhibition and exhibition drill by the Eccentric Firemen's Fife and Drum Corps. The proceeds of the occasion will be turned into the death-burial fund.

Transmission of Power by Leather Belting*

A Diagram Giving, without Calculation, the Size, Speed, Capacity, etc., of Belts, Including Effects of Slip and Centrifugal Force

BY CARL G. BARTH

The common assumption that the sum of the tensions on the tight and slack sides of a belt remains constant was shown to be a fallacy by Wilfred Lewis in 1886.** The coefficient of friction between the belt and the pulley varies greatly with the velocity of slip, and the centrifugal force of the belt has a great deal of effect. The accurate calculation of the size or capacity of a belt is, therefore, a much more complicated matter than the allowance of so many feet per minute of belt to the horsepower, even when the latter calculation is modified to allow for angle of contact.

Mr. Barth has evolved formulas covering all of the variables and enabling him to construct the diagram shown on pages 170 and 171, the nature and use of which can best be described and illustrated by working out a couple of examples.

EXAMPLE 1. The maximum cone step on the countershaft of a lathe is 22 inches in diameter and wide enough to carry a 5-inch double belt. The speed of the shaft is to be 300 revolutions per minute. Assuming the thickness of a 5-inch double belt to be [illegible] of an inch, and the arc of contact of the belt to be 180 degrees: (a) What pull can the belt be counted on to exert, and what horsepower will it transmit with this pull? (b) Under what initial tension will the belt have to be put up and retightened from time to time? (c) And what minimum initial tension must it not be allowed to fall below to insure the above-determined pull without undue slip?

Solution. To get the answer to question (a), we first turn to the small bottom portion of the diagram plate, and on its right-hand side note the point reading 300 revolutions per minute. From this we pass horizontally to the left until we intersect the vertical line from the point reading 22 inches on the scale of pulley diameters at the bottom line of the diagram. From the point of intersection we follow the diagonal line upward to the bottom line of the main portion of the diagram, and there read the velocity of the belt to be about 1700 feet per minute. The points of intersection referred to have been indicated upon the diagram by small circles.

We now note the point that corresponds to this belt speed of 1700 feet per minute in that scale on this same bottom line of the main diagram which is marked "Velocity for Pull of Machine Belt" and interpolate a vertical line extending upward from this point. (The circle between 1600 feet and 2000 feet, about the middle of the left-hand diagram is at the bottom of this line.) Then leaving this for the time being, we turn to the extreme left-hand portion of the diagram and there note the point corresponding to the belt thickness [illegible] inch on the vertical scale to the extreme left, and also the point marked 5 inches on the scale of belt widths at the bottom of the diagram. Following from these two points, respectively horizontally to the right and vertically upward, until they intersect, we now follow the diagonal from this point of intersection, until it terminates against the

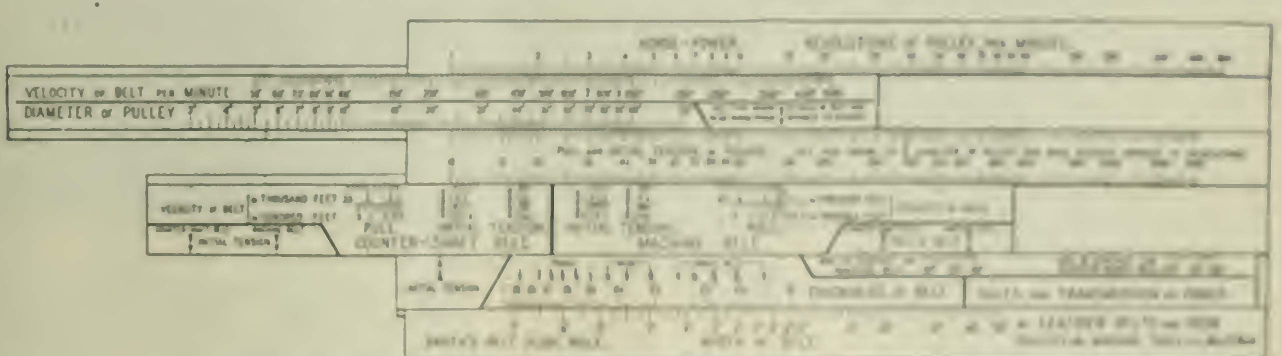

FIG. 2. [illegible] FOR THE MORE CONVENIENT SOLUTION OF BELT PROBLEMS GIVEN BY THE DIAGRAM

**Proc., A. S. M. E., Vol. VII, p. 549.

*Abstract of paper presented at the monthly meeting January 12, of the American Society of Mechanical Engineers.

vertical line marked 140 degrees and then the new diagonal until it intersects the vertical marked 170 degrees at the top of the diagram, in the field marked "Arc of Contact," and then continue horizontally until we intersect the interpolated vertical line for the belt speed 1700 feet already noted.

From the point of intersection we follow the diagonal upward and to the right until we meet the vertical scale of pounds, on which we now read the belt pull to be 140 pounds; and continuing horizontally until we meet the vertical line extending upward from the point corresponding to the belt speed originally found on the scale of belt speeds in this section of the diagram, and from this line diagonally to the vertical scale of horsepower, we read off the horsepower transmitted to be 7.2.

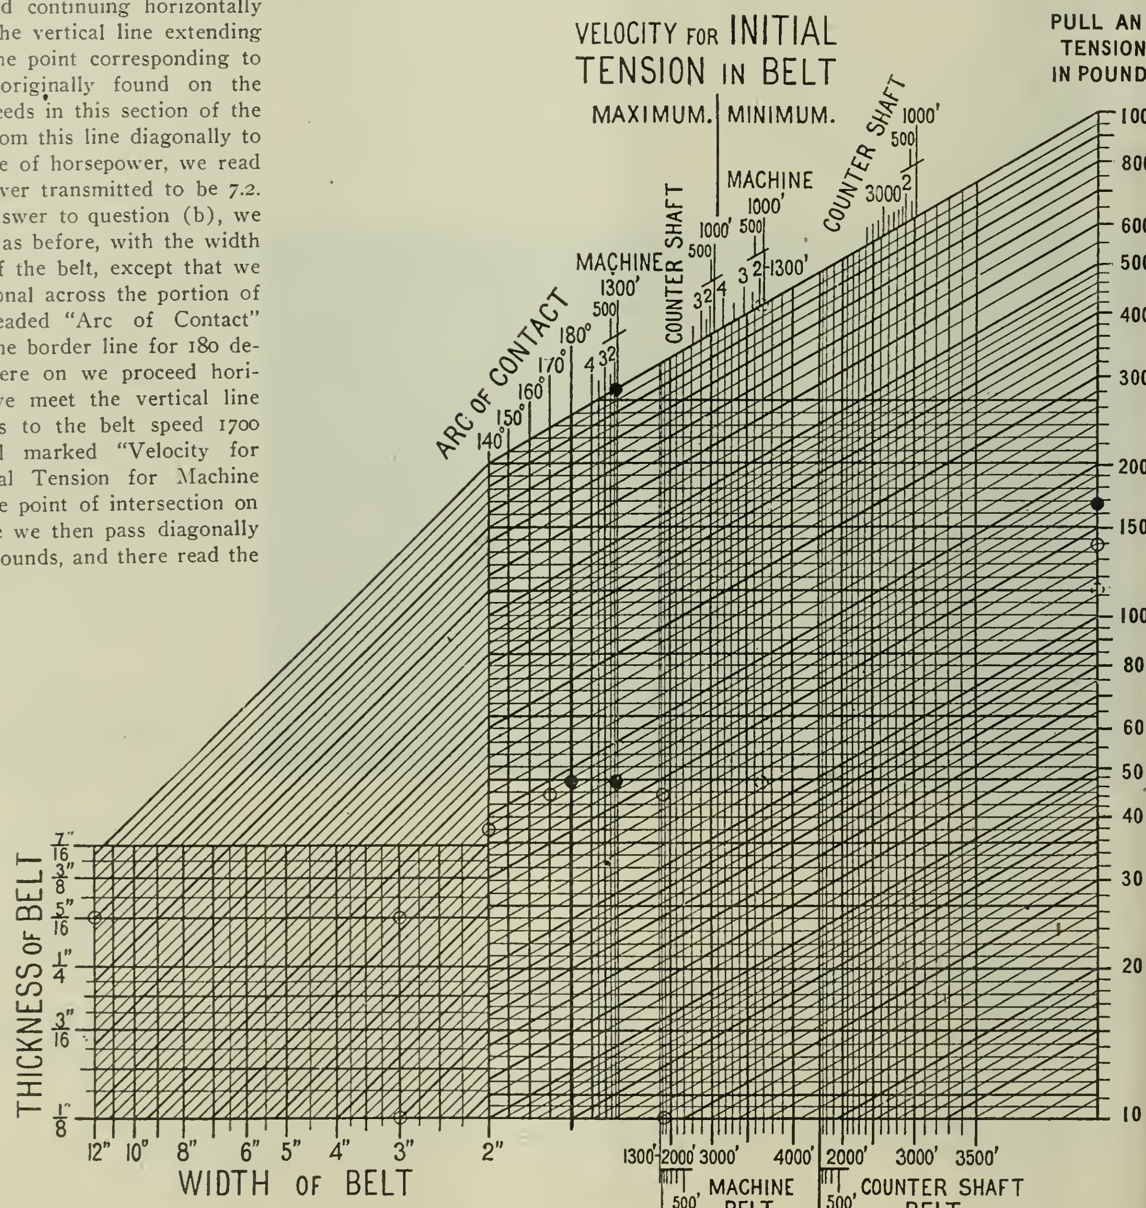
To get the answer to question (b), we proceed exactly as before, with the width and thickness of the belt, except that we follow the diagonal across the portion of the diagram headed "Arc of Contact" until we meet the border line for 180 degrees. From here on we proceed horizontally until we meet the vertical line that corresponds to the belt speed 1700 feet in the field marked "Velocity for Maximum Initial Tension for Machine Belt." From the point of intersection on this vertical line we then pass diagonally to the scale of pounds, and there read the maximum initial tension to be 168 pounds. Those movements for this solution on the diagram that differ from those for the answer to question (a) are indicated by little filled-in circles around the various points of intersection noted.

For the answer to question (c), we proceed in every respect as we did for question (b), except that we, of course, proceed from the point corresponding to the belt speed 1700 feet in that field of the scale on the top line of the diagram which is marked "Velocity for Minimum Initial Tension for Machine Belt." The answer read off on the vertical scale of pounds is 113 pounds. The movements for this solution on the diagram that differ from those for the answer to question (b) are indicated by little dotted circles around the points of intersection.

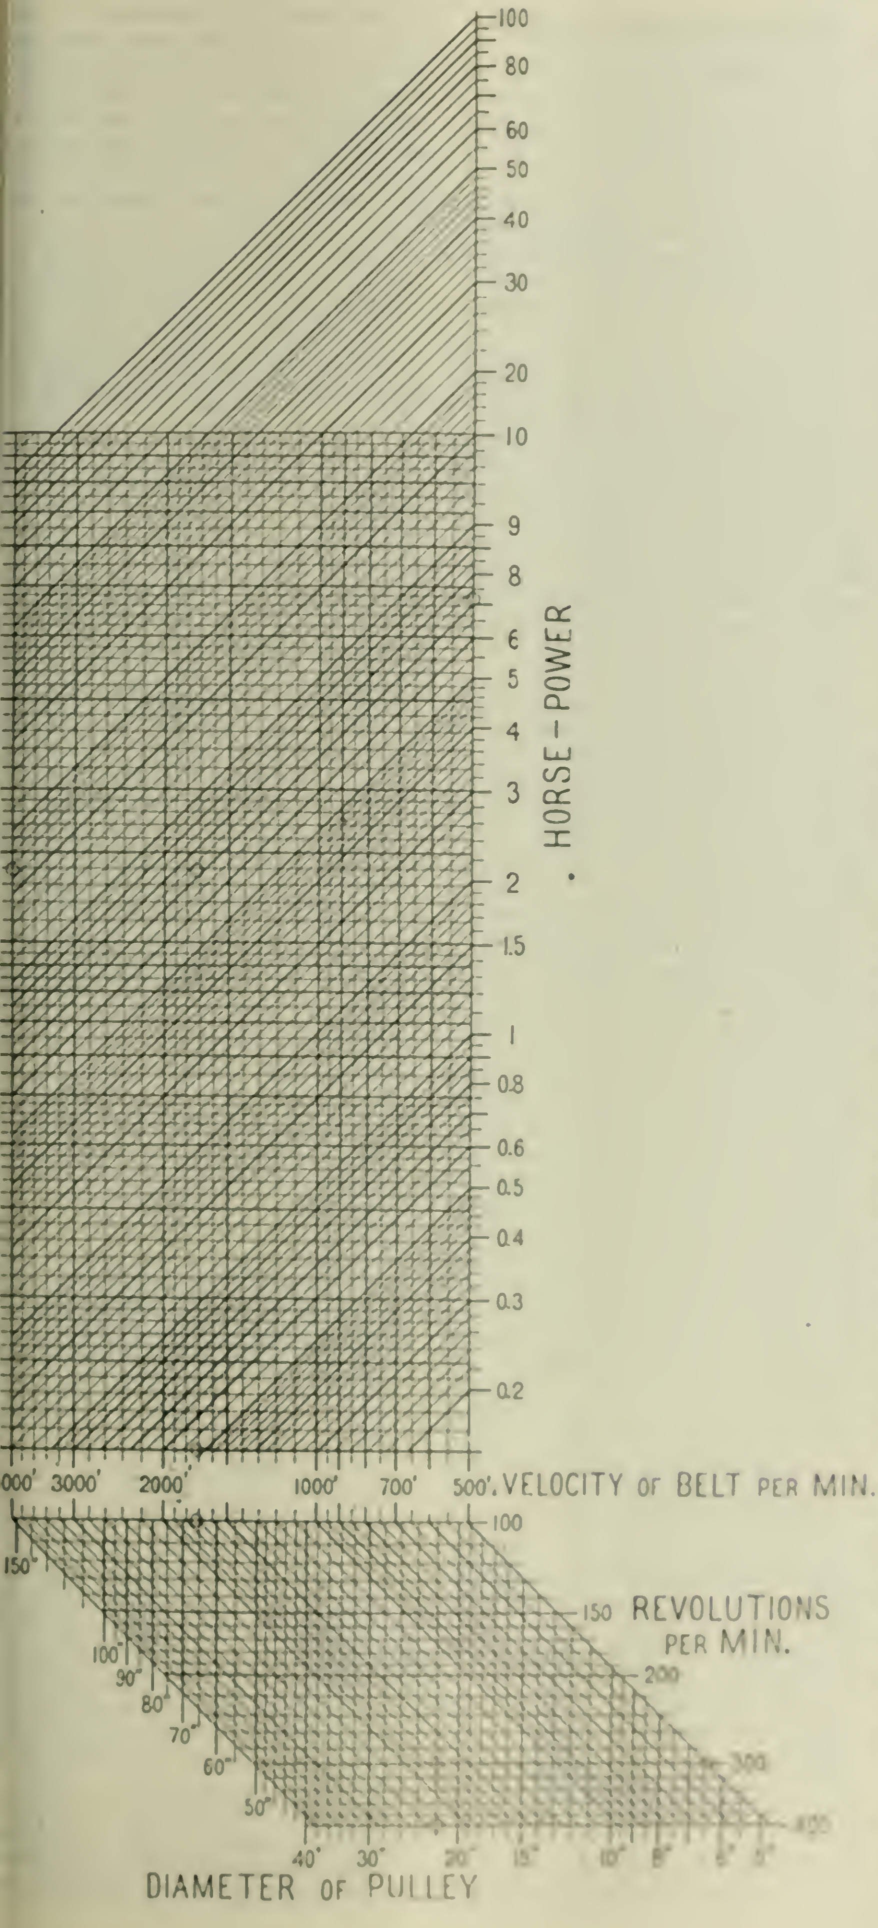
EXAMPLE 2: The countershaft in Example 1 is to be driven by a belt to run at a speed of 3000 feet per minute. (a) What diameter of pulley is required to give this belt speed? (b) What pull must the belt transmit? (c) What width of double belt must be used? (d) And what will be the initial tension under which the belt must be put up, and to which it must be again retightened after falling to the minimum? (e) What will be its minimum tension?

Solution: (a) As the countershaft is to make 300 revolutions and the belt is to run at 3000 feet per minute, we turn to the small diagram at the right-hand bottom corner of the main diagram, proceed horizontally to the left from the point marked 300 on the scale of revolutions on the right, until we meet the diagonal line from the point marked 3000 on the horizontal scale of velocities. From the point of intersection we then go vertically down to the scale of pulley diameters, and there read off 38 inches as the nearest even diameter.

(b) To get the pull of the belt we remember that the cone belt was found in Example 1 to transmit 7.2 horsepower. We therefore note that point on the vertical scale of horsepowers at the extreme right of the main diagram which corresponds to 7.2, and then follow the diagonal from this point toward the left, until we meet the vertical line extending up from the point marked 3000 on the scale of velocities on the bottom line of this portion of the diagram. From this point of intersection we continue horizontally to



VELOCITY FOR PULL OF BELT



the left to the vertical scale of pounds, on which we then read off the pull 80 pounds.

(c) From the point corresponding to these 80 pounds we now continue diagonally to the left until we meet the vertical line extending up from the point corresponding to the belt speed, 900, on the scale marked "Velocity for Pull of Countershaft Belt" at the bottom of this central portion of the main diagram. From this point we continue horizontally to the vertical line corresponding to the arc of contact, which, not being given, we will assume as 180 degrees, and then again diagonally to the extreme left-hand section of the diagram. Any combinations of width and thickness from points in the diagonal along which we are now moving, will then give a proper belt, and assuming as in Example 1 a thickness of 3/16 inch, we find the width to be 3½ inches.

(d) To find maximum initial tension for this belt, we proceed exactly as in Example 1, except that we use the scale marked "Velocity for Maximum Initial Tension for Countershaft Belt" at the top of the middle section of the diagram, and then read this off on the scale of pounds as 137 pounds.

(e) Similarly, we find the minimum initial tension to be 67.2 pounds.

In his paper "Notes on Belting,"* F. W. Taylor referred to belt clamps provided with spring balances for weighing the tension in a belt. In the case of endless belts these scales are put directly on a belt in its final position over its pulleys, while in the case of a belt with wire lacing, this is cut to length under the required tension on the specially designed belt bench illustrated in Fig. 1. As will be seen, this bench is provided with a pair of pulleys which can be so adjusted that a tape line will measure the same around these pulleys as over the pulleys on which the belt is to run. A belt cut and laced to give a certain tension when the bench pulleys have been properly adjusted, will then be of a length to assume the same tension over its own pulleys.

This indirect way of securing a desired tension in a belt was first suggested by our fellow member, Gideon [illegible], who also made the drawings from which the first bench and the first improved belt scale were made by the Bethlehem Steel Company in the year 1900.

To sum up, the writer's work on the subject has mainly consisted of the following:

(a) To establish a mathematical formula for the relation between the tension in a belt and the stretch due to that tension, based on experiments made at different times by Wilfred Lewis, Fred. W. Taylor and himself.

(b) By means of the knowledge of the elastic properties of leather belting, explained by this formula, to develop a formula

*Trans. A. S. M. E., Vol. XV, p. 204.

mula for the relations between the tensions in the two strands of a belt-transmitting power. which formula takes account of the influence of the sag in a horizontal belt, and agrees substantially with the results of the experiments made by Mr. Lewis, when plotted in the manner first done by Professor Aldrich.

(c) To establish a formula to express the relation between the coefficient of friction between a belt and a cast-iron pulley, and the velocity with which the belt slips or slides over the pulley, as revealed by plotting the results likewise obtained by Mr. Lewis.

(d) The construction of a diagram embodying the formula expressing the relation between the two tensions in a belt, the well-known formula for the loss in effective tension due to centrifugal force, and the likewise well-known formula for the ratio between the effective parts of the two tensions, as determined by the coefficient of friction and the arc of contact of the belt on its pulleys. These formulas are so correlated on the diagram that problems dealing with the contained variables may be solved graphically, while a direct algebraic solution is possible only for a vertical belt, or what is the same thing, by neglecting the effect of the sag of a horizontal belt. A plate containing this diagram accompanies Mr. Barth's paper.

(e) Also by means of the better knowledge gained of the elastic properties of leather belting, to develop a formula for the creep of a belt on its pulley due to the difference in the tensions in the two strands, along the lines outlined by Professor Bird in his paper on "Belt Creep," read at the Scranton meeting in 1905.

(f) The construction of diagrams showthe pulling power and other relations of the two tensions of a belt of 1 square inch cross section and 180 degrees arc of contact at different speeds, under certain conditions and assumptions recommended by the writer. Also a modification of these diagrams for extended practical use, on which may be read off: (1) The pulling power of a belt of any width and thickness and any arc of contact, between 140 and 180 degrees: (2) the initial tensions below which the belt must not be allowed to fall in order to confine the slip and the consequent loss of efficiency of transmission within certain limits; (3) the initial tension to which it is recommended that the belt be retightened after falling to this minimum limit. (Plate 2 of the paper, reproduced herewith.)

(g) Finally, the construction of a slide rule serving the same purpose as the diagram just mentioned, but which is much handier than the diagram. See Fig. 2.

An exchange states that sileo-vanadium steel is now used in making transformers, as on account of its improved magnetic quantity it decreases the core loss.

The Effect of Steam Jacketing

To the Editors:

I inclose a copy of a letter written to Bryan Donkin, of London, with whom I had numerous interviews when he was upon the Continent.

This letter is interesting from the theories which are there brought out and which have since been recognized as correct and largely applied.

H. Bollinckx.

Brussels.

M. Bollinckx' Letter to Mr. Donkin

I am in receipt of your kind letter of the second instant, and have just finished reading the pamphlets which you inclose.

I conclude, firstly, that the marine machines are not very economical, as I have always thought, and of which I have had proof in my own country in a compound vertical machine of 500 horsepower consuming nearly 10 kilograms (22 pounds) of steam per horsepower-hour.

All that you say in your paper is perfectly correct according to my idea, and it is by following these ideas that I have constructed my engines for a long time:

(1) The admission of the steam at the top of the jacket in order that the water shall be thrown to the bottom of the jacket and that the cylinder shall be freed from drops of water.

(2) Surfaces carefully polished in order to diminish initial condensation.

(3) The smallest amount of surface possible in the presence of the entering steam, and these surfaces well polished as above stated.

(4) To diminish, if possible, the clearance space; but I attach less importance to this last point.

As I have written you before, I try to make my cylinders as thin as possible, and it is for this reason that I use the heavy reinforcing rings in order to give them the necessary strength. I am going to use the same thing for the heads of my cylinders, and even for the pistons. I am going to heat the pistons, as M. Berger-André, of Thann, has done, as the reason that I have for heating the cylinder wall is the same as that for heating the piston, and it is only the difficulty of heating the latter which has delayed my doing it up to the present. But within the last six months I have been able to obtain tubes strong enough so that I could make a hollow piston rod by which I will introduce the steam, and into which will pass a second tube for taking out the water of condensation. M. Berger-André has obtained in this way an economy of 5 per cent., but the difficulties of construction and of maintenance led him to abandon the idea.

I have read with much interest the account of your tests on the Sulzer engine, in which you introduce the steam during the compression and before the admission. I am astonished that this filling up did not cause the pressure to mount higher in the clearance space, which goes to prove the enormous amount of condensation which is taking place in that space at the moment of the injection of the steam; and certainly if the surfaces are not of a certain temperature one will never obtain a certain pressure by compression in that space.

I come now to the tests in which the jacket was heated by steam having a higher pressure than that which was used in the cylinder. I have read a great many reports of tests made upon this subject, and yours interest me the more because you have approached the subject with so much care. The economy is low but I should certainly have said that it would have been more considerable. I do not know to what to attribute this effect. I have already investigated the subject of the tests on the compound engines constructed by my competitors and myself, but they have only resulted in confusing my ideas, for I have constructed compound machines (and they also) where the jacket of the larger cylinder and the receiver were heated with steam at six atmospheres and the efficiency remains the same as that of machines in which the receiver is not provided with a reheater and in which the jacket of the low-pressure cylinder is heated simply with the charge coming from the high-pressure; that is to say, with the same steam which operates in the low-pressure cylinder itself. It may be that when the jacket is heated by steam of a greater pressure than that which is used in the cylinder, there is practically no circulation and that the water deposited about the cylinder, the film of water, as you say, hinders the transmission of heat. I do not know anything about it, but the fact is there.

I know also of the tests with superheated steam, and Schaerer sent me an apparatus four months ago, but it is not yet in place so that I cannot make tests upon my engine. The superheated steam will, of course, give less advantage when one has a good boiler which furnishes dry steam and a good compound engine which does not consume more than 5.7 kilograms (12.5 pounds) of steam per indicated horsepower like ours.

One thing which astonishes me also is that engines where the steam coming from the boiler circulates in the jacket before entering the cylinder do not give a greater economy when the passages (the entrances for the steam to the valve) are so small as to produce a fall in pressure of one or two atmospheres. In effect, this constitutes a jacket operating at a pressure higher than that of the steam in the cylinder, and the steam itself is somewhat superheated, owing to its sudden loss of pressure.

Hirn and Hallouer pretend to have obtained good results in this way and concluded even that expansion is unnecessary to the economical use of steam and that throttle governing is quite sufficient. Is this your own opinion?

Jackets heated by means of oil must operate poorly, as the conducting power of the oil is not good. I believe that a very thin jacket could be made to give good results, and I believe that if the cylinder barrel is well provided with fins it will transmit heat still more quickly,

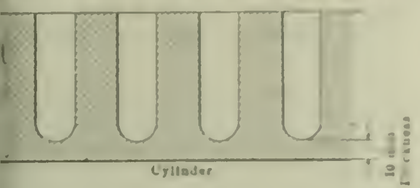


FIG. 1

and that the difference in temperature between the metal interior of the cylinder and the steam will be reduced. If you reduce this difference you reduce also the initial condensation. Is this your idea?

I have also experimented (but the engine, I believe, was not well run during the test) with an apparatus in the receiver for separating from the steam coming from the high-pressure cylinder on its way to work in the low pressure all the water which it contains.

I always use a separator upon the high-pressure cylinder, and I believe that if the water can be separated from the steam before it enters the low-pressure cylinder, it would do a great deal of good.

H. BOLLINCKX

[M. Bollinckx' letter is accompanied by blueprints reproduced herewith, showing

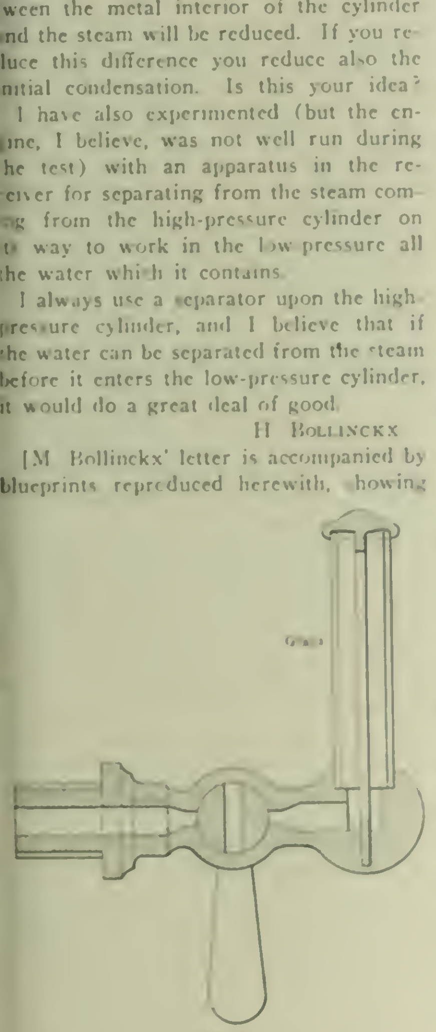

FIG. 2

in Fig. 1 the grooved exterior wall of the cylinder, and in Fig. 2 an indicator for showing the action of the steam. At the period of admission the steam in the glass is foggy. It clears up somewhat during expansion by reevaporation, and the instant the exhaust valve opens it becomes clear, showing the formation by reevaporation of steam which goes to the condenser. Donkin invented such an instrument, but that here shown is claimed by M. Bollinckx to have been invented independently by himself.—EDITOR.]

Alcohol versus Gasolene for Internal Combustion Engines

BY JAMES E. STOREY

There has been considerable comment on the possibilities of denatured alcohol as a substitute for gasolene in internal-combustion engines. A close analysis of the relative merits of the two fuels brings out some facts which are not generally known, and which are of interest to both the engine operator and the designer.

Gasolene consists principally of a mixture of pentane and hexane. The heat value of these compounds is about 21,000 B.t.u. per pound, while that of alcohol is but 13,700 B.t.u. per pound. However, there is a compensating factor which eliminates most of this difference. The reaction which expresses the explosion of gasolene vapor is as follows:

$$\begin{array}{l} \text{Gasolene vapor} \qquad \text{Air} \\ 2\,C_6H_{14} + 19\,O_2 + 76\,N_2 = \\ 12\,CO_2 + 14\,H_2O + 76\,N \\ 2\text{ vols.} + 19\text{ vols.} + 76\text{ vols.} = \\ 12\text{ vols.} + 14\text{ vols.} + 76\text{ vols.} \end{array}$$

Hence, 97 volumes of explosive mixture produce 102 volumes of "burned" gases, there being a certain increase of volume due to the increase in the number of gas molecules. Thus, if 1 cubic foot of the mixture were exploded, 1.0515 cubic feet of gaseous products would be formed even if no heat of combustion were given off. The specific heat of the resulting gases would be about 0.18387 at constant volume. Since 1 pound of pentane requires 15.9 pounds of air, there would result 16.9 pounds of spent gases; 3.11 B.t.u. would be required to raise the temperature of this weight of gas 1 degree Fahrenheit. Taking the heat value of gasolene as 21,000 B.t.u. per pound, the rise in the temperature of the exploded gases would be 6750 degrees, theoretically.

Following the same line of reasoning for alcohol under the same conditions will give results which show the relative values of the two fuels. The equation for the combustion of alcohol vapor is as follows:

$$\begin{array}{l} \text{Alcohol vapor} \qquad \text{Air} \\ C_2H_6O + 3\,O_2 + 12\,N_2 = \\ 2\,CO_2 + 3\,H_2O + 12\,N_2 \\ 1\text{ vol.} + 3\text{ vols.} + 12\text{ vols.} = \\ 2\text{ vols.} + 3\text{ vols.} + 12\text{ vols.} \end{array}$$

or 16 volumes of mixture produce 17 volumes of spent gases. There is, therefore, an increase in volume due to the increase of gaseous molecules, but this increase is not as great as with gasolene vapor. One cubic foot of the original alcohol mixture makes 1.0625 cubic feet of spent gases. The specific heat of the exhaust gases at constant volume is 0.17998. One pound of alcohol requires 10.72 pounds of air, making 11.72 pounds of gas, which requires 2.07 B.t.u. per pound to raise the temperature 1 degree Fahrenheit. The temperature would be raised theoretically 6618 degrees, which is more than 100 degrees less than that computed for the gasolene mixture.

OTHER INTERESTING FACTS

A close study of these reactions brings out some other interesting facts. For example, one volume of gasolene vapor requires about 50 per cent. more air than the same volume of alcohol vapor. On referring to the formula it will be evident that each alcohol molecule contains oxygen, and therefore does not require as much oxygen for combustion as a hydrocarbon molecule. However, that oxygen contained in the molecule greatly facilitates the combustion. Everyone knows that alcohol will burn without smoke, while gasolene always makes smoke unless it is first vaporized and then mixed with sufficient air. It is probable that there would be less trouble from cylinder deposits of soot with alcohol than with gasolene.

As to mixing of the charge, there is little advantage for either fuel. If anything, the alcohol vapor is slightly heavier than the gasolene vapor; therefore the latter will diffuse somewhat more rapidly.

The foregoing facts indicate that gasolene is superior to alcohol in nearly every way. The volumetric increase of the former is over 2 per cent. greater and the theoretical temperature of explosion is 130 degrees higher; consequently, the initial pressure of the exploded gasolene mixture will be greater than that of the alcohol mixture. Tests have probably been made and will be made which show that alcohol is as good as gasolene, or even better, but the blame should be put on the carbureter or the mixture rather than on the fuel. A few years ago when the industrial alcohol craze struck this country people expected too much from this fuel because of the ease with which it could be manufactured and the variety of products from which it could be made. In spite of the fact that the revenue has been removed from industrial alcohol for some two years, the price is still too high to consider it as a fuel on any practical scale. With alcohol at the same price as gasolene, there would still be a difference in favor of gasolene.

Another feature which should not be overlooked is the ease with which alcohol can be diluted with water. Unless the alcohol were bought from a reliable dealer, it would have to be tested before use or it might cause no end of those "mysterious" gas-engine troubles. Gasolene can be diluted only with a hydrocarbon, such as kerosene, and while it may not vaporize so readily, yet the kerosene will develop power when ignited in the cylinder.

With alcohol as high in price as it is and gasolene as low as it is, the proper direction for investigation is along the line of the better combustion of gasolene or other hydrocarbon mixtures.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres and Treas. ROBERT McKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 *we printed and circulated* 1,836,000 *copies of* POWER.

Our circulation for December, 1908, *was (weekly and monthly)* 191,500.

The Line "Recognizes" the Staff

The engineer, realizing his absolute responsibility for the ability of the vessel to move, has been accustomed to shrug his shoulders in the inconspicuous background while press and public and officialdom lauded and feted the captain of a vessel which had made an exceptional run. "Fighting Bob" Evans modestly brushes this credit aside. "I am not the one man who took the fleet to San Francisco," says he. "The man who brought the fleet around the Horn is the man who boiled the water in the fireroom and the man who peeled the potatoes. They have done as much to take it, step by step, as the keen-eyed officer on the deck or the gray-haired captain on the bridge."

The pendulum may hit the engineer in swinging back.

Hackneyed Contributions

There are some engineering subjects which, like the poor, will always be with us; such as how to keep the ashpit clean, methods of firing practiced fifty years ago, necessity of keeping the water level at the second gage, objections for and against valves in the water-column connections, loss of boiler economy for each one-sixteenth inch of scale, whether the pressure should be on the stem or disk side of a globe valve, and whether a belt should be run hair or flesh side to the pulley.

Superheated steam has been a live topic for discussion, and many articles have been written by those who did and did not know what they were talking about; but with the passing of the years, many of the old notions regarding the use of superheated steam have been dispelled, especially regarding its effect upon packing, cylinder lubrication and the operation of valves other than those of the poppet type. Not many years ago, a member of a certain engineering society had under way the preparation of a paper, to be read at the next meeting of the society, regarding the difficulties encountered in using superheated steam, and especially dealing with its nonuse in the ordinary type of steam engine. Doubtless the paper would have been read before an intelligent body of men as planned had it not been pointed out that the difficulties which were singled out as restricting the use of superheated steam had been so overcome that they were not classed as difficulties, any more than any other feature in steam-plant operation.

In posing before the public as an authority the individual should know that his position is unassailable. If a writer makes an erroneous statement it will be strange if someone does not bring the matter to his attention. The one who is mistaken in his beliefs may have some excuse, and the one who does not know may learn through the school of criticism. Both of these kinds of writers are being constantly met with by the editorial force of this paper, and they are dealt with courteously and a helping hand is given when required.

The Future Large Gas Engine

Reciprocating steam engines for land service are built up to about twelve thousand brake horsepower and turbines up to fourteen thousand kilowatts, or about twenty thousand brake horsepower per unit. Twin-tandem gas engines have been built in this country up to five thousand four hundred brake horsepower, or one thousand three hundred and fifty horsepower per cylinder, using a rich gas; with less "snappy" gas the same engine could doubtless be worked up to fourteen or fifteen hundred horsepower per cylinder by building it with higher compression. These figures mean, obviously, that the gas engine of the future for large power-plant service must be built in much larger units than the present knowledge of design permits, if it is to compete with steam. Urban central stations cannot afford to provide one and a quarter square feet of generating room ground plan for each brake horsepower of output, which is about the size of the huge Gary plant. Nor is it usually profitable to divide the total output of even a big station into twenty or more units.

The greatest internal cylinder diameter thus far employed in this country is forty-four inches; somewhat larger cylinders are in successful service abroad, but the difference is not important from the viewpoint under discussion. To develop ten thousand brake horsepower at eighty-five per cent. mechanical efficiency a twin tandem four-stroke engine would need cylinders not less than eighty inches in diameter, which is far beyond any recorded size ever built.

The chief difficulty in the way of building large engines is the enormous quantities of heat to be got out of the cylinder per cycle, which difficulty is augmented by the well known decrease in the ratio of wall surface to volumetric capacity with increasing diameters. Consideration of this feature of the problem alone would lead straight away from the accepted "ideal" of a hemispherical combustion chamber and in the direction of a flattened extension of the cylinder proper, but only actual experiment can determine how far one could go in that direction without developing other difficulties of a more or less prohibitive nature.

Whatever may be the method of doing it, however, it is quite evident that the construction of much larger units than have yet been produced must be made practicable if the gas engine is to gain e standing in large power-plant work that its rapid improvement in operating characteristics bids fair to justify.

Boiler Plant Capacity

The average plant consisting of several boilers is laid out to operate on one stack, and this stack is generally proportioned properly to serve the boilers installed. It often happens that the original capacity is soon outgrown and the need of additional boilers is felt, and these are installed and connected to the stack without any thought being given to the question of whether the stack is of sufficient capacity properly to care for the added boilers.

It sometimes transpires, too, that, owing to several such additions of boilers, the overloading of the stack becomes so pronounced that further additions to the boiler equipment tend to reduce the capacity of the plant as a whole rather than to increase it.

It should be the duty of every progressive engineer to know at what points the capacity of his plant will be reached first, so that when the call for additional power comes he will be ready to suggest how his employer's money can be most advantageously spent to obtain the desired increase in capacity.

In a boiler plant there are three main features of general design that limit the capacity, and each of these is of practically equal importance, although this does not seem to be generally appreciated. The first, and the one which is often assumed to be the all determining factor, is the actual boiler capacity, or extent of heating surface. The second is the grate capacity or area; this is fairly well taken care of as a general thing, on account of additional grate surface being always installed with each addition to the boiler capacity. Thirdly, is the draft capacity, and this is liable to be anything in a plant that has been through several changes. It must be remembered that draft capacity does not mean simply a chimney capable of furnishing a given volume of air, but also that the gas passages from the grate to chimney are of ample proportions and proper shape; also, that the draft be of the correct intensity or sharpness to suit the quality of fuel used. Some of the lower grades of fuel are only burned successfully with artificial draft. The quality of the fuel also affects the grate area required.

If your boiler plant is showing signs of overload, determine individually if the heating surface, grate area and draft are properly related when the class of fuel used is considered, so that they may work in unison to produce the highest plant capacity. This correct proportioning of the several capacities will tend toward the economical generation of steam. Remember that all any boiler can do is to absorb a certain portion of the heat generated on the grate and to generate the full amount of heat that a given boiler is capable of absorbing efficiently, requires the correct grate and draft capacity for the particular kind of fuel used.

A Remarkable Statement

On January 4 the Supreme Court of the United States reversed the decision of the United States Circuit Court declaring the eighty-cent gas law confiscatory. In announcing the decision of the court, Judge Rufus W. Peckham made public an abstract of the opinion in which the following statement was made:

"The proof unquestionably shows great possible if not probable danger of explosion in the mains or other pipes if the pressure demanded were applied to them as they now are."

The State law in question required that gas of at least twenty-two candle power should be supplied at a pressure not exceeding two and one-half inches of water. It surely cannot be this pressure to which the court refers, as the stress set up in the walls of a twelve-inch cast-iron pipe three-fourths inch thick by this pressure would be too small to be measured. But what else can the decision refer to and why should that portion of the law be declared null and void? Illuminating gas does not explode on the application of pressure; in fact, we seem to have heard somewhere that air or rather oxygen in rather large quantities must necessarily be present along with illuminating gas in order that an explosive mixture be formed, and even then a spark or external heat is required to start the action.

It is not often that misinformation of this order appears in the decisions of our Supreme Court and it is highly probable that when the full text is made public the difficulty will have a rational explanation. However much the intricacies of the legal mind may be beyond the understanding of the average engineer, the basic principles of physics and chemistry are common property, and with the assistance of the public school system should be possessed by every citizen.

Steam Boilers and Dynamite

Boiler explosions have occurred from many causes other than that of low water, and as plenty of these causes are natural or legitimate enough of themselves, it is not necessary for the owner to celebrate the occasion by [illegible] or for the fireman to assert that some enemy had put dynamite into the boiler. The fact should not be overlooked, however, that careless superintendence begets careless workmen, and that when handling either a steam plant or high explosives certain rules and special precautions must be taken that would not be required of a man operating a wheelbarrow. That either dynamite or a steam boiler can be used for its respective work with perfect safety is known. That both have been used in ways resulting in great destruction of life and property is also known, but to intrust the use of either to incompetent persons is dangerous.

The incident related herein about the thawing of dynamite in a boiler room may seem to engineers as a case of "served them right for doing such a crazy thing" but maybe you are doing something just as careless in your own boiler room. To those not acquainted with the habits of dynamite, it may be explained here that at temperatures below 50 degrees Fahrenheit it is in a frozen condition, and that for effective use it must be thawed out. It is this thawing operation that has given so many opportunities for carelessness and ignorance to decrease the death-benefit funds of a certain class of fraternal organizations. The dynamite cartridges are thawed properly by placing them in a watertight vessel surrounded by water which is heated to a temperature not exceeding 130 degrees Fahrenheit.

In the power plant of a certain Western mine two 60-horsepower return-tubular boilers were installed and operated at about 80 pounds pressure. One of the miners soon discovered that it was an easy matter to thaw his giant sticks by placing them on a sawdust bed on top of one of the boiler drums. Now the miner did not know that the temperature of steam at 80 pounds pressure is about 324 degrees Fahrenheit. It was not long before the bed of sawdust was scattered and the remainder became soaked with the leakage from the dynamite sticks, thus bringing the nitroglycerine in contact with the heated boiler plate. The inevitable explosion happened on schedule time, but fortunately no employee was in range of the debris. Besides the effect of the shock on the boiler setting and the general wreck of the boiler-house covering, the only damage done was to "dish in" the top and sides of the drum until it looked like a derby hat that had been struck at an angle of 45 degrees by a foot-ball. That was on both of the boilers. All the [illegible] was fortunate.

[illegible] conducting electric current. If the distance between the terminal plates be halved, only half the number of ions will be formed and hence the current will be halved instead of doubled. Up to the point of saturation the current is directly proportional to the voltage, but above this point there is no further increase in current.

Hopkinson Flashlight Indicator

It is generally admitted that for engines running at more than 200 or 300 revolutions a minute the ordinary indicator does not give satisfactory results.

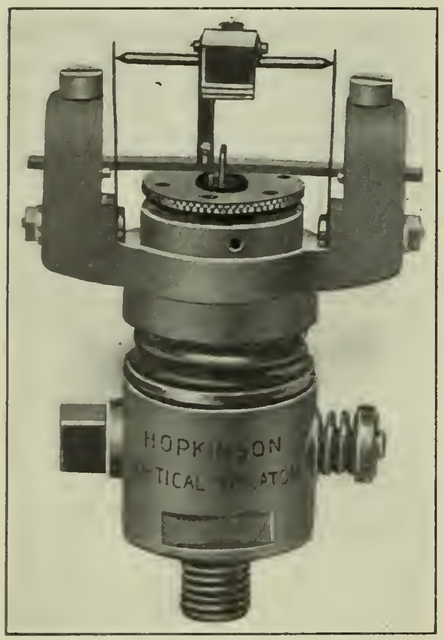

FIG. 1

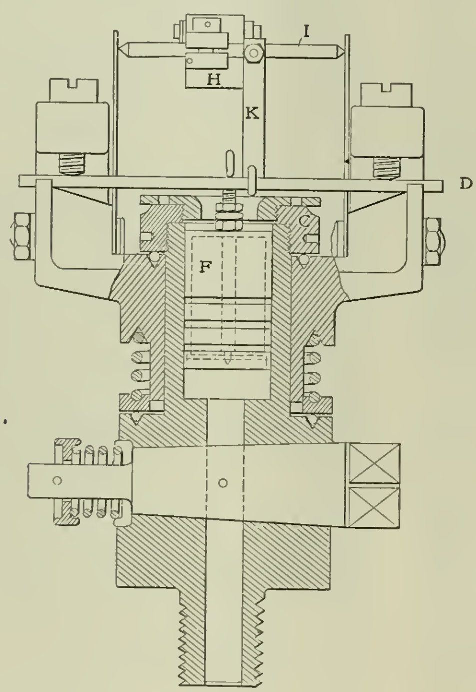

FIG. 2

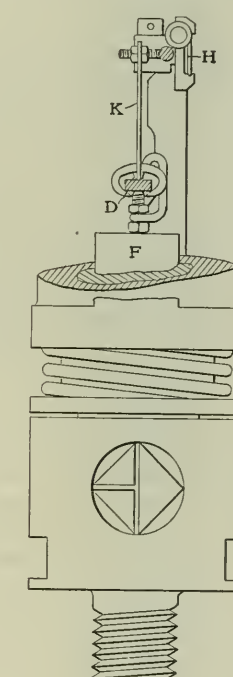

FIG. 3

FIG. 4

The inertia of its piston and parallel motion seriously distort the diagrams, while slackness of the motion joints and friction of the pencil on the paper introduce other errors which are by no means negligible. When we come to really high speeds, such as those of petrol and other engines, the only practicable form of indicator is the optical type, in which a minute motion of a diaphragm or piston, subject to the cylinder pressure, is magnified and made visible by means of a beam of reflected light. The optical principle at once does away with inertia troubles, and when embodied in a suitable type of apparatus is capable of giving valuable results at the highest speeds at which any engine can run. Very good work has been done with such indicators, which have now been in use for some years.

In the usual form of optical indicator the pressure of the steam or gas acts underneath a metallic diaphragm, which is attached to a mirror. The deflections of the diaphragm cause the mirror to rock, so that a spot of light reflected from it traces out a line on the card. The objections to this form are twofold: Firstly, that the deflections of the diaphragm are not exactly proportional to the pressure acting upon it; and, secondly, that the heat of the steam or gas is likely to affect the calibration of the instrument by altering the elasticity of the diaphragm. To avoid any possible source of error or trouble from these causes, Prof. Bertram Hopkinson, of Cambridge University, has devised the instrument shown in Figs. 1 to 3, which is manufactured by Dobbie-McInnes, Limited, of 57 Bothwell street, Glasgow, and sold under the name of the Hopkinson Flashlight Engine Indicator.

The distinctive features of the Hopkinson indicator are shown in Figs. 2 and 3. The body of the instrument is bored to receive a piston *F*, the top of which is fitted with a wire-hook arrangement which embraces at the center a flat steel spring *D* fixed transversely above the piston. The hook does not hold the spring tightly enough to prevent the piston taking its position freely in the bore. The spring is clamped at each end to the rotating head of the instrument in the manner hown. Before insertion it is slightly urved, but when in position it is held traight by a moderate pressure of the wo binding screws. Above the spring nd parallel to it, is a spindle I, to the cen- er of which a small mirror H is fixed

illustrated but in which an eccentric is fixed to the engine crank shaft, and a spring clip to the indicator head, although we understand that Dobbie-McInnes are prepared to supply better mechanical arrangements for most cases.

[illegible]

FIG. 5

FIG. 7

[illegible]

The spindle is carried on pointed centers, against which spring clips press. It, and therefore the mirror, are caused to rock by means of a thin steel strip K connecting the spring and spindle, the flexibility of the strip allowing it to accommodate itself to the circular motion of the spindle. The length of the diagram is obtained by rocking the head of the instrument around the body, the motion taking place on the ball bearings shown in Fig. 2. A motion of the head through an angle of about 3½ degrees gives a diagram 2 inches long. The motion of the mirror is only 1/40 inch, so that inertia effects are very small indeed. The indicator may be driven through a motion which is not

To render the diagram visible or to obtain a photographic record of it, a camera like that shown in Fig. 1 is attached to the indicator. A concave reflecting mirror is used, which throws a spot of light upon a ground-glass screen or photographic plate at the outward end of the camera. Should no permanent record be required, the object being simply to observe the pressure at one point of the stroke, or to note the general shape of the diagram, a telescopic arrangement as shown in Fig. 5 is used. The optical principle is illustrated in Fig. 6. [illegible]

FIG. 6

FIG. 8

[illegible]

Veeder Liquid Tachometer

The liquid tachometer described and illustrated herewith is manufactured by the Veeder Manufacturing Company, Hartford, Conn. This instrument makes use of a liquid in a device similar to a

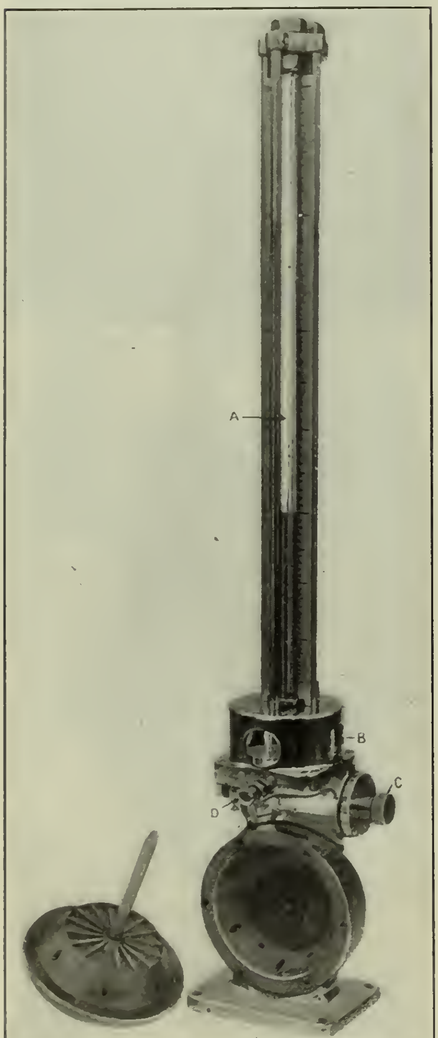

FIG. 1. VEEDER LIQUID TACHOMETER

centrifugal pump. Its principle in action is that the pressure developed by the centrifugal force of the liquid, when the instrument is running at a certain speed, is a definite quantity. This pressure forces liquid up the indicating tube *A*, Fig. 1, and is balanced by the pressure due to the hight of the column of liquid in the tube. Fig. 2 is a sectional view.

The instrument shown in Fig. 1 illustrates one of its present forms with the paddle removed. The only moving part is in the paddle, which imparts the necessary centrifugal force to the liquid contained in the body. A small reservoir *B* is located directly over the paddle case, in the center of which is a glass tube through which the liquid flows to the indicating tube *A*.

A suitable zero mark is provided around this small tube in the center of the reservoir. The liquid rises by capillary attraction in this small central tube somewhat above the level of the liquid in the reservoir. This enables the tachometer to be set at zero, a displacement clutch operated by small thumb nuts (shown at *C*) enabling the operator to raise or lower the hight of the liquid so that its surface shall be exactly at the zero mark.

A free passage is provided from the reservoir to the center of the paddle wheel, allowing the liquid to flow freely to the paddle wheel, from which it is thrown out through very small orifices in the periphery of the paddle case. A small handle *D* is placed at the front, with which to operate a valve to choke the passage from the pump to the indicating column. This is to prevent the dancing or vibration of the liquid column, due to

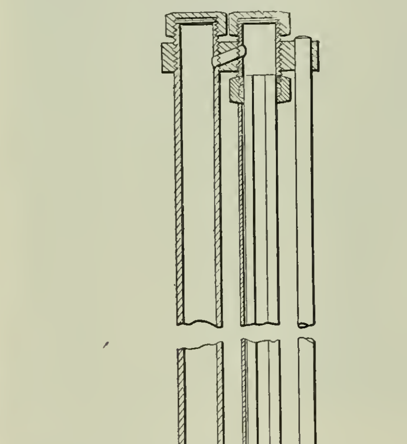

FIG. 2

any fluctuation in the speed of the revolving body whose revolutions are being indicated.

The blades of the paddle are radial so the device may be reversed. A ball thrust bearing is provided for the paddle shaft, thus eliminating any wear that would prove injurious. The outlets for the liquid consist of a number of small radial holes, equally spaced around the periphery of the paddle case.

The apparatus is so sensitive that at the maximum speed for which it has been constructed, namely, 2500 revolutions per minute, a difference of one or two revolutions is very noticeable. It is portable and there is no difficulty in holding the column practically vertical. It may be used either by holding it in the hand, the paddle-shaft wheel being driven by a short, flexible shaft thrust against the end of the revolving member whose revolutions are to be measured, or it may be fastened down and driven by gears.

Among the many applications to which the tachometer has been adapted is that of testing dynamos, engines and other machines having revolving members. It has also been adapted for switchboards, grouped with the other instruments, and gives a continuous indication of the revolutions per minute of either the engine or generator.

Obituary

Alfred R. Wolff, who died on January 7, at his home, 15 West Eighty-ninth street, New York, after an illness of several months, was born in Hoboken, N. J., March 15, 1859. His early life was marked by evidences of great ability and he graduated from Stevens Institute in the first half of his eighteenth year. He entered the United States revenue cutter service, where he remained for some years, leaving to become assistant to Charles E. Emery. Later he became a member of the firm of Whitman & Wolff, consulting engineers, and afterward opened an office and devoted his energies to heating and ventilation. He was an engineer of rare ability and wrote to some extent on engineering topics, such as "The Most Economical Point of Cutoff," "The Windmill as a Prime Mover," "Value of the Study of the Mechanical Theory of Heat," "Expansion of Steam and Water," "Friction of Noncondensing Engines," "The Influence of Steam Jackets on the Pawtucket Pumping Engines," "Recording Pressure Gages," "Steam Consumption of Engines and Water Meters." He served on several committees for the American Society of Mechanical Engineers, among the most important of which was the committee on standard pipe sizes.

The annual stag banquet of the Louisville Association No. 1, N. A. S. E., was held Thursday evening, January 7, at 8:30 o'clock, at the Galt house, Louisville, Ky.

Three 3500-kilowatt Curtis horizontal turbo-generators will be installed in the new power house of the California Electric Generating Company, Oakland, Cal.

Inquiries

Questions are not answered unless they are of general interest and are accompanied by the name and address of the inquirer.

Alternating and Direct Current

What is the difference between alternating and direct current, as regards direction of flow?

R. B.

Alternating current flows alternately in opposite directions; direct current flows always in one direction. Read the editorial on page 335 of the August 25 number of Power and The Engineer.

Absolute Terminal Pressure

Will you please explain what is meant by absolute terminal pressure?

A. W. P.

The term "absolute," as used in speaking of steam pressures, means pressure reckoned from a perfect vacuum of 14.7 pounds below atmospheric pressure. The absolute terminal pressure would be the terminal pressure reckoned from vacuum and expressed in pounds pressure absolute. If the terminal pressure were two pounds absolute, it would mean that the pressure was 12.7 pounds below the pressure of the atmosphere, or about 26 inches of vacuum.

Cylinder Ratio for Compound Engines.

What is the proper cylinder ratio for compound engines?

E. H. S.

This must be settled by the conditions under which the engine is to be operated. With a steam pressure of from 125 to 200 pounds, if the engine is to run noncondensing, the cylinder ratio that will probably be found to be the best will range from 2½ to 1 to 3 to 1. For condensing engines with a fairly steady load, and for steam pressures from 125 to 150 pounds, a cylinder ratio of from 4 to 1 to 5 or 6 to 1 will give economical results.

With noncondensing engines there is little to be gained by compounding for a steam pressure of less than 125 pounds.

Ratio of Expansion

Will you please explain what is meant by ratio of expansion and how to find it?

M. O. D.

Ratio of expansion is the proportion the total volume of the steam in the cylinder bears to the volume at cutoff. To find the ratio of expansion, divide the stroke in inches by the number of inches of the stroke completed when cutoff takes place. To be exact in calculating the ratio of expansion, the clearance must be known and taken into account. If, for instance, the effect of the clearance is such that it adds 1 inch of cylinder length to the volume of the cylinder at each end, this must be added to the stroke of the piston and to the piston travel before cutoff. Suppose the stroke of the engine to be 30 inches and the cutoff to take place after the piston has traveled 6 inches. Nominally the cutoff would be at one-fifth stroke and the ratio of expansion would be 5, but actually the cutoff would be 7/31 of the stroke and the ratio of expansion would be 4.428.

The Horsepower of Belting

I have a belt, 16 inches wide, passing over two pulleys, each of which is 5 feet in diameter and running at 200 revolutions per minute. What is the greatest limit of horsepower that it will transmit?

W. M. C.

There are a great many different rules for calculating the horsepower of belting, all based on the results of practice under different conditions. One rule very commonly used says that a belt 1 inch wide running 1000 feet per minute will transmit one horsepower. In your case you have a belt 16 inches wide running 3140 feet per minute and, according to the rule, it will transmit

$$\frac{16 \times 3140}{1000} = 50.24$$

horsepower. Another rule says that at 70 feet of belt surface per minute one horsepower will be transmitted. Applying this rule you will have

$$\frac{3140 \times 1.33}{70} = 59.65$$

horsepower. These rules are meant to be applied to single belts. Double belts will transmit from 70 to 100 per cent. more power than single ones. They may also be overloaded 200 or 300 per cent. for some time, but this practice destroys the elasticity of the belt and shortens its life.

Book Reviews

The Steam Turbine. By James Ambrose Moyer. John Wiley & Sons, New York. Cloth, 370 pages, 6x9 inches, illustrated. Price, $4.

The author has been instructor of experimental engineering at Harvard, has been an engineer on experimental work in the steam-turbine department of the General Electric Company, and is now engineer with Westinghouse, Church, Kerr & Co., so that he is well equipped to treat the subject, both by analysis and from observation. The book is intended as a manual for the practical engineer, who is designing, operating or manufacturing steam turbines, "rather than a compilation of manufacturers' catalogs combined with a digest of standard books on thermodynamics and mechanics." It was intended primarily for the use of the author's assistants in the experimental testing and engineering departments of the companies with which he is connected. An introduction of nine pages tells of the development of the turbine and includes the familiar pictures of the productions of Hero and Branca, without which no writer upon the subject seems able to get started. A chapter upon the Elementary Theory of Heat explains the entropy diagrams and the calculation of the available energy is shown in an easily understandable way. The real turbine work starts with a chapter on Nozzle Design, followed by one on Blade Design. Mechanical Losses in Turbines are then considered, and a chapter devoted to the Method for Correcting Steam Turbine Tests. Seventy-eight pages are then devoted to the description of commercial types. Succeeding chapters deal with Governing, Low-Pressure Turbines, Marine Turbines, Testing, Steam Turbine Economy, Stresses in Blades, Drums and Disks, Gas Turbines, and Electric Generators for Turbines. The book is written in such a way as to be understood by the practical engineer of moderate attainments and is an excellent presentation of the things which a turbine man ought to know by a man who has had exceptional opportunities for finding them out, and who knows how to tell them simply and well.

Cyclopedia of Civil Engineering. By Frederick E. Turneaure, [illegible] dean of the College of Engineering, University of Wisconsin, assisted by a corps of civil and consulting engineers and technical experts. Published by the American School of Correspondence, Chicago, Ill. Eight volumes, each containing about 400 pages, 7x10 inches, with more than 3000 illustrations. [illegible]

It would be next to impossible properly to review this encyclopedia in these columns; therefore, no attempt will be made to do so. It is a general reference work on Surveying, Railroad Engineering, Structural Engineering, Roofs and Bridges, Masonry and Reinforced Concrete, Highway Construction, Hydraulic Engineering, Irrigation, River and Harbor Improvement, Municipal Engineering, Cost Analysis, and kindred topics. The list of authors and collaborators includes the leaders in the fields designated. In addition, the standard technical authorities of America and Europe were freely consulted and the best that they have to offer has been incorporated in this work.

The aim has been throughout to prepare a work which, while adequate to meet all demands of the technically trained expert, will appeal equally to the self-taught practical man, and [illegible] has been attained. The work covers not only the fundamentals that underlie all civil engineering, but their application to engineering problems of every sort. In effect, it is a compilation of [illegible] instruction books of the American School of Correspondence, incorporating what is believed to be an ideal method for the education of the busy workingman. The [illegible] and illustrations are [illegible], and altogether it is a work which it will [illegible] to have on [illegible]

Business Items

W. H. Smead, formerly mechanical engineer for the General Fire Extinguisher Company, Atlanta, Ga., has opened an office for himself in the McAdoo building, Greensboro, N. C., where he will make a specialty of designing steam-power plants and heating systems. While with the fire-extinguisher company he designed the power piping for the New Orleans waterworks, White Oak Cotton Mills and other plants.

James H. Jarvis, chief engineer of the Charlotte General Electric Company, of Charlotte, Mich., has sent a letter to C. P. Bassett, of Charlotte, manufacturer of the McNaughton grate bar, in which he says: "We have had some of your McNaughton sectional grate bars in use for more than a year and we find them to be very economical of fuel. They do not overheat or clog and they are just as straight as the day they were put in, the construction of the bar being such that they will not warp, and they make a nice even surface to fire on."

The business heretofore carried on by the American Engineering Specialty Company, with headquarters at Chicago, and branches and agents in various cities through the middle West is now conducted in the name of Warren Webster & Co., with main office and works at Camden, N. J. This change will give to architects, engineers, contractors, users and intending purchasers of "Webster" apparatus the full advantages of the "Webster" organization, which now covers all parts of the country. It implies no change in the personnel. The same representatives with whom the trade is already acquainted will be glad at all times to give inquiries their best attention.

The Northern Electrical Manufacturing Company, Madison, Wis., announces the enlargement and removal of its St. Paul district office to 1046 Security building, Minneapolis, Minn. This betterment of their sales office facilitates closer relation with their customers in the twin cities and improves their office surroundings. T. E. Drohan, who has been representing them in the St. Paul office, will continue in charge of the Minneapolis office. His experience as superintendent of the Northern works makes it possible for him to serve customers in his territory to excellent advantage, as his sales interest is coupled with an intimate knowledge of manufacture and design.

Methods of cooling water for steam-condensing and other plants are fully described in Bulletin 104, "Water Cooling Towers," just issued by the Wheeler Condenser and Engineering Company, of Carteret, N. J. After explaining the physics of water cooling, the different types of cooling tower are discussed, more especially the Wheeler-Barnard tower, the essential feature of which is the use of galvanized, woven-wire mat as the "filling" medium over which the water trickles. This tower is built in the forced-draft, natural-draft and open styles, and the numerous full-page illustrations adequately show its construction and manner of installation. There are also various tables on humidity, air and vapor mixtures, etc., which should be of value to engineers.

The Westinghouse Machine Company reports good progress during recent months in the steam-turbine business, despite the general depression existing in the machinery market. While business has been considerably below normal, there have been many encouraging features in all directions of power application. Out of the most important business covering some twenty machines ranging in size up to 10,000 horsepower, they find the usual activity in electrical, power and traction work, and a fair demand from various industries, including phosphate, cement and rubber mills, steel car works and oil refineries. Inquiry for exhaust steam turbines is active, and several equipments have been contracted for. While there have been important power extensions in turbine equipment, the steam-engine business of the Westinghouse Machine Company has been fairly active, as is evidenced by the number of orders for engines recently received.

Cia Azucarera del Panuco, Tampico, Mex., has placed an order with the Westinghouse Machine Company for a complete producer gas-electric power plant. This initial installation will consist of a vertical, 3-cylinder, single-acting engine and a 150-horsepower suction producer, designed to operate on small anthracite. The use of the suction producer in such large sizes has proven thoroughly practicable, and considerable business is anticipated along this line. Even larger sizes of producers of the suction type are contemplated by the builders. The New York Standard Watch Company, of Jersey City, N. J., also operates a suction producer gas plant of considerable size, and recently added another unit to its plant. A number of contracts have been let for gas engines operating temporarily on natural, or illuminating gas, with the intention of later changing over to producer-gas operation. A 200-horsepower plant has been ordered by Seaver & Co., Chelsea, Mass., and by the Cambridge Gas Company, Cambridge, Md. The Shelbourne Falls (Mass.) Electric Light Company has adopted the power gas system and has ordered a 175-horsepower Westinghouse suction producer for anthracite.

C. S. Davis, president of the William B. Pierce Company, of Buffalo, N. Y., recently gave out the following interview: "Notwithstanding the business depression of the past year, we have more than held our own in business. The fact that we have increased both our factory and office forces during the past year would seem to bespeak a healthy state of affairs. The fact of the matter is, our proposition, the Dean boiler-tube cleaner, is a fuel saver of the first order. As a rule in busy times people are prone to overlook the loss of fuel due to scale. Then, too, lots of fellows are willing to let 'well enough' alone. 'Maybe we have scale, as you contend,' they tell us, 'but we really haven't the time to investigate.' So the waste goes on. Well, this past year our words fell on fertile soil. People wanted to cut down expenses. They had time to investigate. Were they wasting coal? Did they have scale without their knowing it? Here was an opportunity to find out. Lots of concerns, with only remote thought of purchase, ordered the Dean on trial just to ascertain its merits. When they saw what the Dean did, they were only too glad to send us their check. So, we reaped a good harvest."

New Equipment

The Orofino (Idaho) Electric Company is constructing a hydroelectric plant.

The Seattle (Wash.) Ice Company is erecting a new plant, which is to cost $300,000.

The Merchants Power Company, Memphis, Tenn., is erecting an addition to its plant.

The citizens of Tacoma, Wash., will vote on proposition to build a municipal power plant.

The citizens of Conroe, Texas, voted to issue $77,000 bonds for construction of water-works.

St. Joseph's Hospital, Baltimore, Md., has awarded contract for the erection of a power house.

The Findlay (Ohio) Table Manufacturing Company will install a new steam turbine in its power plant.

The Cincinnati (Ohio) Traction Company has filed plans for a new power house to cost about $32,000.

It is said the Paxton (Ill.) Electric Company is considering plans for the installation of a 20-ton ice plant.

The Humbird Lumber Company, Sandpoint, Idaho, is considering plans for a power plant in connection with mill.

W. T. Wingate has been granted franchise by the City Council to operate an electric light system in Maysville, Mo.

It is reported that the Merchants' Heat and Light Company, Indianapolis, Ind., will erect an additional power house.

The Fairfield (Iowa) Gas and Electric Company contemplates remodeling plant at an expenditure of about $40,000.

The Kentland (Ind.) Light and Ice Company is planning to build an electric light, water and ice plant. Hugh Hill, president.

The Independent Ice Company, Nashville, Tenn., has been granted permit to erect factory building, boiler and engine rooms.

It is reported that the Citizens Electric Company, Williamsport, Penn., will install additional boilers, engines and generators.

The Charleroi (Penn.) Water Company is considering the installation of a filtration plant and a new duplicate pumping station.

Bids will be received until 11 a.m., Feb. 5, by Capt. C. H. Lanza, Key West, Fla., for furnishing condenser, filter, feed-water heater, etc.

The Prospect Rock Heat, Light and Power Company, Georgetown, Penn., is being organized, and site has been secured for power house.

It is reported that the City Council, Kearney, Neb., has passed an ordinance providing for the issuance of $100,000 bonds for water-works system.

The Paulding County Electric Company is asking bids on dam and power house to be erected on Punking Vine creek, near Dallas, Ga. W. S. Lotus, of Dallas, is president.

The citizens of Blacksburg, S. C., voted to issue $15,000 bonds for the construction of an electric light plant, etc. P. H. Freeman is chairman of Public Works Commission.

Bids will be received until Feb. 2 by the board of Water Commissioners, Kenosha, Wis., for a horizontal cross-compound high duty pumping engine of 6,000,000 gallons capacity in 24 hours.

The Southern New Hampshire Street Railway Company is contemplating the erection of a new power station in Methuen, Mass. The present power plant is located at Portsmouth, N. H.

It is reported that the Rock Island Southern Railroad Company will shortly place contracts for the construction of power plant on Edwards river. W. W. McCullough, Monmouth, Ill., is general manager.

Setting the Valves of the Cummer Engine*

An Old Time Engine with Special Eccentric Shaft. A Study of Valve Movement and Explicit Directions for Overhauling and Valve Setting

BY H. E. COLLINS AND J. H. FRANCIS

The Cummer engine is probably not as well known as many of our American automatic cutoff engines, due largely to the fact that not many engines of this type have been built in the past 15 years. Previous to this time, say from 1884 to 1893, quite a large number were built ranging in sizes from 50 to 3000 horsepower. Nearly every State in the Union has one or more Cummer engines in use at the present time, and consequently there are many engineers more or less interested in a description of a simple method of setting the valves on this engine. A description of the valves, the valve mechanism and the governor might also be of interest to some not familiar with this type of engine.

The general design and arrangement of the engine is shown in Fig. 1. The cylinder is provided with two steam valves, two cutoff valves and two exhaust valves. These valves are of the flat gridiron type, and the seats for the steam valves are vertical, being on the side and at each end of the cylinder. Each seat has three steam ports. The exhaust-valve seats are horizontal, and located under the steam chest.

The exhaust-valve stem connects to the lower end of a rocker arm which is pivoted at its center and located about the center of the frame. To the upper end of the rocker is connected the steam-valve stem and also the eccentric rod, thus giving the steam valve a direct motion with the main eccentric, while the exhaust valves travel in the opposite direction. The valves all move toward the center of the cylinder in opening and toward the ends of the cylinder in closing.

The cutoff valve has two ports and its stem is connected to a slide to which also is attached the cutoff eccentric rod.

The eccentrics are mounted on a shaft running parallel with the crank shaft and driven by a train of three spur gears inclosed in an oil-tight case, which also serves as a bearing for one end of the eccentric shaft and the intermediate-gear spindle. This arrangement gives the same direction of rotation to the eccentrics as to the crank and the same speed, as the gears are all of the same size. The advantages claimed for this arrangement are a smaller shaft for the governor and consequently smaller eccentrics and, of course, less friction by reason of this. The arrangement allows also for the eccentrics being set in line with the valves, so that they can be driven directly without offset eccentric rods. As the eccentrics are smaller than would be required on the

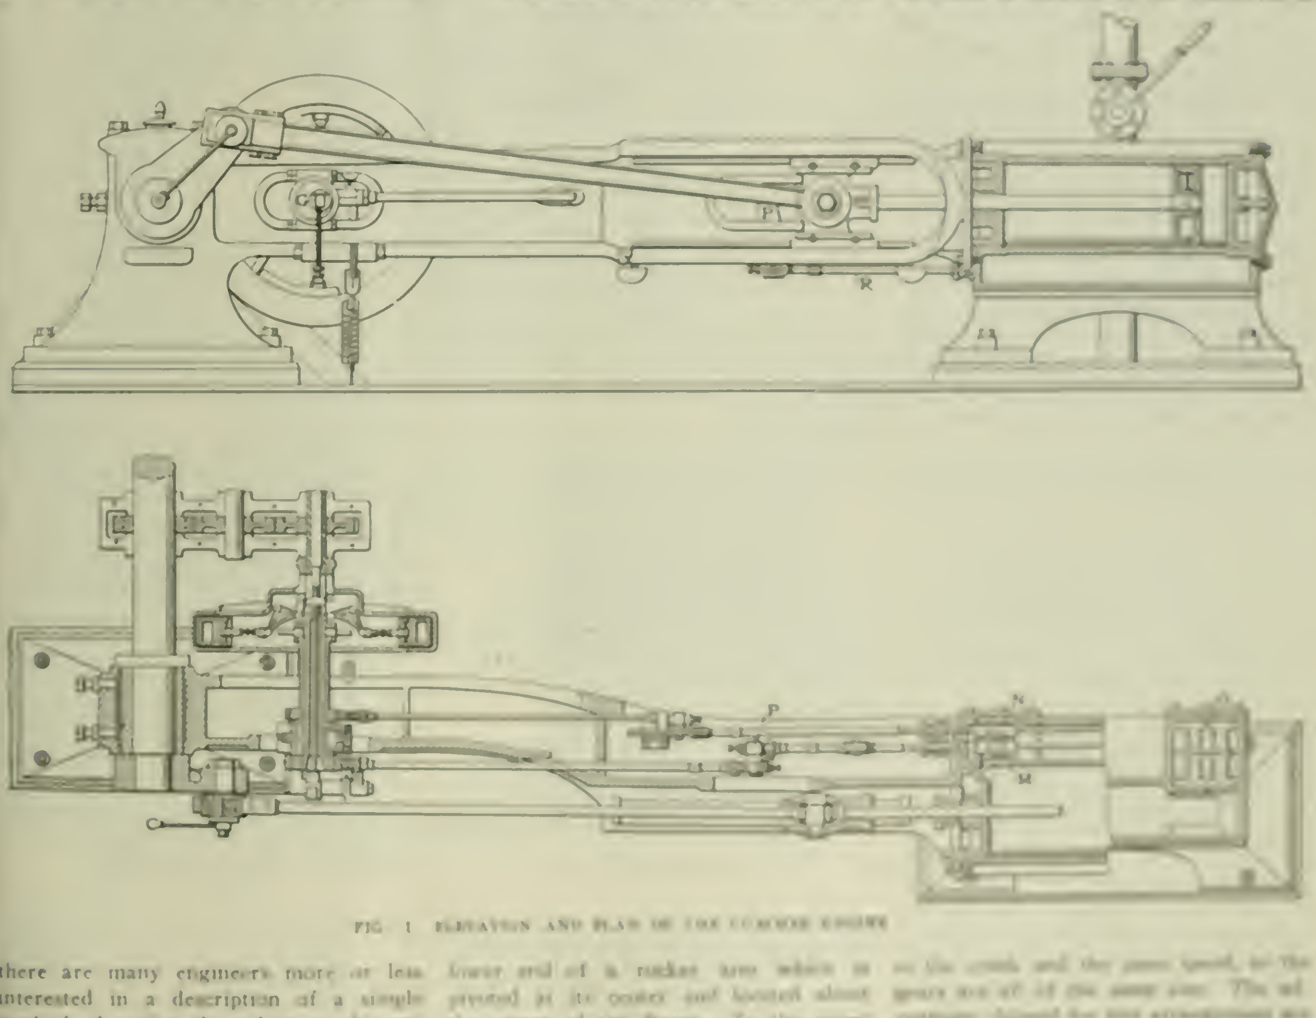

FIG. 1. ELEVATION AND PLAN OF THE CUMMER ENGINE

*Two articles were received simultaneously on this subject and have been combined in the presentation herewith.

main shaft, a shorter range of movement for the governor to operate the cutoff eccentric is obtained. With this particular design the working range of the governor is reduced to one-fourth that of many other designs. Another feature of this governor is the fact that speed changes can be made while the engine is running.

In Figs. 1 and 2 the main eccentric is at *G* and the cutoff eccentric at *H*. The main valve on the crank end is at *M*, the cutoff valve at *N*, and the exhaust valve seat on the head end at *O*. The main eccentric rod is connected to the top end of a reciprocating rocker *P*, from the lower end of which the exhaust valves are driven by the exhaust rod *R*.

By referring to Fig. 2 a clearer understanding of the governor and eccentric arrangement will be obtained. It will be noted that the eccentric shaft has one bearing in the engine frame at *S* and the other in the gear case at *T*. The governor case and cutoff eccentric ride on the main eccentric shaft, the cutoff eccentric and sleeve slipping on the shaft up to a shoulder, and extending back to the collar *U* which clamps to the cutoff-eccentric sleeve. The collar *U* has two pins to which are attached the links *V V*, shown in Fig. 3, so that when the weights *W W* fly out, they act on the cutoff eccentric, throwing it forward in its travel, or back when the weights come in again. The action of these weights is held in check by the weight and spring attached to the large bell crank *X*, shown in Fig. 2, which is under the engine frame and pivoted at *Y*. On the other end of this shaft is a rocker arm which acts on the thrust rod *A* in the hollow governor shaft. At the end of the rod is a crossbar *B* which extends through slots in the governor shaft. To each end of the crossbar *B* are attached the links *C C*, which in turn are attached to the small bell cranks *D D*, pivoted at *E E* and secured to the governor weights *W W* by the adjustable links *F F*.

With this arrangement the weight and spring on the large bell crank tend to hold the thrust rod in a direction toward the gear-case end of the shaft, and through the crossbar *B* and the bell cranks *D D* tend to hold the weights *W W* always toward the shaft center. Aside from friction the work that the centrifugal force of the governor weights has to do is to lift this dead weight and overcome the spring tension, and when it does that or is in turn overcome by these forces, the changing position of the governor weights operates the cutoff eccentric. By turning the screw *G'*, Fig. 2, the tension can be altered, and the purchase of the spring on the lever can be changed by putting the pin *H'* through any one of the holes provided for it. The dead weights can be lifted off or placed in position while the engine is in motion.

In Fig. 4 the main steam valve, the cutoff valve and the exhaust valve are shown in plan and section. The main valve admits steam through its three ports direct into the cylinder ports, and the cutoff valve uses one of its outside edges for a cutting edge and thus controls the three ports of the main valve with its two. In the same way the exhaust valve, with only three ports, controls the four exhaust ports under it. Figs. 5, 6 and 7 show more clearly the arrangement of the valves in the cylinder. The main valve *M*, cutoff *N* and exhaust *G'* can all be located.

VALVE ACTION DURING ONE REVOLUTION

Figs. 8 to 17 inclusive are used to illustrate the relative positions of all the valve edges for a given position of the crank and under varying conditions. In these illustrations the main steam and cutoff valves are shown in section over the steam ports for convenience in grouping and to avoid the use of dotted lines. As the true relative position of the valves in the cylinder are shown in the previous illustrations, this arrangement should cause no confusion.

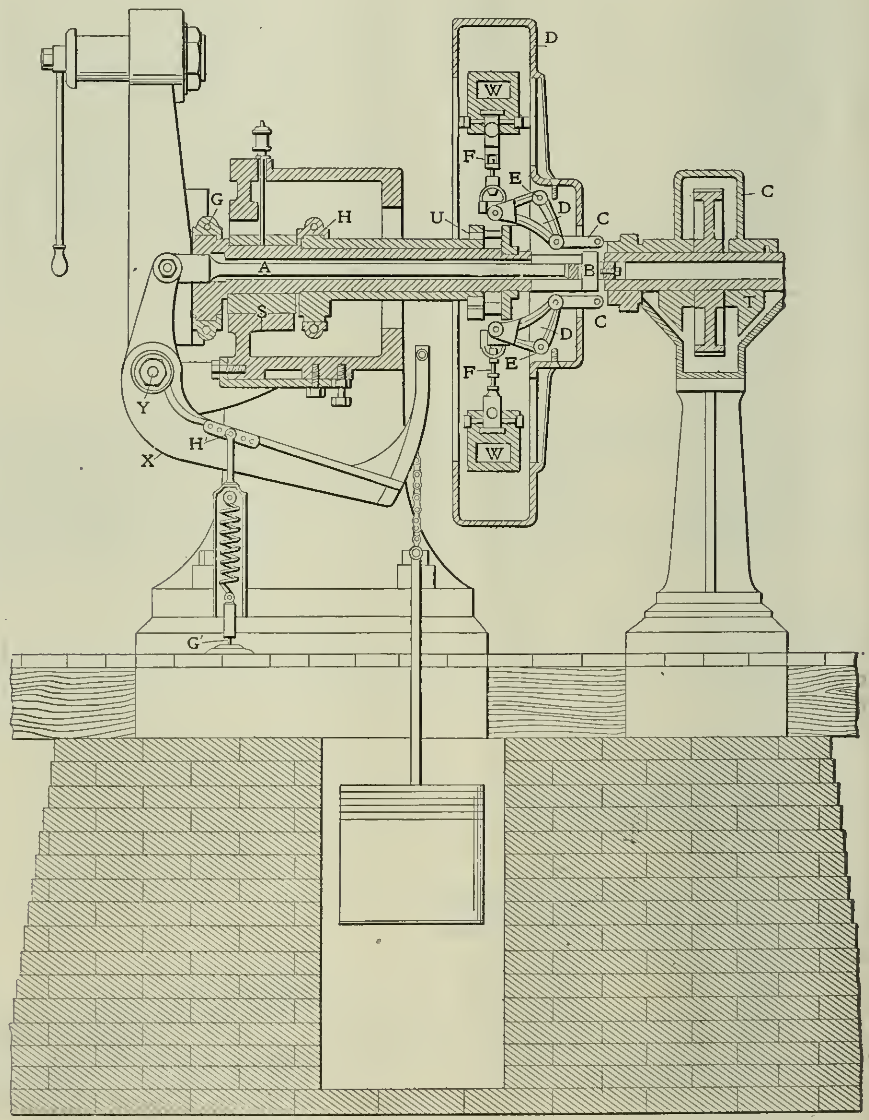

FIG. 2. VERTICAL SECTION ALONG THE CENTER LINE OF THE GOVERNOR SHAFT

Steam enters the steam chest *H'* at the top and passes the main and exhaust valves into the steam port *I'*, exhausting into port *J'* through exhaust valve *G'* into the exhaust passages *K'* and finally out at *L'*. The valve stems *K*, *L* and *R* in each case extend through the entire length of the steam and exhaust chests respectively.

The cylinder is equipped with six separate valves, two on each valve stem, or in other words three separate valves in six parts do the work of one ordinary slide valve.

In Fig. 8 the valves are all shown central on their travel over their respective ports. On the center line *A B* in each illustration are shown the valve circles or diagrams. The cutoff valve has greater travel than the main steam and exhaust valves, and the larger circle denotes the path of the cutoff eccentric, the inner circle denoting the path of the main eccentric. The position of the crank will be shown at *C*, the main eccentric at *M* and the position an exhaust eccentric would occupy at *E*, while the position of maximum cutoff is shown at $C\,O$. It will be noted in Fig. 8 and succeeding figures that the outside edges and inside edges of the cutoff-valve ports are the cutting edges, while the inside edges of the main steam-valve ports are the admission and cutoff edges for that valve. For the exhaust

FIG. 8

valve the outside edges of the valve and the inside edges of the ports are the working edges. To return to Fig. 8, the crank C is on the head-end center with the eccentrics and valves central. In Fig. 9 the eccentrics are advanced to the proper positions for operation with the crank C on the head-end center. The angle of advance for the main eccentric M is 30 + 90 degrees ahead of the crank C, and the cutoff $C\,O$ is advanced to 90 degrees beyond the main eccentric for the position of maximum cutoff. In this position of the eccentrics the main valve should have from 1/32 to 1/16 inch lead and cut off at about eight-tenths of the stroke, the cutoff valve performing its function at the same time. It will be further noted that the main valve on the head end is open for lead and is traveling fast to overtake the cutoff valve which is moving in the same direction. This insures a full steam-port opening through both valves. The exhaust valve is open on the crank end and closed on the head end.

Fig. 10 shows the main eccentric M advanced to its extreme travel to the left, which allows the main valve to open full to the head-end steam port and the cutoff valve to open full on the crank end, while the piston has advanced to about 20 per cent. of its stroke. It can be found here why the cutoff valve is given wider ports than the main valve. To insure quick action on the cutoff, greater travel is given, and for unrestricted port area, the cutoff ports must be wider. It will be noted that the cutoff valve does not restrict the main-valve ports when the latter are open full to the cylinder ports, although the cutoff valve is now traveling opposite to the main valve. From this point the main and cutoff valves travel together, but the cutoff valve travels fast enough to overtake the main valve and assist in the cutoff on the head end, when the piston has reached eight-tenths or more of its stroke, as in Fig. 11. In this figure the exhaust is [illegible] closed on the crank end and traveling toward release on the head end.

Fig. 12 shows the relative positions at the point of exhaust closure on the head end. The piston has traversed about 95 or 96 per cent. of its stroke, with the exhaust closing on the crank end. On the head end release will occur immediately at about 97 per cent. of the stroke. The cutoff valve still covers the main valve ports on the head end, but the eccentric *M* is now moving the fastest and will cause the main valve to overtake the cutoff by the time the piston has reached the end of its travel. This is shown in Fig. 13, where the crank *C* has reached the crank-end dead center. Here the main valve is shown open for lead on the crank end, and the head-end exhaust is open for release.

Fig. 14 shows the crank *C* advanced to the position opposite to that in Fig. 10, but the piston is not advanced as far on its return stroke as it was for the same angle of advance of the crank *C* on the other end. In other words when the crank-end steam ports are full open, the piston is at an earlier point of its stroke than on the head end. The head-end exhaust is also shown full open.

Fig. 15 shows the main steam and cutoff valves at the point of cutoff for the crank end, the exhaust traveling toward closure on the head end. In Fig. 16 the valves have advanced to the point of exhaust closure on the head end, from which point all parts will again reach the positions shown in Fig. 9. On account of the angularity of the connecting rod, all the functions of the valve are performed at an earlier point in the piston stroke on the crank end than on the head end.

The diagrams shown in Figs. 8 to 16 inclusive, represent valve action with the governor centrifugal weights at their inner position and the cutoff eccentric *C O* in the position shown. To give a minimum cutoff the *C O* eccentric must be advanced to the position of minimum cutoff, as shown by the full line in Fig. 17, the position for maximum cutoff being shown by the dotted line. The crank *C* has advanced far enough on its travel for the piston to have moved about one-thirtieth of its stroke. At that point the cutoff valve should cut off for minimum operation. The relative positions of the other valves at this point are indicated in the drawing.

Overhauling the Engine

In overhauling an engine it would be well for the engineer to examine the exhaust-valve clamp where it fits in the exhaust valve. As a rule, considerable lost motion develops at this point and some of the travel of the valve is lost. The ends of the slots in the valves should be dressed out, and a steel plate riveted to the side of the clamp. The clamp can then be fitted snugly into the valve. Care should be taken that the valve-stem hole is parallel with the face of the exhaust valve; also note that the travel of the thrust rod, which connects to the large

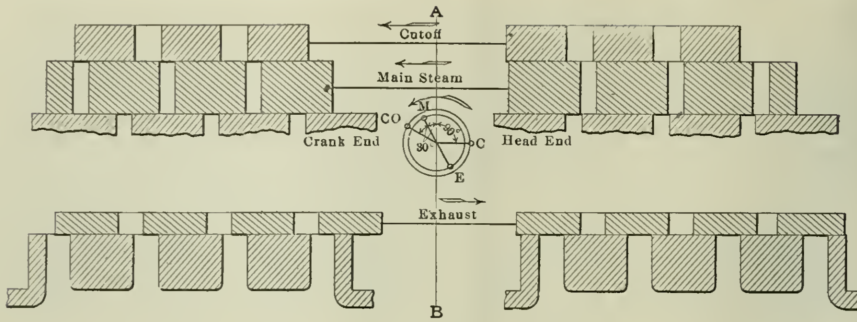

FIG. 9

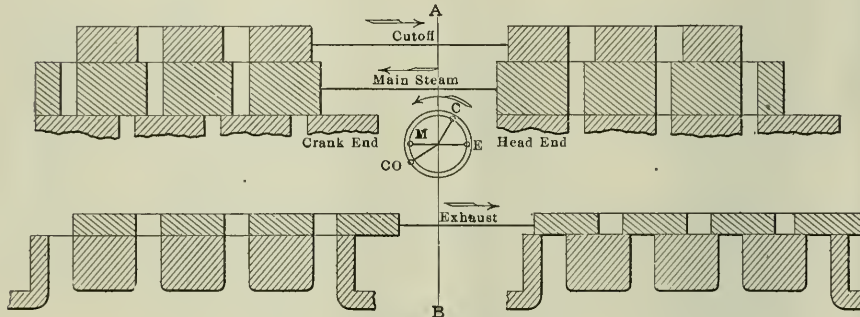

FIG. 10

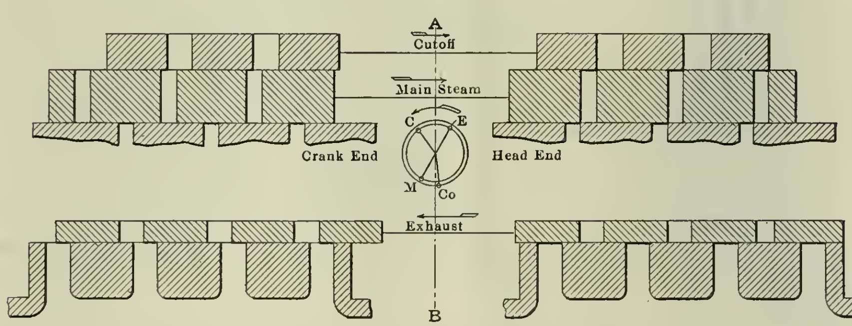

FIG. 11

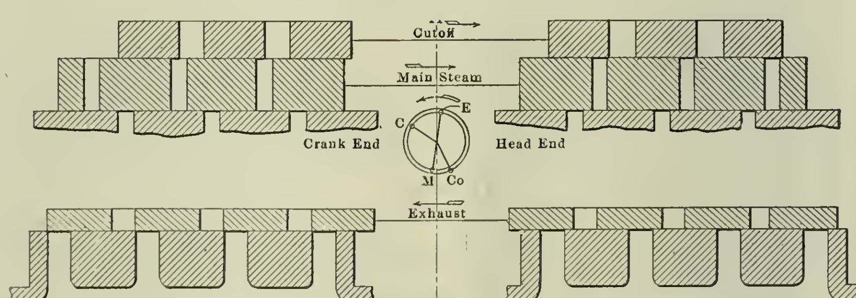

FIG. 12

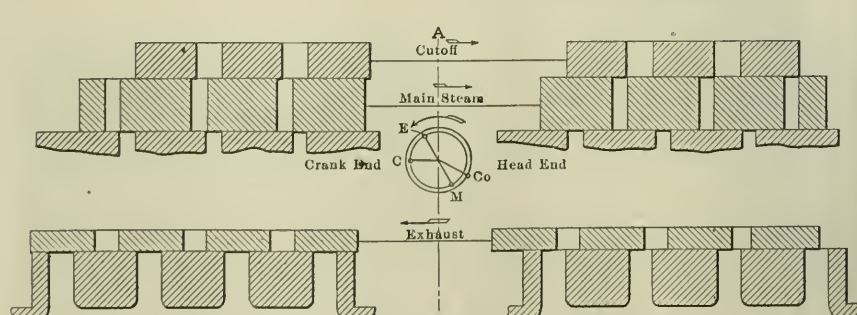

FIG. 13

bell crank, should be about 2½ inches for a 10x20-inch, up to 3½ inches for engines with 48-inch stroke. If for any cause this amount of travel is not obtained, the range of the cutoff is limited. It has been discovered on several engines where the governor had been dismantled for repairs, in the reassembling of the parts, the two knuckles that fit over the ends of the crossbar which passes through the governor shaft, had not been folded in between the two connecting links as shown at *A* in Fig. 18 or at *C* in Fig. 2. They had been connected as shown at *B*, Fig. 18, thus reducing the travel of the thrust rod about one-half, and instead of the engine being able to carry steam up to three-quarters of the stroke, the cutoff valve would close at less than one-half the stroke.

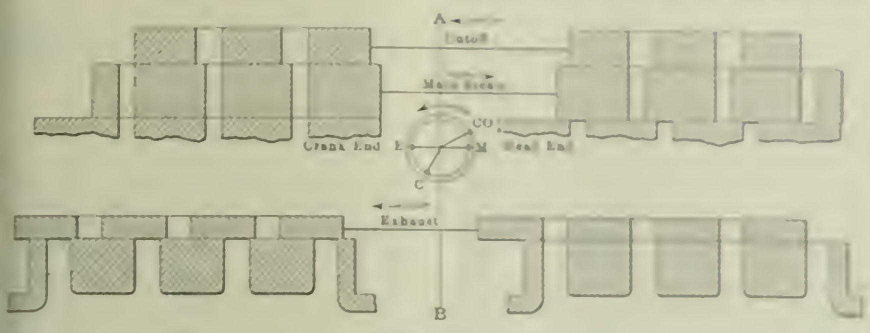

FIG. 14

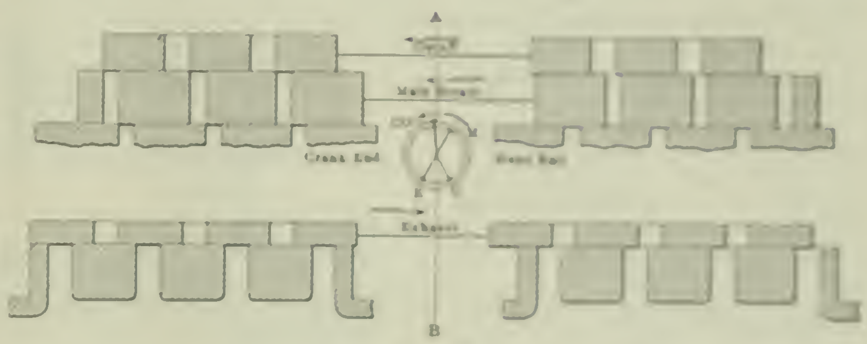

FIG. 15

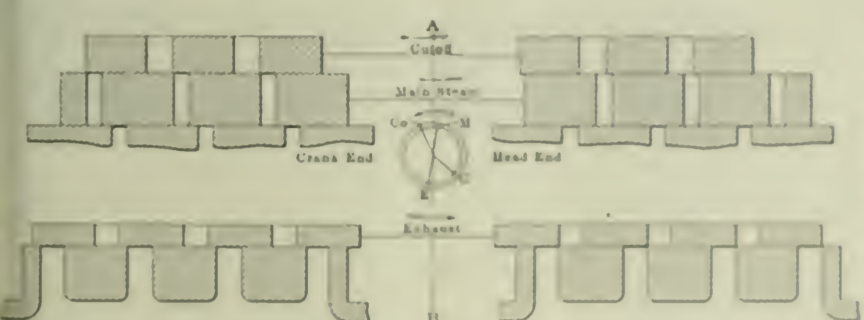

FIG. 16

FIG. 17

Setting the Valves

It will now be assumed that the engine is connected and the points mentioned taken care of. The upper half of the gear case and the intermediate gear should be removed. The weights also removed, and the spring disconnected on the bell under the engine frame. Adjust the main and cutoff eccentric so that when the eccentrics stand plumb up or down the rocker arm is in exactly a vertical position, and the cutoff slide is central in the bracket. These rods can then be secured permanently. The next step is to locate the steam valves in the relation to the ports in the cylinder and the main eccentric. Turn the eccentric shaft so that the throw of the main eccentric is on a horizontal line with the center of the shaft and toward the crank shaft. Locate and clamp the steam valve at the head end of the cylinder so that the ports show full open. Clamp the valve temporarily to the valve stem. Turn the eccentric shaft through 180 degrees, or so that the throw of the eccentric is toward the cylinder and locate the steam valve at the crank end of the cylinder in the same manner. Place the crank pin of the engine on one of its dead centers, say the one nearest the cylinder, and turn the eccentric shaft so that the steam valve at the head end of the cylinder shows about one-sixteenth lead. If the engine runs over, the relative positions of the crank pin and the eccentric will be as in Fig. 15. If the engine runs under, the pin and eccentric will be in the positions shown by the dotted lines.

The intermediate gear cover can now be placed in position, care being taken that the valve shows the proper lead when the gear is in place. Clamp the exhaust valve at the crank end of the cylinder so there will be 1/8 to 3/16 inch opening. Turn the engine in the direction it is to run. The steam valve should close at about three-fourths and the exhaust valve at about seven-eighths of the stroke. Turn the engine to the opposite dead center and adjust the steam valve on the crank end and the exhaust valve on the head end in the same manner. It may be necessary, if the exhaust valves do not open and close as desired, to advance or retard the eccentric one or more teeth of the driving gear. In case this is done the valves should be readjusted, giving them the proper lead as in the first trial. Up to this point the operation is similar to a slide-valve engine, with the exception that the steam and exhaust laps can be changed by either closing or extending the valves to their maximum extent. The setting of the cutoff valves is somewhat more puzzling, but if the following directions are carefully carried out no difficulty should be experienced.

The first step is locating the cutoff valve in relation to the steam valve and the cutoff eccentric. Turn the engine until the throw of the main eccentric is horizontal and toward the crank shaft. Now turn the cutoff eccentric, which as yet should not be connected to the governor weights, so that it stands in line with the main eccentric. Set the cutoff valve

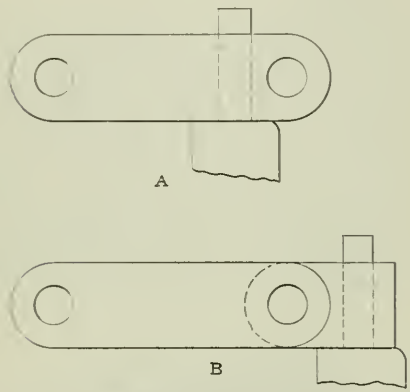

FIG. 18. A COMMON ERROR IN REASSEMBLING

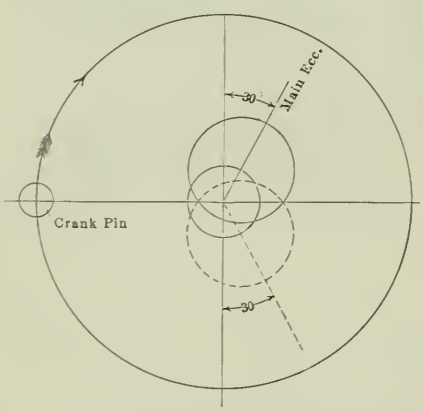

FIG. 19. RELATIVE POSITIONS OF CRANK AND MAIN ECCENTRIC AT DEAD CENTER

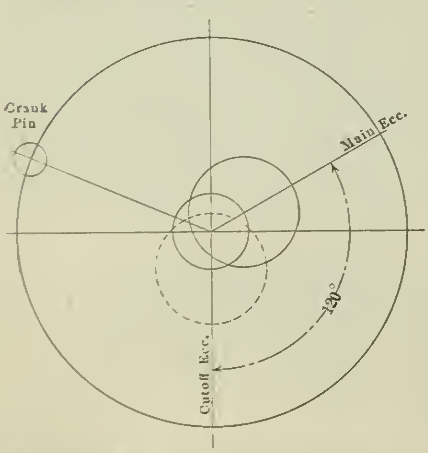

FIG. 20. RELATIVE POSITIONS OF CRANK, MAIN AND CUTOFF ECCENTRICS

at the head end of the cylinder so that its ports are lined up with the ports in the head-end steam valve as shown in Fig. 8. Rotate the engine until both eccentrics stand with the center of their throw toward the cylinder and locate the crank-end cutoff valve in a similar manner, bearing in mind that the outside ports of the steam valves are covered by the outside edges of the cutoff valves. The next step is to locate the cutoff eccentric in relation to the main eccentric.

Place the crank again on the dead center, say the one nearest to the cylinder. Now turn the engine in the direction it should run until the crosshead has traveled ¾ inch. Turn the cutoff eccentric over until the cutoff valve at the head end of the cylinder just closes the ports of the steam valve at that end. Move the governor weights out to their extreme outer position, care being taken not to disturb the position of the cutoff eccentric, and secure the weights to the cutoff sleeve by means of the clamp provided for that purpose. The relative positions of the crank, main eccentric and cutoff eccentric, if the engine runs over, will be as shown in Fig. 20. Turn the sleeve so that the weights are in their extreme inner position, and if the cutoff eccentric and valves have been properly located, the ports of the steam valve at that end will not be covered by the cutoff valves. Turn the engine again until the crosshead is in the same position at the other end of the stroke. Throw the weights out as before and if necessary adjust the cutoff at the crank end of the cylinder so that it just closes the ports of the steam valves. A slight readjustment of the valves may be necessary after an indicator card is taken.

A sufficient number of weights should be added to the bell crank to bring the engine to the required speed. The purpose of the spring on the bell crank is to give steadiness to the governor, and just sufficient tension should be given it to keep the governor from hunting.

To change the direction of rotation of the engine, the governor weights must be disconnected and reversed. The case is provided with two holes for the fulcrum pins at the ends of the weights for the new position of the weights. The valve setting will have to be entirely changed to suit the opposite direction of rotation.

Use and Abuse of Follower Bolts

By W. H. Wakeman

An engineer was sent to a distant city by a prominent engine-building firm to erect one of their large horizontal cross-compound engines. While he was assembling the parts he twisted off one of the follower bolts by bringing too much leverage to bear on it. Removing the broken stub he inserted another and broke that in the same way. Not daunted by this experience he put in another and caused it to share the same fate. The fourth victim was screwed in and practically twisted off like its predecessors, but it was down into position, and owing to the fact that the material was not completely severed, the head remained in place. The engineer sent to the shop for three more bolts, succeeded in getting them in, all other parts were assembled and the engine was started.

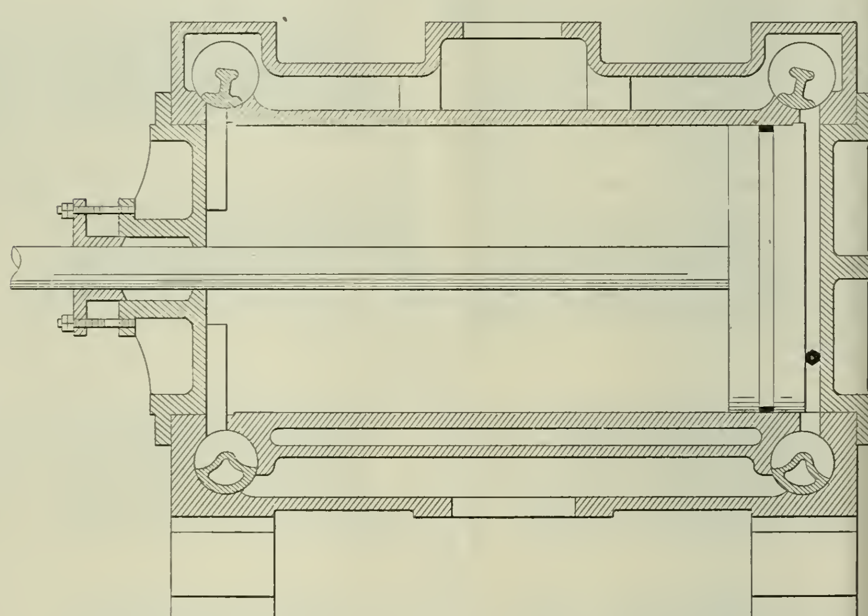

FIG. 1. SHOWING WHERE BOLT HEAD LODGED

After the engine had been in service a short time, the head of the bolt that really was broken when put in, but did not fall apart at that time, came off and, while falling toward the bottom of the cylinder, was caught between the head and the piston, as illustrated in Fig. 1. This shows that it stopped at a thin part of the head, and due consideration of the momentum of the heavy parts as shown, also of the very great leverage exerted by the crank due to its position near the inside center, makes it plain that something was broken before that piston began to move in the opposite direction. The cylinder head proved to be the weaker part; consequently, the bolt head was forced through between two webs as shown in Fig. 2, although the hole is made comparatively larger than it was originally.

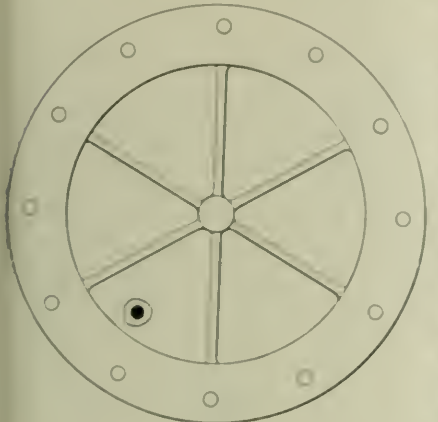

FIG. 2

The head was removed, taken to a machine shop and the ragged hole bored round. It was tapped with a 3-inch pipe tap, a plug screwed in and in $1\frac{1}{2}$ hours the engine was in service again.

There are several lessons to be learned from this incident. Of course, the follower bolts ought to have been a better fit in the threads made to receive them, but taking this condition as actually found the erecting engineer should have discovered the imperfection before he twisted off the first bolt, because they ought always to be loose enough to screw down into place without using a leverage of more than 12 inches, which is sufficient to force a bolt down properly, if it is a good fit, yet is not enough to spoil it if only a tight fit has been provided.

Having destroyed one bolt by applying too much force, there certainly was no excuse for repeating the operation once, while the repetition of it twice causing the failure of a third bolt under the same conditions shows that experience is not always a competent teacher, although failure of a scholar to comprehend the lesson presented is not always to be charged against the instructor. If we take into account the fracture of the fourth bolt, which was really accomplished the same day, the evidence of poor judgment is greater still, but this was not demonstrated until a later period.

A Defective Bolt Discovered in Time

The first engine that I had charge of was fitted with Dunbar packing rings and a follower plate held in place by four bolts. I took these out one day for cleaning and examination, and while replacing the bolts I twisted one of them until it was practically broken in two, but having a well developed sense of feeling, even while lifting on a wrench, I was aware of the fracture, or crack, before the parts became entirely separated; consequently, I not only instantly ceased turning the bolt head, but was able to turn the whole bolt backward, thus removing the lower part of it without further trouble. This was a defective bolt, as the leverage was not sufficient to ruin a sound one.

A socket wrench with a square, straight handle was made for these bolts, and I always used a monkey wrench of a certain size on this square handle, as shown in Fig. 3, which is a plan of the cylinder and piston. From this handle to the place where force was applied by hand was 10 inches. For about 30 years I have used a similar wrench on various engines, and have not increased the leverage mentioned. Having never fractured another follower bolt, nor had one work loose in practice during this time, it is good evidence that the rule adopted is practical and safe to follow.

Intelligent Application of the Wrench Requisite

A little practice in connection with intelligent application of the wrench used, and due observation of results secured will enable any engineer to avoid much of the trouble and worry that we frequently hear of along this line. For illustration, when screwing in a follower bolt, it is not difficult to decide whether it is binding in the threads, or if it is going in loosely until the head strikes the follower plate. In the former case it ought to be taken out and a suitable tap turned into the hole, or, if this is not practicable, a die may be used to cut the threads down until the bolt will fit tight but still will go in until the head holds the light of a tallow dip or a smoking petroleum oil lamp, in the very early morning, after some weary hours of labor on repair work; therefore, the tendency is to be less careful than under better conditions. If a follower bolt is too tight it may still have sufficient torsional strength to be forced into place without fracture, but remember that the action of steam tends to fasten it more securely in place, and the time will surely come when somebody will have to take it out. Due consideration of the "golden rule" and the possibility of having to remove it yourself should be sufficient to prevent leaving it in bad condition.

If the bolts are too small there is usually but one remedy, which is to put them in and get the engine started on time, but measurements ought to be taken and new bolts made without delay. Put them in place, not the first chance that is presented to find the engine dismantled for some other purpose, but make an opportunity in the very near future.

In any case where five or more follower bolts are used in a piston, it will do no harm to leave one out for a day to be used as a model by which to make new ones that are a snug fit in a hole in a piece of cast iron tapped out for the purpose, into which the old bolt is a loose fit. Of course, it is better to use micrometer calipers if they are available, but having completed many such jobs in a satisfactory manner with only common and inexpensive tools, it seems appropriate to make suggestions along this line for the benefit of others. Although expensive tools are now available for making repairs in one plant, there is pleasure sometimes in using less advanced methods where good results are secured, and I am free to admit that in some cases the work is done in less time than a more scientific but less practical machinist would require.

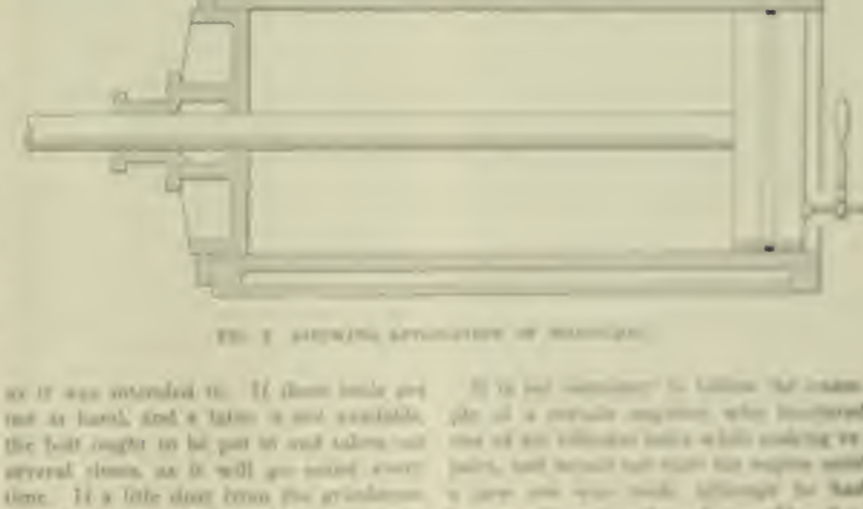

FIG. 3. SHOWING APPLICATION OF WRENCH

as it was intended to. If these tools are not at hand, and a lathe is not available, the bolt ought to be put in and taken out several times, as it will go easier every time. If a little dust from the grindstone trough is put on the threads it will assist in shortening the time required to make a good fit. Personal experience has taught me that such jobs are frequently done by

It is not necessary to follow the example of a certain engineer, who fractured one of his follower bolts while making repairs, and would not start the engine until a new one was made, although he had been given time to do so. The day was lost because he [illegible] his [illegible] in the engine room, [illegible] the loss of many dollars.

Blowing the Works Whistle Automatically

Interesting Description of an Arrangement for Doing This, without Depending upon the Human Element, Except to Wind the Clock

BY FRANK SAWFORD

There are probably very few works of any pretensions without a steam whistle for giving the signal to start or quit work, as the case may be; ranging from the small shrieker for the little shop, to the deep-toned chime whistle for the large works. In most cases the whistle is left to the care of the watchman or fireman, who pulls a string at the appointed time, and very often the only guide he has to rely on for indicating the appointed time is a pocket timepiece of greater or less reliability.

It is thought the following description of an arrangement for blowing the whistle automatically, and dispensing with the human element entirely, except so far as is necessary to wind and check the clock, will be found useful in many works. The arrangement consists of four principal parts: the whistle, the magnet for blowing it, the relay for closing the circuit and the clock.

The clock may be of any pattern desired, but should preferably be of the regulator type, with a pendulum beating seconds, and should be capable of keeping time to within five seconds per week. An additional wheel is required in the clock movement making one revolution in 24 hours, and also a circuit-closing arrangement to operate the relay. The relay in turn closes the power circuit and operates the whistle magnet. The clock should be placed in a suitable position, where it will be free from vibration and where it can be readily checked and corrected. The office is the best place.

The relay may be near the clock or the whistle magnet, as may be desired, the only connections required being a pair of wires from the clock and another pair to the magnet. The magnet should be placed as near to the whistle as possible, and connected to the whistle valve by a small flexible steel wire or chain.

The whistle will, of course, need to be above the roof of the boiler house, and steam should always be left on right up to the valve, the valve being attached to the whistle, and the bottom of the pipe should be drained to insure dry steam. The whistle will then respond promptly when operated. If there is much pipe exposed to the open air above the roof of the boiler house, it is preferable to have the pipe well lagged with nonconducting composition, for, if it is left bare, it is quite possible that considerably more steam will be condensed than will be used by the whistle.

The Clock

Referring to the sketches and taking in hand the clock first, Fig. 1 shows an outline of the circuit-closing device fitted to the movement, *A* being the minute hand, *B* the hour hand. On the minute-hand arbor is fixed the double cam *C* on which rest two ⅛-inch diameter steel rods *D*. These rods are fitted into little hard-rubber blocks *E* which insulate the rods from the clock frame, and from each other. The rods are held by small pinching screws in the rubber blocks. A piece of

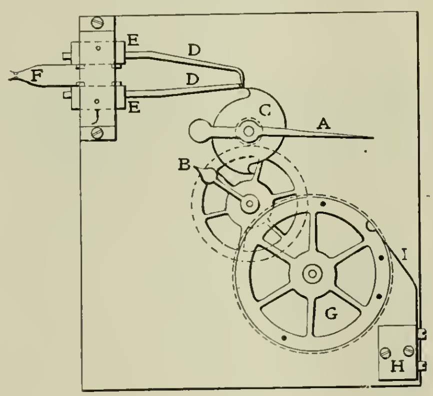

FIG. 1. CIRCUIT-CLOSING DEVICE FITTED TO CLOCK MOVEMENT

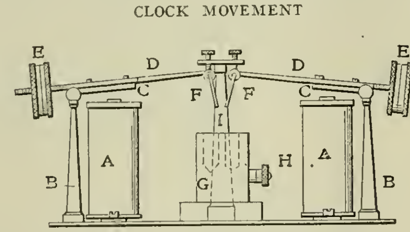

FIG. 2. THE RELAY

steel rod, shouldered at each end to form pivots, is fitted tightly into each rubber block at right angles to the steel rods *D*, and insulated from them. The complete rods are mounted in the brass frame *J*, which supports the pivots at the front end, the rear-end pivot being supported by the clock plate. At *F* are shown the contact springs, of phosphor bronze about 0.005 inch thick, with small platinum tips at the outer ends, the inner ends being secured to the hard-rubber blocks by two small screws. The action of this arrangement will be apparent. Upon the cam *C* advancing, the lower of the two rods *D* falls, bringing the bronze spring *F* into contact, and closing the circuit. The circuit is again broken when the upper rod falls.

The duration of contact may be made as long as desired by adjusting the distance between the ends of the rods *D*. The ends of the rods *D* which rest on the cam *C* should be bent at right angles, so as to lie across the cam, and both the tips of the cam and the ends of the rods should be filed square to knife edges to allow the rods to fall clear and also to permit a close adjustment. If nicely fitted, the duration of contact may be made as short as five seconds if desired. This make and break will take place every half hour.

Another contact-making device is necessary to complete the circuit at the times when it is desired to blow the whistle. On the arbor of the hour hand *B* is fitted a pinion meshing into a wheel *G*, which should have a ratio of 2 to 1, wheel *G* thus making one revolution in 24 hours. If wheel *G* has 48 teeth and the pinion on *B* 24 teeth, each tooth on *G* will correspond to half hours. This will be found very convenient for locating the contact pins, which are of brass about 1/16 inch in diameter by 3/16 inch long, riveted into the rim of the wheel *G*. The positions of the contact pins on the wheel rim may easily be found by dividing the rim into 24 parts corresponding to 24 hours and fitting the pins at the times it is desired to blow the whistle. At *H* a hard-rubber block is secured to the clock frame. This rubber block carries a phosphor-bronze spring *I*, which makes contact with the brass pins in wheel *G*. It is not necessary to have a platinum tip on this spring, as, owing to the revolution of wheel *G*, a rubbing contact is obtained and the pressure of the spring may be made comparatively heavy, the thickness being preferably about 0.025 inch.

The action of these two contacts is as follows: Contact is made by cam *C* every half hour, and the duration of this contact is made as long as it is desired to blow the whistle. This half-hour contact is connected in series with the contact on wheel *G* and spring *I*, and current cannot flow until both contacts are made, and it is interrupted when either contact is broken.

Thus the whistle blows at the times determined by the pins on *G*, and for a length of time as determined by *C*. If it is desired to blow a code call, this could easily be arranged fo by providing a suitable cam at C. The rest of the clock may be of ordinary first class construction and calls for no description beyond that previously given.

The Relay

The relay, Fig. 2, which is operated by the clock circuit-closing device, and which in turn operates the whistle magnet, should be capable of being operated by about six ordinary dry cells, and should have magnets and contacts in duplicate, to eliminate the chances of failure as much as possible. The type shown in Fig. 2 was adopted by the writer and proved very satisfactory. As may be seen it is extremely simple. The magnet spools *A* are 1 inch in diameter by 2 inches high, and wound with No. 28 Brown & Sharpe silk-covered copper wire, the cores being 3/8-inch diameter soft steel, with hard-rubber washers fitted tight at each end

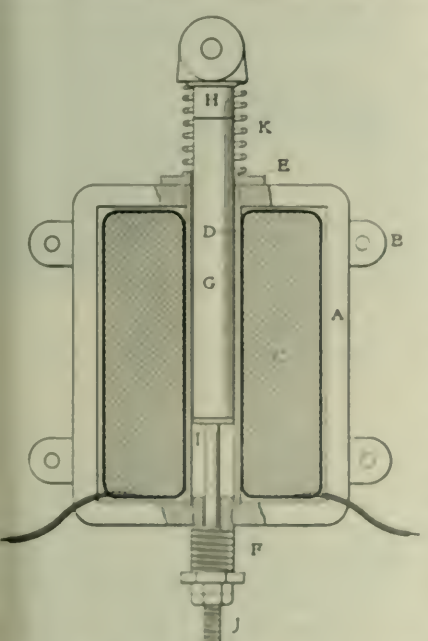

FIG. 3. SECTION THROUGH WHISTLE MAGNET

to form the spool. The soft-steel cores are riveted to a yoke of similar material 1 inch wide by 1/8 inch thick. The complete magnets are secured to a brass baseplate by screws through the yoke. The armatures *C* are of the same size and material as the yokes, and are mounted above the magnets *A* on brass edges which fit loosely into holes drilled in the top end of *B*. Across the armatures and at right angles to them are secured brass rods *D*, 1/4 inch square, the outer ends being turned and screwed to carry the adjustable counterweights *E*, and the inner ends carrying the forked pieces *F*. These forks are simply small pieces of No. 14 Brown & Sharpe gage copper wire fitted through hard-rubber bushings in the ends of the rods *D*, the ends of the forks pointing downward. At *G* are shown two mercury cups. These cups are brass blocks secured to a hard rubber base and have two 3/8-inch holes drilled in the upper end of each to contain the mercury, and a terminal *H* for connection to the circuit.

At *I* is a brass pillar carrying a cross piece on top with two small adjusting screws, as shown. Normally the ends of the rods carrying the forks *F* are held up against the adjusting screws by the counterweights *E*, the hight of these adjusting screws determining the distance between the forks and the mercury cups, and also the distance between the armatures and the poles of the magnets. The distance between the forks and the mercury cups should not be less than 1/8 inch, and not more than 1/4 inch between the armatures and the poles of the magnets. Any desired adjustment within these limits may be made by means of the counterweights *E* and the adjusting screws on *I*.

The two pairs of magnets *A* are connected in parallel to the wires from the clock, and the mercury cups *G* to the whistle circuit. When the clock circuit is closed, the magnets *A* pull the forks *F* into the mercury cups *G*, which closes the whistle-magnet circuit, and upon the clock circuit being again opened the counterweights *E* pull the forks out of the mercury cups up to the screws on *I*. The counterweights should be adjusted so as to pull the forks up smartly, but not heavy enough to prevent the magnets operating the forks. A drop of oil should be floated on top of the mercury in the cups *G* to prevent oxidation by the arc formed on breaking the whistle-magnet circuit. All of the various parts are mounted on a brass baseplate of suitable size, and should be fitted into a dust-proof box with glass top and sides.

Whistle Magnet

This is of the solenoid type and is shown in section in Fig. 3. At *A* is the magnet yoke which is a rectangular forging and has four lugs *B* attached for mounting. The coil *C* is fitted into the yoke *A* and is wound on a wooden former about 1 1/4 inches in diameter with No. 20 Brown & Sharpe silk-covered copper wire and the completed coil should measure about 4 inches in diameter by 6 inches long. The former is removed after winding, and the coil completely covered by linen tape wound lengthwise through the hole and round the outside, and then varnished. Short pieces of flexible lamp cord should be soldered to the ends of the winding to facilitate connection to the circuit. The coil is held in position within the yoke by a brass tube *D* which should be a moderately tight fit inside the coil.

The brass tube is secured by a brass plate *E* screwed to *A* by two small screws, the bottom end of the tube *D* being let into a recess 1/16 inch deep in the yoke *A*. At *F* is an adjustable plug with a check nut screwed into the yoke *A* and entering into the tube *D*. The soft-steel plunger *G* has a brass head *H* screwed and pinned into the top end, the bottom end having a brass washer *I* soldered thereto. A short piece of 1/4-inch brass rod *J* is also screwed tight into the bottom end of the plunger, this rod passing loosely through the plug *F* and having two nuts as shown. The brass spiral compression spring *K* holds the plunger up in its highest position, that is, with the nuts on *J* resting against *F*. Upon the coil *C* being energized, the plunger *G* is pulled downward against the tension of spring *K* until the washer *I* strikes *F*. The function of this washer is to prevent the plunger sticking to plug *F* by the residual magnetism retained in the magnetic circuit, thus insuring a prompt return of the plunger when the coil is deenergized.

The stroke of the plunger may be varied by adjusting the nuts on rod *J*, and the most effective pull of the plunger is found by adjusting plug *F*. A hole is drilled through the top end of *H* for

FIG. 4. DIAGRAM OF CONNECTIONS

attaching the cords or chain leading to the whistle valve. Care must be taken that the cord leads straight in line with the center line of the plunger to allow it to work freely, otherwise sufficient side strain might be put on the plunger to prevent its working. The plunger should be 15/16 inch in diameter, and the bore of the brass tube 1 inch.

The whistle calls for no special description beyond that already given, except that the valve should operate freely, and the cord should be led from the whistle lever at the most effective angle. The magnet is powerful enough to operate any size of whistle which can be operated by hand. The larger sizes of whistle usually have a small pilot valve to operate the main valve.

Electrical Connections

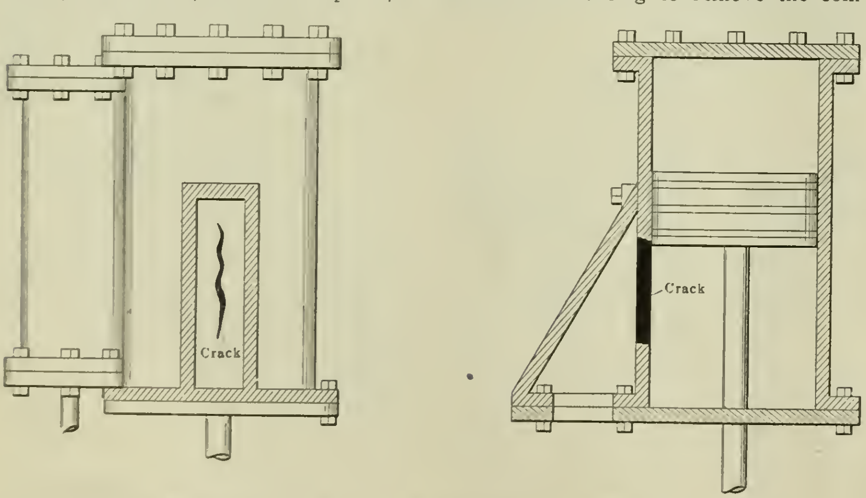
Fig. 4 shows a diagram of connections, *A* being the clock, *B* the relay and *C* a six-cell battery of ordinary dry cells; *D* is a single-pole switch for cutting out the relays when it is desired to stop the whistle; *E* is a pair of terminals which may be used to connect to a fire-alarm system, or to a push button; *F* is the whistle magnet, and *G* a double-pole switch for connection to the power circuit.

The magnet as described is suitable for connection to a direct-current circuit of 110 volts. For any other voltage the winding of the coil may be modified accordingly. This apparatus may appear somewhat elaborate from this description, but it may be said that a similar rig has been in use for many years, and has never been known to fail, and moreover has had practically no attention beyond winding and adjusting the clock.

A Split Cylinder on the Steamship "St. Paul"

The fact that the American line steamship "St. Paul" arrived at New York two days late upon a recent trip was attributed by the press to stress of weather, but was partly due to a cracked high-pressure cylinder.

Steam was reported coming in considerable quantities from the high-pressure gland of the port engine and a shutdown was ordered. An examination showed that the steam was not coming from the gland, but from an opening in the bottom of a bracket, as shown in the accompanying sketch. The bracket was hollow, and a crack, which was open 1/16



SHOWING THE CRACK IN A CYLINDER ON THE STEAMSHIP "ST. PAUL"

of an inch and 2½ feet long, connected its interior with that of the cylinder.

The high-pressure cylinder was cut out by blocking the piston valve in the mid-position and admitting the steam directly to the first intermediate receiver. The revolutions were cut down on this engine to 66 per minute, but the full speed of 86 revolutions was kept up upon the starboard engine. Some six hours was occupied in making the repairs. The piston rings in the high-pressure piston were found broken, and one of them jammed over another in the same slot.

Catechism of Electricity

923. *If the commutator is eccentric or too rough to be smoothed evenly by means of a file, what should be done with it?*

It should be turned down in a lathe. If the armature is large and difficult to remove from the machine, a portable lathe or truing device can be attached directly to the shaft of the armature as shown in Fig. 282, and the commutator turned down without removing the armature from the motor. The armature should be held stationary and the device revolved around the commutator by hand, using the shaft as a bearing. The tool is moved across the commutator by a screw feed actuated by a detent clamped to the shaft.

If the armature is small and easy to remove from the machine, it should be placed in an ordinary stationary lathe and the commutator turned down in the usual manner.

924. *In case it becomes necessary to remove the commutator from the armature, how should this be done?*

The simple device shown in Fig. 283 is convenient for this purpose. It consists of two pieces of iron *c* and *c*, shaped to fit back of the collar *b* on the commutator spider. Through holes in the ends of *c* and *c* are passed bolts *e* and *e*, and over the outer ends of the bolts is slipped the bar *f* which bears against the shaft *d*. Before commencing to remove the commutator it is necessary to have all the wires disconnected from it. By screwing up the nuts *g* and *g*, the spider and commutator will be drawn off. After producing the first strain on the bolts, however, it may be necessary to give the commutator a light rap to start it.

925. *What characteristic features are present when the sparking is caused by weak field magnets?*

The speed of the motor will be unusually high with weak field magnets unless the magnetism is very low or lacking altogether, in which case the motor will run very slow, stop or perhaps run backward. If the pole pieces are tested by holding a piece of soft iron near them there will be little if any attraction.

926. *How may the trouble be definitely located?*

Place wooden chips under the brushes so they do not come in contact with the

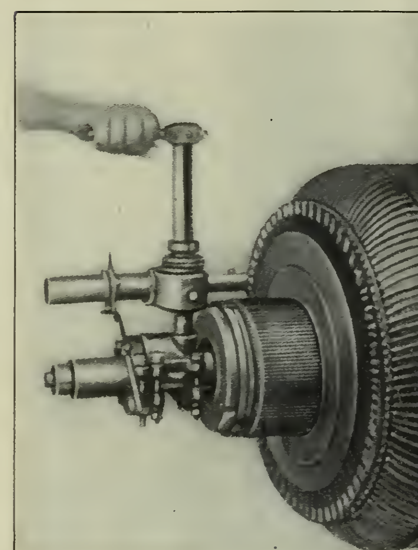


FIG. 282. COMMUTATOR-TRUING DEVICE MOUNTED ON THE ARMATURE SHAFT AND OPERATED BY HAND

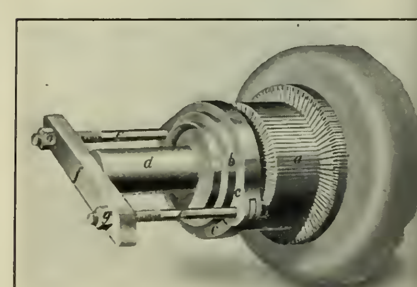

FIG. 283. SIMPLE DEVICE FOR REMOVING THE COMMUTATOR FROM THE ARMATURE

commutator, and with the field rheostat short-circuited, close the field coils upon the supply circuit. If upon opening this circuit there is no spark there is a broken wire or connection somewhere in the circuit. If there is a spark the circuit is not broken, but one of the magnet coils may be short-circuited. This may be determined by testing with a piece of soft iron which when held between the pole piece of the short-circuited coil and the adjacent pole piece will be attracted to the latter, but not to the former. Another method of testing for a short-circuited field coil consists in passing a current through the field circuit and measuring the drops of potential across the different coils. A short-circuited coil will show little or no drop in comparison with he others. A short-circuited coil may be caused by its wire being grounded at two points on the frame.

One of the field coils may be reversed, producing a weak field. This can be determined by passing a current through the field circuit and moving a compass needle from one pole piece to the other in succession. The needle will reverse its direction at each succeeding pole if none of the coils is reversed.

Condenser and Back Pressures in Refrigerating Plants

By F. E. Matthews

How does a refrigerating engineer know when the condenser pressure and back pressure of his plant are right for most economical operation? What are the proper pressures?

In general, with an engineer who is familiar with the underlying principles on which the efficiency of refrigerating systems depends, it is largely a matter of judgment. Such judgment must be based on knowledge of the temperature of the condenser water, whether there is sufficient condenser surface for the compressor and whether or not the condenser pipes are free from uncondensable foreign gases. With these things known to be right, condenser pressure for different temperatures of cooling water should be approximately as follows:

1 gallon per minute per ton per 24 hours—							
Temperature of cooling water, degrees F	60	65	70	75	80	85	90
Condenser pressure, gage, lb	153	200	220	[illegible]	[illegible]	[illegible]	[illegible]
Temperature of condensed liquid ammonia, degrees F	95	100	10[illegible]	110	11[illegible]	[illegible]	[illegible]
2 gallons per minute per ton per 24 hours—							
Condenser pressure, gage, lb	130	1[illegible]	168	18[illegible]	200	[illegible]	[illegible]
Temperature of condensed liquid ammonia, degrees F	77	85	90	[illegible]	[illegible]	[illegible]	118
3 gallons per minute per ton per 24 hours—							
Condenser pressure, gage, lb	125	140	1[illegible]	170	18[illegible]	[illegible]	215
Temperature of condensed liquid ammonia, degrees F	75	85	90	95	[illegible]	[illegible]	[illegible]

Similarly, the evaporating or back pressure within the expansion coils of a refrigerating system depend upon the temperatures on the outside of such coils, i. e., the air or brine to be cooled. For average practice back pressures for the production of required temperatures should be approximately as follows:

Temperature of room, degrees F		10	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Back pressure, gage, lb	[illegible]	10	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Temperature of ammonia, degrees F	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

In every event the condenser pressure should be kept as low as possible and the back pressure as high as possible, narrow limits between such pressures being as important to the efficiency of a refrigerating system as wide ones are to that of a steam engine in which the economy increases with the range between boiler pressure and condenser pressure.

The full importance of this truth is seldom recognized by either the operating or the supervising engineer, and neither strives for the last pound of increased back pressure half so diligently as for the last inch of vacuum in the steam condensers, although the pressure is of relatively far more importance than the latter in its effect on the general efficiency and economy of the plant.

As regards both condenser and back pressure, the limit that should be striven toward, but which, of course, can never be reached, and produce work, is when the pressures in the condenser and expansion coils, respectively, are such that the corresponding liquid temperatures are the same as that of the condenser cooling water and the cold-storage brine temperature, respectively, to be produced.

Atmospheric ammonia condensers employed in temperate climates where cooling water of from 55 to 70 degrees Fahrenheit is available usually contain about the square feet of heat radiating surface per ton, and as indicated in the first table, are cooled by from one to three gallons of water per minute per ton per twenty-four hours.

Not only does the amount of cooling water required per ton vary with its temperature, but also with the cooler temperatures required and the condensing pressure encountered.

If, for example, a cooler is to be maintained at 20 degrees Fahrenheit, a back pressure of 15 pounds is to be carried resulting in 0 degree ammonia within the expansion coils, and the head pressure be 145 pounds, only 0.75 gallon of cooling water will be required, provided it be sufficiently cool to rise 20 degrees in temperature and still be 10 degrees cooler than the temperature of the condensed ammonia corresponding to the pressure.

Now, the temperature corresponding to 145 pounds head pressure is 82 degrees Fahrenheit, so that 82 − 30 = 52 degrees, the required temperature of the cooling water.

Where there is only one temperature to be produced in the cold-storage compartments a back pressure is usually carried, such that the temperature corresponding to that pressure will be about [illegible] degrees Fahrenheit below that of the cooler temperature. Under average operating conditions the cost of the amount of expansion pipe required to allow of this range in temperatures balances up fairly well with the loss in efficiency that would be encountered if less expansion piping were installed and a lower back pressure carried.

Where several different temperatures are to be maintained with one back pressure no fixed rule can be followed, and each individual case must be figured out separately. If only a small per cent. of the total cooling work be low temperature, it is usually advisable to reduce the temperature range between the liquid ammonia and the surrounding air making up for the reduced range by the installation of inversely proportionately more pipe. In this case the expenditure of an abnormal amount of pipe in a small per cent. of the entire duty allows of an increase in efficiency of the entire plant.

While the necessity of producing a low temperature in a single box reduces the efficiency of the entire plant—or that part of it which is required to carry the low back pressure because of that low temperature—there is a slight compensation for the decreased efficiency in the way of decreased first cost of expansion piping for the higher temperature boxes. The ammonia pressure and temperature being reduced in order to cool the low temperature box may be sufficiently colder than the high-temperature boxes as to allow the pipe surface in the high-temperature boxes to be reduced often as much as [illegible] per cent. This condition would obtain when the difference between the ammonia and the high-temperature boxes becomes 41 degrees Fahrenheit.

In general, the engineer should endeavor so to manipulate his expansion valves as to carry the highest back pressure possible and still produce sufficient refrigeration in his coldest coolers. The limit to possibilities in this direction is when no more ammonia feed can be put on the expansion coils without causing liquid ammonia to return to the compressor, causing it to pound and the ammonia rod stuffing boxes to leak.

The back pressure can be carried materially higher and the efficiency of the plant can be materially increased by keeping the expansion coils free from the insulating effect of ice on the outside and oil on the inside. Opportunity should be taken to remove the oil from the expansion coils every two or three months at most, and oftener if a considerable oil is thought to have worked into the system.

If the engineer is always on the alert he can [illegible] opportunity to shut his machine down for a few hours sufficiently often to allow the ice to melt off the expansion coils, not only allowing the system to operate more economically when it is running but also to save a considerable number of hours operation without [illegible] temperatures and consequently materially reducing the operating expenses of the plant.

[illegible] the refrigerating effect of [illegible] by [illegible] down expansion [illegible], reducing the back pressure, and [illegible] away [illegible] the refrigeration is not needed, [illegible] the doors of the various boxes will [illegible] than they are a little colder than required, [illegible] down the machine. [illegible] will be surprised at the saving that can be effected.

Inaccuracies Due to Drum Motion Distortion

A Practical Analysis of This Cause of Errors in Indicator Diagrams, with Results of Tests to Determine Their Magnitude in Various Cases

BY JULIAN C. SMALLWOOD*

Everyone who has considered the subject is aware that that exceedingly useful device, the indicator diagram, is full of errors. The straight-line motion of the indicator and the apparatus for reducing the motion of the engine crosshead may be faulty in principle or workmanship, or both. The indicator spring rarely records steam pressures truly and the drum motion does not, by any means, accurately correspond with that of the crosshead. Of these four sources of error, however, the first three are under control and, if they exist, constant. Thus, a high degree of excellence in workmanship may render negligible any errors in the duplicating and straight-line motions when their design is correct. Indicator springs may be accurately calibrated and compensation made for their error. But inaccuracies due to drum-motion distortion are neither constant for different conditions of speed nor easily determined for particular ones. Therefore these inaccuracies are worthy of special attention. It is the purpose of this article to make an analysis of them and to present the results of tests made to determine their magnitude under different conditions.

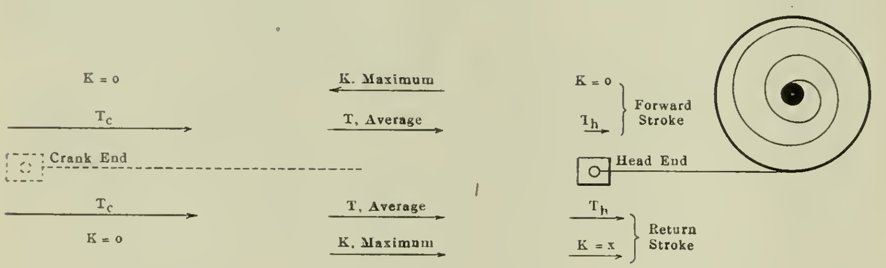

FIG. I

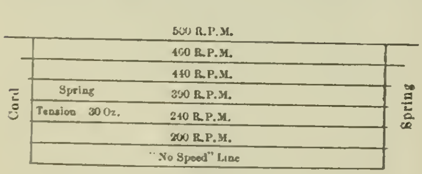

FIG. 2

It is well first to consider the cycle of events in the nature of an indicator and the forces controlling it. Fig. I represents a plan section of a drum, the string of which is attached to the pin of a device to reduce the movement of the crosshead of an engine to the length of the indicator diagram to be taken. The pin is shown at the head-end dead center in full and the dotted figure represents the other end of its stroke. The spring is shown by the spiral, one end of which is fastened to the drum, the other to the axis upon which the drum oscillates. Beginning at the head-end dead center there is a certain pull in the cord which is resisted by the spring tension T_h at this point. As the crosshead moves to the left, this tension will increase in a rate proportional to the extension of the spring, becoming maximum, T_c, when the drum has revolved as far as it will go in a clockwise direction. Thus the average value of the spring tension is $(T_h - T_c) \div 2$. The work done by this force is expended in overcoming the kinetic energy of the drum. This latter varies as the square of the drum's speed. Now, the motion of the crosshead is approximately harmonic and therefore the velocity of the drum is zero at the extreme positions of its travel and maximum in its mid-position. These forces are represented in Fig. I by the arrows. It is obvious that the least distortion will ensue when the maximum value of K (or the force of acceleration at mid-stroke) is just balanced by an average drum-spring tension.

Considering, now, the reverse motion, it is seen that the spring tension is the only force acting and that it is maximum at the crank-end dead center and diminishes in the same way as it has increased. This force imparts kinetic energy to the drum which stores part of it until the end of the cycle, when it is delivered in an effort to stretch the cord. The tension T_h also operates to do the same.

In the foregoing discussion no attempt has been made to point out the inaccuracies of the drum motion between its limits, the object being to determine the deformation only at the ends of the stroke. It will be seen that this is dependent upon five quantities, namely, the spring tension, the revolutions per minute, the elasticity of the cord, the mass of the drum and the length of the diagram, the first and last of which may be conveniently varied to suit any particular conditions. Further, the deformation at the crank end will be produced by an abnormal stretch of the spring, while that at the head end will be permitted by the elasticity of the cord. The former may be expected approximately to vary directly as the mass of the drum, length of diagram and square of the revolutions per minute, and inversely as the spring tension. Similarly the latter will vary directly as the spring tension and the elasticity of the cord.

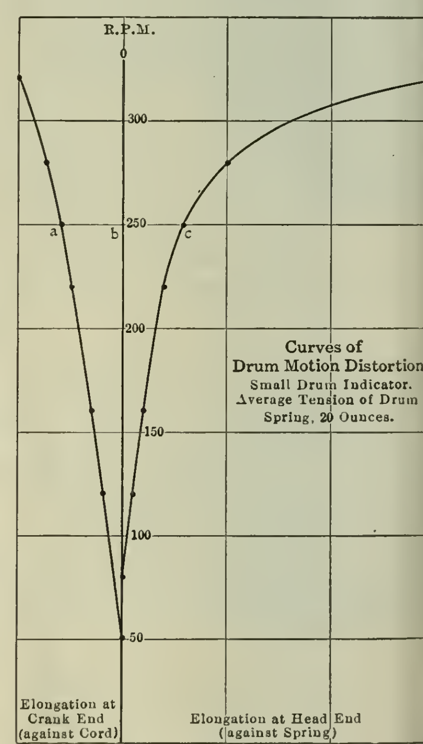

FIG. 3

To Minimize Drum-motion Distortion

It follows from the above considerations that to reduce drum-motion distortion to its minimum it is necessary to have the mass of the drum as small as possible, the

*Instructor in mechanical engineering at the University of Pennsylvania.

cord as nearly nonelastic and as short as may be and the reducing motion such as to give the smallest diagram that will be convenient to use. Further, and more important, the spring tension should be adapted to the speed of the engine to be indicated, so that its average value just balances the force of acceleration of the drum in its mid-stroke and is no greater, for, if it is greater, the effect will be to increase the deformation due to the stretch of the cord.

With these considerations in mind an attempt was made to measure by tests the magnitude of the deformations produced by drum-motion distortion. The results of these tests are presented by the curves accompanying this article. Two indicators, whose drums were of different weights, were used. They were connected to a crosshead of 4 inches stroke which derived its motion from a small motor supplied with a heavy flywheel to obtain uniformity of rotation. Speeds were varied through fine gradations by changing the motor resistances and braking the crank shaft. Determinations at various spring tensions were made, each set being begun by making two vertical lines with the indicator pencil at the ends of the "no-speed line." In this way overtravel at each end could be determined, care being taken to keep the diagram in one position on the drum for each run. Fig. 2 shows one of the diagrams taken. The results were plotted as shown in Fig. 3, where horizontal distances represent percentages of elongation laid off to either side of the vertical zero line, and vertical distances represent revolutions per minute. Thus the groups representing the action of the

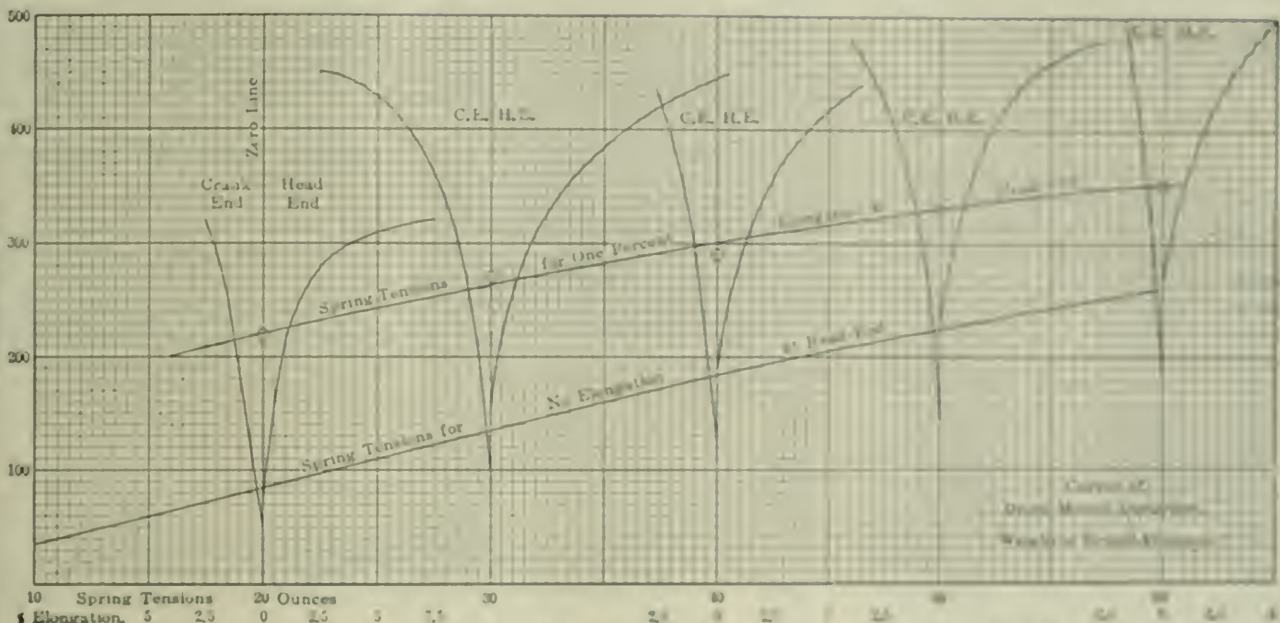

FIG. 3

lighter of the two drums tested with an average spring tension of 20 ounces, shows that up to 50 revolutions per minute the drum follows the reduced motion of the crosshead very closely, but that above this speed the distortion at the crank end, against the stretch of the cord becomes measurable and increases rapidly with increasing speed. The elongation on the head end against the tension of the spring does not begin until a speed of 80 revolutions is reached. At 250 revolutions the elongation at the head end is equal to *a b*, and on the crank end to *b c*, each equal to about 1½ per cent. At a little above 300 revolutions the fling is sufficient to throw the drum against the stops on the head end and no increase of speed would be practicable at this drum tension.

Diagrams Made with Different Spring Tensions

In Fig. 4 a number of such diagrams made with different average spring tensions are grouped upon the same chart for each of the two drums. The points at which distortion begins upon the head end are formed by the curve *A B*, which represents, therefore, the number of revolutions per minute at which overtravel at the head end commences for any particular spring tension. Another curve is drawn through the points at which head-end elongation is 1 per cent. Overtravel at the crank end is ignored, since it is permitted by the stretch of the indicator cord which is in turn dependent upon its length and texture. It would therefore be impracticable to apply a general rule for setting the drum spring for this end.

The weight of the moving parts of the heavier indicator drum was found to be about 37 per cent. greater than that of the lighter.

The indicator cord used in the tests was 2 feet long. Although of very good quality, it showed in a preliminary test a stretch of 0.05 of an inch per foot per pound dead weight, and this after it had been previously stressed.

Inspection of the curves may astonish some engineers who are accustomed to place unquestioned reliance upon the truth of indicator diagrams. The inaccuracies shown, however, may easily be verified by a simple trial. It appears that deformation begins with comparatively low speeds and that the speed corresponding to the beginning of deformation increases with the increase of spring tension. With low spring tensions the deformations become enormous at high speeds. It will be noticed, too (considering the curves for the lighter indicator), that though the deformations at the two ends of a diagram are nearly equal immediately after the critical speed has been reached, beyond this the elongation due to overtravel against spring tension becomes greater in a progressive ratio. This is as would be expected since the cord is limited in its elasticity, while the spring is not. The difference is not so marked in the curves for the heavier indicator, but this is probably due to the fact that higher spring tensions here are needed to overcome the inertia of a greater mass. Thus, upon the return stroke both T_h and K have a greater value than would obtain in the small drum, and the cord stretches accordingly. And, finally, it may be observed that the head-end elongation varies approximately as the square of the speed, that the crank end varies at a somewhat lower rate and that the head-end elongation at constant speed varies nearly inversely as the spring tension.

Consider, now, the error introduced into an indicator diagram by the inaccuracy of the drum motion. Fig. 5 represents a diagram which has 3 per cent. elongation at one end and 1 per cent. at the other. An inspection of the curves will show that this amount of distortion may ordinarily be met with. The mean ordinates obtained from the distorted and correct diagrams are 1.06 and 1.03 inches, respectively; that is, an error of about 3 per cent. In measuring the cutoff from such a diagram it will readily be seen that the error may be still greater. In some cases, however, the error due to increased area of the indicator diagram may be offset by the increased base length, so as to make the error in the mean hight negligible.

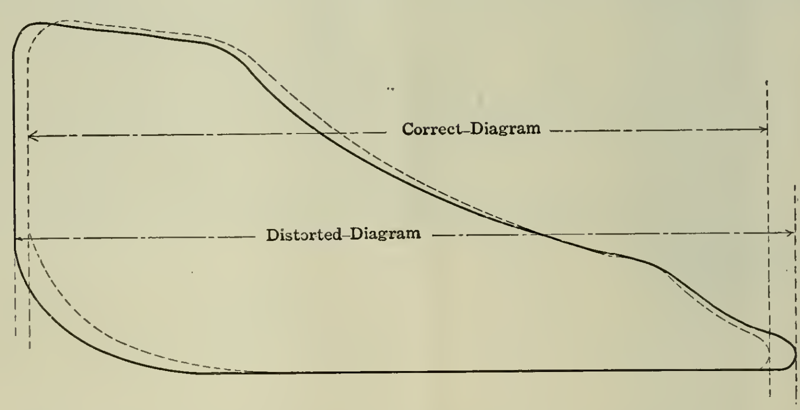

FIG. 5

Deformation at Mid-stroke

Hitherto nothing has been said concerning the amount of deformation in mid-stroke. This is difficult to determine and requires special apparatus, but it is hoped that a presentment of the subject may be made at some later time. For the present purpose, however, it will be sufficient to make the following observations:

Starting from the head-end dead center the tension of the spring is small, while the opposing force due to the velocity of the drum is zero. Hence no appreciable distortion can result since the stretch of the cord is small. If this initial stress could be maintained in the cord the drum's motion would be an exact duplicate of that of the crosshead. According to the best setting of the drum spring as previously determined there will be, however, no stress in the cord at mid-stroke. Beyond this the work done by the spring increasingly exceeds the kinetic energy of the drum and therefore the pull in the cord will increase and deformation due to its stretch will increase up to the end of the stroke. Upon the return stroke the tension in the string is diminishing up to the end of the crosshead's travel. It is thus seen that under the best conditions there is a varying stress in the cord throughout a complete motion of the drum and we may therefore expect distortion of the diagram in all its parts, and the farther the stress in the cord departs from a uniform one the greater will be the inaccuracy. Obviously if the spring tension at mid-stroke is greater or less than is necessary to overcome the effect of inertia at this point this departure will be more marked.

The results and considerations presented lead to the conclusion that a perfect indicator diagram correctly representing the relation of pressure to piston position cannot be made with a spring-actuated drum, because of the inaccuracies introduced by drum-motion distortion. These inaccuracies may be reduced to the minimum by using piano wire instead of cord, as short as possible in length, and by properly adapting the spring tension to the speed of the engine to be indicated.

Allowing for Errors

The following simple procedure is suggested to allow for errors when accurate determinations are desired: Before putting in the indicator spring when indicating an engine two vertical lines may be drawn to correspond to the ends of its stroke. These are perpendiculars at the extremities of a "no-speed line;" that is, a line drawn by turning the flywheel at such slow speed that no effect of inertia is produced. Leaving this card on the drum, if the engine is now run at the various speeds at which it is to be indicated and horizontals drawn at these speeds, the elongation will be shown by the distances of the ends of such lines from the neighboring verticals. The corrections may then be made after the engine has been indicated. These corrections, of course, involve only the elongation of the diagram and do not consider deformations at mid-stroke, but the former is very likely the more considerable.

It is suggested that the device for tightening the spring of an indicator be marked in such a way that the tension of the spring may be adjusted for any desired amount without actual measurement. This may be simply accomplished by first measuring with a spring scale the tension at the limits of the drum travel for each adjustment and marking with a series of lines the locking device to correspond. From the curves presented in this article the indicator may then be conveniently adjusted for any particular test so that the least error results.

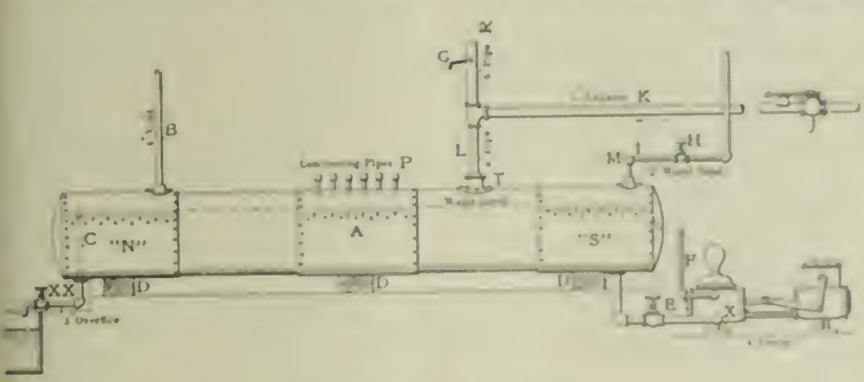
Reservoir Moved by Internal Forces

By J. O. Frazier

A few years ago the writer had an exciting experience with an old boiler which was used for the collection of water from the heating coils in a sugar house. The boiler was 36 inches in diameter and 60 feet long, and when nearly full of water was moved endwise about 1 foot from an internal conflict of exhaust steam and water. An unusual combination of circumstances was necessary to produce the results brought about, whose remote probability of simultaneous occurrence, as well as the necessities of rush work in connection with other machinery, had perhaps been the reason why the matter had not received more serious consideration and some means provided for their accommodation. The action of the contributing elements will best be understood by reference to the sketch.

In this illustration, *A* represents the reservoir, which many years before had served as a plantation boiler, when plain cylinder boilers without any flues were the prevailing type on the plantations. This reservoir received all the condensed steam from the evaporating apparatus of the house, which entered through the pipes *P*. There was a 5 inch exhaust steam connection *L*, which served to admit a small portion of such surplus exhaust steam as might exist at any time into the reservoir, from which all the boiler pumps received their supply. Another outlet, which then existed on the other side of the house, gave relief to the greater portion of the exhaust.

In putting up a double-effect evaporating apparatus the preceding year, the system had been piped to the new apparatus. Considering it was to run nearly all the time (and when it didn't run there were presumably few of the pumps or engines running) and to prevent the expense and time of changing the pipes *K* and *R*, which were only 6 inches in diameter, they were left as the sole outlet for such surplus of exhaust as might exist at any time. There were about 300 engine horsepower in the house and about 50 steam pumps, with steam cylinders ranging from 16 down to 5 inches in diameter, so it will be seen that the size of the pipe depended upon to carry off the surplus was out of all proportion to the sizes of the engines and pumps. It is a usual condition in such houses that when the double-effect evaporator, which generally



RESERVOIR AND CONNECTIONS

consumes all the exhaust steam, is not running but few of the machines are in operation, and thus the strong probability that the pipe would never be called upon to relieve more than a small portion of the total supply. So the larger pipe system which served the evaporator, some of it of 8-inch and 10-inch pipe, was just piped through the relief valve *I*, which was loaded to carry a pressure of 7 pounds in the exhaust system for supplying live exhaust steam evaporating apparatus, and that gave final relief to a presumable could discharge, the other outlet having been plugged.

The homemade butterfly valve, shown in pipe *K* at *G* had been put in years before to deflect exhaust, which then could never be considerable in amount, into the reservoir, for its value in mingling with the boiler-feed water. There were a vent pipe *B*, 4 inches in diameter, to prevent there ever being any pressure in the heater, as they called the reservoir, a 2-inch overflow pipe *C* and a 2-inch water inlet *T* to supply such additional cold water as might be necessary to make up the boiler supply. There were four boiler pumps feeding from the reservoir, all coupled about as the one shown at *X*. The reservoir was resting on wide wooden blocking *D* only a few inches from the ground.

While making the rounds one day and while in front of the boilers, behind which the reservoir was located, the writer heard and felt a commotion of unfamiliar sounds and it took several seconds before these sounds could be located behind the boilers in the neighborhood of the reservoir. Rushing around to this point a sight met the gaze which will not grow dim for a long time to come. There was that heavy reservoir of water, which could not weigh much less than 15 tons, actually bouncing, first in the direction of *N*, then in a few seconds, with a greater movement toward *S*. There was surely too much steam from somewhere, and the only possible source was the evaporator. Upon investigation it was found that the evaporator had been shut off, and the steam of the whole house, which was in full blast, had been turned toward the heater. The first move was to raise the weight on the relief valve *I* and turn the steam back into the evaporator.

Back in the boiler room the commotion had subsided; the heater was there, or nearly there, but what havoc among the piping. Suction pipes of all four pumps, as at *E*, were broken and all the hot water was running out of the reservoir over the floor. All boiler-feeding apparatus was disabled, and there were 15 boilers with a working head of steam. Well, the fires were all covered with dirt, ashes, water and anything else that would smother a fire; then began a rush for chain tongs, pipe fittings and all the paraphernalia of a hurry-up job, and by pressing everybody and everything into service, and with considerable good luck, which came in a while coming the engineer's way, the plant was running again in about three hours, with many makeshifts in the way of pipe fittings. It is well to explain that in those houses very hot feed water is so universally used that the possibilities of independent feeds with an injector is scarcely thought of and is practically unknown in the sugar house.

Even with the disaster which was wrought to the piping, there was on the whole less damage done than would be expected from such a commotion. The pipes *B* and *K* extended up through an old iron roof and did not suffer; overflow *C* was broken near *XX* and also the elbow *M* on the cold-water inlet. All the smaller pipes connected with the reservoir had enough spring in them to allow it to escape.

As to the combination which brought about the trouble and the action of the conflicting forces, the man who operated the evaporator was new at the business and had not learned how to keep the apparatus working by feeding water when the supply ran short. He threw the relief valve J open and the steam, endeavoring to get out through an opening far too small at best, found the butterfly valve, which had not been shut for a long time, closed and consequently deflected all the steam down into the reservoir on top of the water. When the commotion began the water tender put more water on at the supply pipe I, which would quite naturally make matters worse. First, the volume of steam coming in through L would force the water to the end N and plug up the vent B, which under the circumstances would be of little service. Then the flood of cold water coming in at I would so condense the steam as to create a lower pressure at the end S, which would cause the water to surge back toward that end, to be followed by an accumulated pressure sending it back toward N.

It would be hard to form an accurate idea of how long this action continued, but judging from circumstances perhaps from five to eight minutes. During this period it was evident that the reservoir was acted upon in alternating directions, with a period of about ten seconds each way, that it launched toward N about 1½ inches, then about twice that amount toward S, making a total gain toward S of 14 inches before the commotion was over. Among the provisions made for the prevention of a possible repetition of the trouble, at least in such violent form, was a sheet-iron flange, with only a 1-inch hole for drainage between the flange T and the reservoir. The butterfly valve G was taken out altogether.

Experiments on Gas Producers

By W. H. Booth

In a recent paper read before the British Iron and Steel Institute by W. A. Boru, some interesting facts relating to producer gas were made known. These had to do very largely with gas as produced for furnace work to which the regenerative principle is applied, and the experiments bear upon the use of water vapor in the air fed to the producer. The argument put forward by the authors, for R. V. Wheeler collaborated in the work, was that it was not advisable to put more steam into the air blast than corresponded with a saturation temperature of 60 degrees Centigrade; that is to say, assuming air at 60 degrees Centigrade to be saturated with water vapor that amount of water vapor would be the ratio of steam to be supplied. With any higher ratio of steam the thermal efficiency falls and the gas becomes less suited for furnace work. Experiments showed that with even less ratios of steam better results were obtained in rapidity of gasification and high efficiency.

With a 60-degree Centigrade saturation temperature a producer rated to consume 16 hundredweight per hour (1792 pounds) was successfully worked at 24 hundredweight (2688 pounds) with a fuel depth of 42 inches.

The saturation temperature was successively lowered to 55, 50 and 45 degrees Centigrade, with the result as between 60 and 45 degrees that the average coal consumption (night and day) rose from 17.5 to 18.4 hundredweight per hour; the CO_2 produced fell from 5.10 to 2.35 per cent., the carbon monoxide rose from 27.3 to 31.6 per cent.; and the hydrogen fell from 15.5 to 11.60 per cent., methane remaining the same at 3.05 per cent. and nitrogen rising from 49.05 to 51.40 per cent.

The total combustible gas increased from 45.85 to 46.20 per cent., and its calorific value from 178.7 units per cubic foot to 180 gross, and from 166.9 net units to 170.5, the yield of gas per ton falling from 135,000 to 133,700 cubic feet. The steam consumption per pound of fuel was diminished from 0.454 to 0.2 pound, and while in the first case only 76 per cent. of the steam was decomposed, all was decomposed at the 45-degree Centigrade test. The ratios of the oxygen from the steam and from the air were 0.44 and 0.33, respectively, and the efficiency ratios 0.725 and 0.73. Thus the efficiency was practically the same.

As to the use of gas in furnace work, the authors state that their previous convictions as to the greater suitability of carbon monoxide have been confirmed and they emphasize the importance of carbon monoxide for steel melting or reheating furnaces.

Needless to say, where hot gas is being supplied direct from a producer to a furnace it is important that as high a percentage as possible of the steam should be decomposed, or otherwise there must be loss of excessive cooling without additional calorific capacity of the gas produced. The reactions in a producer are probably very complex. The general reactions expressed by $C + 2\,OH_2 = CO_2 + 2\,H_2$ comes more and more into play as compared with the reaction $C + OH_2 = CO + H_2$, when more and more steam is added; so that the equilibrium point of the reversible reaction $CO + OH_2 = CO_2 + H_2$ becomes shifted more and more to the right, as does also the reversible reaction $2\,CO = C + CO_2$. In one test the raising of the steam saturation temperature from 45 to 80 degrees Centigrade increased the carbon dioxide sixfold; doubled the hydrogen and halved the carbon monoxide. This question of equilibrium is one of the phenomena of mass action which deserves greater study than perhaps practical men have yet accorded it. This is especially so with regenerative working, for action and reaction occur in the gas during its passage through the regenerator. Equilibrium of any gaseous mixture, such as one of hydrogen, steam, carbon monoxide and carbon dioxide, is dependent upon the relative proportions of the gases and upon their temperature. At any given temperature the state of equilibrium is defined by the expression

$$\frac{CO \times H_2O}{CO_2 \times H_2} = K,$$

the product of the concentrations of the monoxide and the steam being a definite ratio to the product of the concentrations of carbon dioxide and hydrogen.

Hahn showed by experiment that for temperatures of 1086 to 1205 degrees Centigrade, which fairly correspond with the temperatures in the hottest parts of a regenerator, K varies between 1.95 and 2.10, so that practically we may assume K equals 2.0. Any mixed gas of the above order passing through a regenerator which has a higher limit of temperature of about the above figure will tend to arrange or rearrange its dynamic equilibrium until the above equation is fulfilled with the value of 2 for K; and the tendency will be the greater when the initial ratio is most removed from $K = 2.0$, for the stress tending to rearrangement will be greater. It is therefore useless to start with a gas too rich in CO_2 and H, for equilibrium will tend to produce $CO + H_2O$. A producer gas heated to 1100 degrees Centigrade will attain equilibrium with $CO_2 = 10.2$, $CO = 20.6$ and $H_2 = 18.0$, and was found to do so when it contained initially the above three gases in the ratios 17.8, 10.5 and 24.8.

The authors do not express any dogmatic opinions, but base their arguments on the assumption of the correctness of Hahn's formula for K and consider that this should be further investigated in order to prove or disprove its correctness. Incidentally the thought arises that the reactions within the cylinder of a gas engine are probably extremely complex, consisting of an innumerable rapid series of changes of equilibrium in the mass of the burning gas. But such violent reactions only make their joint effect felt as an integrated result in the shape of fairly even pressure, for the waves which appear on an indicator diagram and often form the subject of much speculative writing do not seem to live when the indicator spring is changed for a stiffer one of less movement.

The presentation of further experimental data in regard to superheated steam will be looked forward to with great interest, but what we now need is a thorough review of the properties of saturated steam. At present our knowledge of the heat required above saturation is probably more accurate than what we know about saturated steam.—Prof. R. C. H. Heck.

Governor Link Arm Caused Trouble

Our company bought a 16 and 25 by 4-inch cross-compound engine. The governor was of the type shown in Fig. 1. This engine was belted to a 175-kilowatt generator and was operated at a speed of 250 revolutions per minute. It was concluded to make a direct-connected outfit of it, so a new subbase and field frame and an outboard bearing for the armature shaft were made. The flywheel was removed and a flanged coupling used to couple the crank and armature shafts together. In testing, the load was obtained through a water rheostat. When everything was ready, the engine was started, and when the speed got up to about 200 revolutions per minute the governor began to hunt, the speed running from 200 to 300 revolutions per minute, and then down again and so on. The engine was shut down and after several trials and many examinations the trouble was located. What made it more difficult was the fact that with a load the engine ran all right. I finally removed the cover plate E, Figs. 1 and 2, and found the eccentric strap F pulled back at the top, causing the cover plate to bind against the eccentric at A, and the strap against the eccentric at B, Fig. 2. I slacked off the springs and pulled the strap square on the eccentric, after placing three paper liners, each 0.01 inch thick, between E and F, Fig. 2.

I next removed all tension from the springs S, put more tension on springs S' and started up the engine; although it governed well the speed was only 180 revolutions per minute. I shut down the engine, took off the springs, disconnected the link L and placed the eccentric strap square on the eccentric. When I tried to put the link L back into the slot of the weight W I found the link was 3/16 inch out of line with the weight arm, so it had to be sprung into place (see the dotted lines in Fig. 2). When the tension was removed from the springs S there was so much play in the pins that the link would not bind, but when both springs were tightened they pulled the weight arm to its true center and held it there, and the link L had to be sprung into the slot in the weight, pulling the eccentric strap with it.

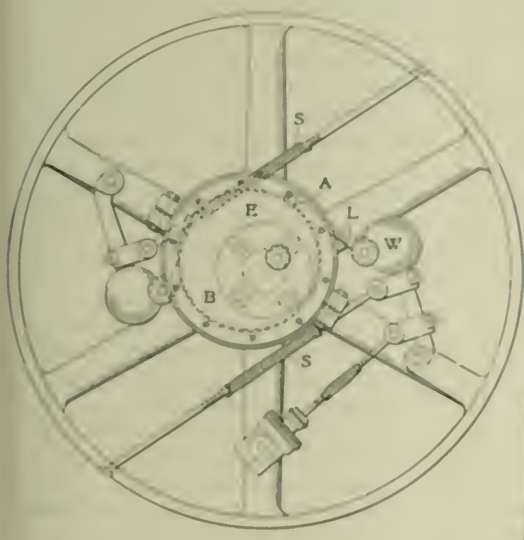

FIG. 1

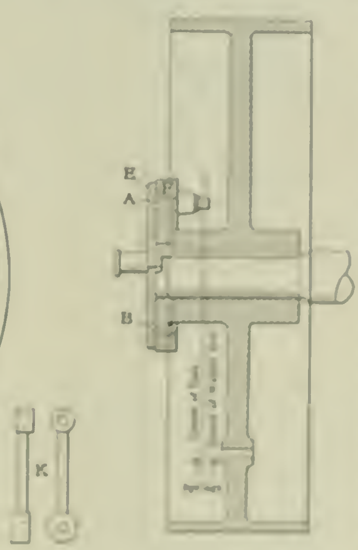

FIG. 2

I had a new link made with a 3/16-inch offset, as shown at K. The engine is governed very nicely by that means.

The superintendent could not see how it was that the engine had not given any trouble before. The reason is that it was belted to a large generator and had enough load to keep it steady, and there never was any time when the load was all off at once.

Chicago, Ill.

Induction Motor Operates as a Generator

Recently the local electric-light and power company installed a [illegible]-horsepower induction motor to run in multiple with a water wheel. The mill where this was done is situated on a small stream furnishing about [illegible] horsepower at full head, but is at the present time giving about [illegible] horsepower, which is not enough to run the mill.

The power company offered to put the motor in for a two months' trial, charging only for the current used during that time, but if the installation proved successful, the owner was to pay for the motor and installation, and a minimum bill of $2 per horsepower per month, the usual charge being $1. A smaller motor would have taken care of the installation, but would not have run the plant at times of low water.

The motor acts as a governor to the water wheel, which is without such a device, the speed running up and down, depending upon the rate of feed of stock to the machines. The motor is left on continuously and with the garnet machine running alone acts as a generator, supplying power to the feed line and running the meter backward. If the picker is thrown on, the meter immediately starts forward and the speed drops about 2 per cent., the motor running slightly above synchronous speed as a generator and below as a motor. But as this made a variation of speed of nearly [illegible] per cent. without the motor, it is considered more than satisfactory. With the garnet machine running alone the meter runs sometimes backward, sometimes forward, depending upon the flow of water to the wheel. The wheel gate is set to take the full flow of the stream, thus getting the entire benefit of the head.

This arrangement has been running one month, continuously, day and night except Sundays. It has turned out about [illegible] pounds of shoddy a day, which before it turned out only [illegible] per day of [illegible] hours.

It has used [illegible] kilowatt-hours, which sells at six cents, making $[illegible] for the month, or less than the minimum charge.

The owner is satisfied and will accept the motor, as he could not get this service with a steam engine, and he is already planning to run his garnet machines at a higher speed in order to get full benefit of the minimum bill.

The electric company is satisfied, as the customer runs his picker at non-peak hours and is helping them out at peak-load hours to a small extent.

Hygrometry

Referring to W. Vincent Treeby's comments on Mr. Hart's contribution on hygrometry which appeared in the issue of January 5, Mr. Treeby says that when we state that steam is saturated we intend to convey the idea that it is saturated with heat units. The word "saturation" applied to any physical material is usually taken to mean that it is saturated or contains all of a given substance that it is possible to hold without losing any. For instance, in the case of a salt solution, brine is saturated when it contains or dissolves all of the salt possible without precipitation.

I believe that the word "saturation" when used in connection with steam is more or less a misnomer and does not convey a true meaning in this sense. By "saturated steam" I understand that the steam is generated and is held in contact with water. It certainly is not saturated with heat because heat can be added indefinitely, thereby producing superheated steam, except that it is in another sense saturated with heat units, or it contains as many heat units as it will contain while in contact with the water.

Technically, to my mind, it is saturated with water; that is, dry steam contains all the water it will hold without precipitation if it remains in a quiescent state.

C. W. C. CLARKE.

New York City.

Sea Water Caused Foaming

At one plant where I was employed we dug a well near a river in which salt water flowed. The soil was loose-sand gravel and the well was dug 12 feet below the river level at low water. We used 8x8-inch timber cut so as to form a hexagon curb 14 feet across, each tier of curb being 1 inch smaller on each side than the one below, thus forming a bell-shaped curbing. The ends were cut to fit, and were spiked at the corners and toe-nailed at the sides. The weight of earth on the outside assisted in pushing the curb down.

We dug out about a foot below the curb all around and six men standing on the curb, each with a piece of timber, gave a few blows all together on top of the curb to drive it down.

The well worked all right until a dry spell came and our supply of fresh water for the well, which came from the hills, failed, and we were soon pumping brackish water into our boilers.

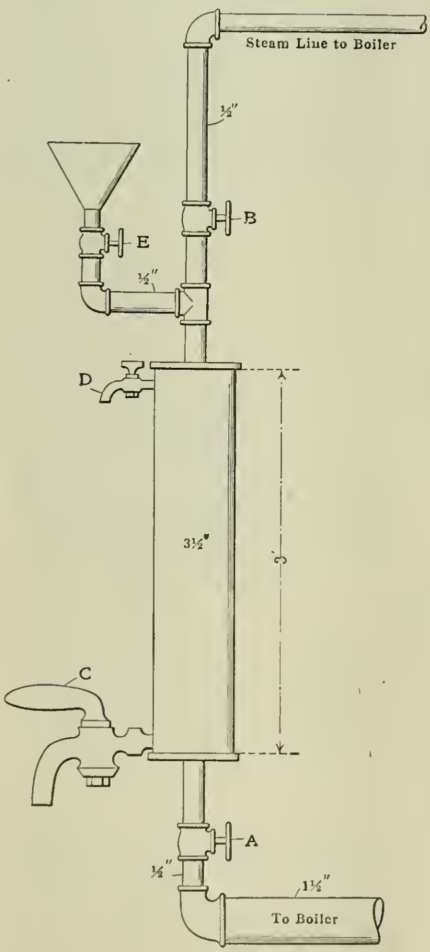
Dutch ovens were used, and when one was fired a little harder than the other that boiler would get busy passing water into the engine, and in five minutes there would be no water in the water glass. The engine, a 24x30-inch, was usually flooded to a standstill, or nearly so. When this happened we deadened the fire as quickly as possible, and after again getting the boiler filled to its proper level, it was put to work. This kind of trouble continued until the end of the summer.

D. F. BEDFORD.

Brantford, Can.

Compound Feeder

Referring to the illustration, it will be seen that this feeder operates with con-



BOILER-COMPOUND FEEDER

densed steam. It is made from a piece of 3½-inch pipe, 3 feet long, with the ends capped, the caps being tapped for a ½-inch pipe. It can be placed in any convenient part of the boiler room, preferably near the feed pipe and always below the water line in the boiler, the lower end being connected to the feed pipe between the check valve and the boiler with a ½-inch pipe.

The condenser pipe leading from the upper end to the dome or steam space should be about 6 feet high above the water level in the boiler. To fill, close the valves *A* and *B*, open the drain and air cocks *C* and *D*, and, after draining, close the drain cock *C* and fill by means of the funnel through the valve *E*.

By making the solution extra strong it is not necessary entirely to fill the body of the feeder, as it will finish filling with clear water from the feed pipe by slightly opening the valve *A*. When full, close the air cock *D*, open the valve *B*, and the feeder will operate, its rate of feed being regulated by the valve *A*.

GEORGE RUSSELL.

Spring City, Tenn.

High Water Level

This question of the proper hight of water in boilers is too often left to the fireman, who cannot, in many instances, tell how far below the gage the tubes are located.

A maker of boiler-feed regulators experimented as to the proper hight of water for economical steaming and found that the result of lowering the water line from three gages down to one gage was not very marked, but when lowered to 2 inches above the tubes a great difference in economy was made. In many localities the law requires the bottom of the gage glass to be placed 2½ inches above the flues, and the fusible plug about the same. So we have in practice at least 5 inches of water over the tubes, with the probability that the water will show at least 6 inches in the glass and more than 8 inches above the tubes.

If the tubes are carried high in the boiler the water line is so high that it is well up to where the cross section is narrow, and provides a small disengaging surface for the steam, causing extra friction and resistance for the steam to rise and separate, which is reflected back and means extra coal consumption. Having the largest space for the easy disengaging of the steam from the water means carrying the water line as low as possible.

It is true that piping will sometimes shake a boiler, but the water line should be carefully looked after in such cases.

In one steam plant feed-water regulators were put in. The old gage columns were left in place and the regulators placed on the side of the boilers. In these regulators the feed valve was held in position by the float, so that the valve was always open, a constant stream entering the boiler. The pressure in the feed pipe operated a pressure regulator on the pump, which was of such design that the only pressure on the metal diaphragm was the difference between boiler pressure and that in the feed pipe. With no more than 5 pounds extra pressure in the feed pipe the pump would supply the boilers with perfect regulation, with the feed valve well open.

The bottoms of the old gages were 4

inches above the flues and the engineer wanted the regulator set to carry 2½ inches of water in the old glass, making 6½ inches of water above the tubes. Carrying the gage half full would bring the water level nearly 10 inches above the tubes.

After awhile the water could not be kept up except by carrying about 30 pounds excess pressure in the feed pipe. As the water came in under the valve the excess pressure tended to raise it and depress the float which had to be more immersed so as to shut off the valve, and this tended to carry the water line higher.

The trouble was that the firemen were afraid to see the water so low in the glass and took measures to fill the boiler up so that it showed a half glass and the engineer partly agreed with them.

The result was that the water was carried 10 or 12 inches above the tubes, with increased cost for coal and increased moisture in the steam.

Broadalbin, N. Y.

Air Compression Under Difficulties

As an example of what may be expected in air compression when running the compressor with restricted inlet passages or valve opening, the accompanying indicator diagrams, Figs. 1, 2 and 3, should prove of interest to engineers who have compressors in their plants.

In Figs. 1 and 2 are shown normal conditions in the air end of a two-stage, 28 and 17 by 26-inch tandem compressor, connected to a 16 and 30 by 36-inch cross-compound Corliss engine. The first stage compresses to 25 or 26 pounds, and in the high pressure cylinder the compression is completed to 100 pounds. Recently an accident to the low-pressure side of the engine put that side out of business for twenty-four hours. As it was impossible to get along without air for any length of time, and still keep all parts of the plant in operation, the master mechanic de-

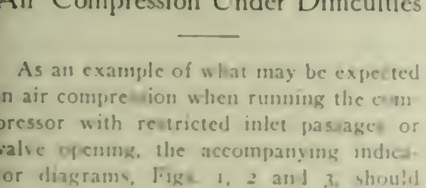

FIG. 1

cided to run the compressor on the high-pressure side alone. This was done in the following manner:

The low-pressure connecting rod was taken off, both steam and exhaust valves taken out and the bonnets replaced; also the positive-motion air-inlet valves and several of the poppet type of discharge valves on the first stage were taken out. This change allowed free exhaust of steam through the low-pressure steam cylinder, an air inlet, unrestricted as possible, through the low-pressure air cylinder, and an intercooler into the high-pressure cylinder.

When the compressor was started again it took over an hour's running at full speed to get the line pressure up to 80 pounds, whereas, with both sides "hooked up" we could always get the required 100 pounds in 10 minutes. It soon became evident that unless the demand for air was lessened, the pressure could not be raised above 80 pounds, which was about 25 pounds too low to operate some of the pumps and hoists.

After speculating on the interesting question of how much air the compressor was turning out in its one-sided condition, we decided that the trouble lay in the intake resistance to the air, due to taking it at atmospheric pressure (only about 12.5 pounds here) through passages and inlet poppet valves designed for air at 25 pounds.

The master mechanic then decided to get the required line pressure by running a 1-inch bleeder to the third stage of the four-stage high-pressure compressor alongside. The pressures of the different stages

FIG. 2

were 25, 115, 380 and 1000 pounds, and although the second stage would have suited the purpose better, the bleeder was connected to the third stage for reasons of despatch and convenience. A valve was placed in the bleeder to throttle the pressure and, the other end being connected to the discharge line of the crippled compressor, we soon had air enough for the demand. A couple of hours later when the quantity required was greatly reduced the compressor was able to hold 100 pounds with the bleeder valve closed, and then, wishing to see exactly what was doing in that hard working air cylinder, I put on the indicator and got the diagram shown in Fig. 3.

As expected, the admission line proved to be almost 7 pounds below atmospheric pressure, as compared with 1.5 pounds on the diagrams shown in Fig. 1. The diagrams also show that the piston actually traveled about one-fourth of the entire stroke before getting the pressure back to the intake pressure, as shown at A, Fig. 3, and about two-thirds of the stroke before reaching 25 pounds, as shown at B, which would be the regular intake pressure under ordinary conditions. By comparing the volumes V discharged per stroke, Figs. 2 and 3, it can be readily seen how the capacity was reduced.

Another interesting point is in comparing the compression curves under the different conditions. By plotting out the isothermal curve on Fig. 3, it will be seen that the actual curve gets much nearer to an adiabatic-compression curve than on Fig. 2, thus raising the mean effective

FIG. 3

pressure and hence the power required per unit of free air.

While Fig. 3 represents an extreme case, it goes to show that too much attention cannot be given to air intakes and inlet valves. For example, in making new valve springs to replace broken ones it is quite possible to make them much stronger than the old ones, or, in the case of positive-motion inlet valves, the point of admission might easily be too late, due to a slipped eccentric, lost motion in rod ends, etc., all of which would necessitate a greater degree of vacuum at the time of admission, and thus throw unnecessary work upon the compressor.

A case in point is that of an engineer who extended his intake from a few hundred feet out into a field, to get the intake away from the coal dust; and the first fall afterward the intake became clogged with leaves to such an extent that it took a 17-inch vacuum to get anywhere near enough air for the demand.

I have noticed that there seems to be very little practical information on air compression in the bulk of engineering journals, and if more attention were given to this important branch of our work, I am sure it would prove most acceptable to a large number of us who have compressors included in their plant. More light could easily be shed upon some phases of the work. For instance, I read not long ago the statement of an engineer to the effect that the only function of a receiver on an air line was the same as that of an air chamber on the discharge of a pump. I have always thought one of the most important reasons for a receiver being installed was to provide a place in which to cool the air, thus separating most of the contained moisture and allowing it to be blown off; also to provide a storage place, thus tending to prevent sudden reductions in pressure. When is the opinion of other readers on this subject?

J. A. Carruthers.

Bankhead, Can.

Criticism of Turbine Installations

I wish to make some comments upon the criticisms by E. H. Lane in the issue of January 5.

Mr. Lane comments upon the small size of the condenser, and also upon what he calls a deficiency in circulating water capacity in the condensing equipment. He states that the American practice is to allow not less than 60 pounds of condensing water per pound of steam; and, further, that the temperature of the water the year round must be considered. His figure of 60 pounds might be all right for New York City and vicinity, but it certainly would be insufficient in Florida and excessive in Labrador.

I will not attempt to answer Mr. Lane's question as to what temperature of circulating water is necessary to maintain the condensed steam at 28½ inches vacuum, as this would depend somewhat upon the design of the condenser.

As regards the size of the condenser, that is, the square feet of cooling surface, Mr. Lane states that the latest American practice is to allow 4 square feet of cooling surface per kilowatt for turbine installations. This was latest American practice in 1904. About 1906 the engineers of the country, and I suppose the manufacturers afterward, awoke to the fact that this rate of surface was excessive, especially in the larger units, and today the standard American practice for large units in temperate latitudes is about 2 square feet per kilowatt maximum rating, or practically half that quoted by Mr. Lane.

Another factor enters into this particular machine which, as I understand it, has a normal rating of only about 7000 kilowatts, the 10,600-kilowatt rating being a periodic maximum.

From the foregoing it will be seen that the ratio of the cooling surface to kilowatts at the normal load is 2.3 to 1, and at the maximum capacity is 1.3 square feet per kilowatt. The condenser provided is very close to the American practice today for large steam turbines. There are a number of 14,000-kilowatt turbines operating today in this country, having a maximum rating of 14,000 kilowatts for 24 hours, which are equipped with condensers containing 25,000 square feet of cooling surface, which maintains a vacuum of 28½ inches under all conditions and which gives a ratio of 1.8 square feet per kilowatt.

There are other machines which have a rating of 9000 kilowatts normal, which are provided with the same condensers. The steam consumption of these big turbines is practically the same as quoted for the Buenos Aires machine.

The reason for the small surface in this condenser not taking into consideration the temperature of water may be due to efficient design. The ordinary condenser as manufactured is far from efficient inasmuch as the steam does not get the best kind of action on the tubes.

I have a case in mind where the condenser surface was reduced about 15 per cent., which resulted in increase in vacuum of over ½ inch. This condenser had a ratio based on normal rating of turbine before changes were made of 3.4 square feet per kilowatt. After the changes were made the ratio was 2.9 square feet per kilowatt on the normal rating basis.

Where salt circulating water is used it is desirable from a maintenance standpoint to have as few tubes in a condenser as possible.

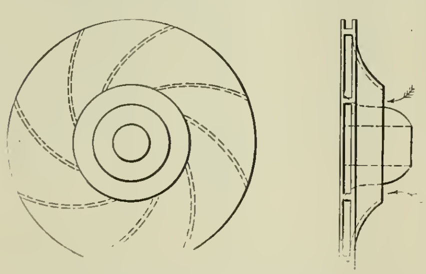
In reference to the installation of electric auxiliaries I can but agree with Mr. Lane that this is apparently a step backward rather than forward.

C. W. C. Clarke.

New York City.

Centrifugal Pumps

The recent discussion regarding the action of centrifugal pumps has brought



ONE TYPE OF IMPELLER

out some very interesting points. That it takes less power to run one of these pumps with the discharge valve partially or wholly closed is logical, and any operator of this type can easily demonstrate the fact to his own satisfaction, although the exact amount may vary greatly, depending on different details of construction, etc.

In regard to George P. Pearce's criticism of Mr. Kellogg's article, I beg to differ with him, especially where he compares a centrifugal pump to the water brake used by the Westinghouse Machine Company, as described on page 1025 of the June 30, 1908, issue. While the centrifugal pump is built on easy curves, to reduce friction loss to a minimum, the water brake is constructed to give the greatest possible resistance, resulting in the power being quickly transformed into heat. The appearance of the steel impeller and casing, after a few hundred hours' use, gives an idea of the violent impact between the moving parts, while the cast-iron impeller in a centrifugal pump will run month after month at 1000 revolutions or more per minute and not show any particular wear or sign of excessive friction.

The construction of impellers differs with different manufacturers, but in considering the type shown in the accompanying illustration the water, as it enters the center of the impeller, flows through easy bends to the periphery and here, where the velocity and friction are greatest, a smooth, narrow disk is found, which offers a minimum of resistance to the surrounding water. With the discharge closed there is no water flowing from the suction to the impeller and consequently no discharge at the periphery, and the body of water inside the impeller is motionless relative to the impeller, due to the pressure in the casing. The only power required would be that necessary to overcome the friction of this smooth water-filled impeller rubbing against the surrounding water, plus the friction in the bearings, etc. Altogether this friction cannot amount to a great deal and the fact that a turbine pump of this type will run in this condition for several minutes before there is any appreciable increase in the temperature of the water in the casing would tend to prove that such is the case.

R. Cederblom.

Gary, Ind.

Dashpot Does Not Seat

Why will not the head-end dashpot seat when the load is below 300 amperes and the hooks push it down?

The engine is a 30x48-inch Corliss, with seven-eighths cutoff and double eccentrics. The valves open away from the center of the cylinder and have equal travel; the same is true of the wristplates.

By using the starting bar and working the wristplate, the hook engages the catch block with a little clearance and the dashpot seats nicely. Why should it act so?

Elsworth Davis.

Zanesville, O.

Pumping Hot Water

In regard to C. R. McGahey's article under the above title, in the December 15 issue, I cannot see why it should be any more difficult to pump hot water than cold, if machinery designed for the work is supplied.

I have worked in three different plants, all over 2000 horsepower capacity, each equipped with open-type heaters, and this part of the plant was one of the least of our troubles.

If a plant is equipped with an outside-packed plunger pump, with either brass or good hard-rubber valves, large enough to handle the necessary volume of water, no trouble will be experienced beyond the ordinary amount of repair work. In two of the plants the pressure on the feed line was maintained by a pump governor, and the water level in the boilers was controlled by automatic feed-water regulators.

A pump should be provided with pet cocks on top of each water cylinder, in order to release air in case of failure of the water supply to the pump.

I have pumped water at 210 degrees and, in case of losing the water in the heater, have used a cold-water line to supply the pump until normal conditions were regained. The only perceptible change shown by the pump was the leakage at the glands, which gradually ceased as soon as the pump began to warm up with the return of hot water.

Occasionally in changing from cold to hot water it became necessary to open the pet cocks to relieve the water cylinder of steam or air, but we were not compelled to stop the pump, as this was only momentary, usually lasting over three or four strokes. In such a system the extra air chamber would be superfluous, and I disagree with Mr. McGahey about using a valve to choke the pump discharge, as this would compel the check valve at the boiler continually to open and close, due to insufficient pressure to hold it open, thus causing undue wear and a certain amount of hammering at this point. It would be better to throttle the pump discharge at the valve between the check and the boiler. I cannot understand why this could not be done with one boiler, the same as with two boilers connected to the feed line.

CHARLES A. CRYTZER.

Windber, Penn.

Cause of Trouble with Oil in Bearings

In the December 8 issue was published a sketch of bearings and shaft supporting a pulley, in which the writer describes a method employed in overcoming an oil trouble, but there was no explanation offered as to the reason why the oil in both outside chambers, in which oil rings were hung, were drained of their contents in the manner described.

Perhaps it is not generally known that in turning journals it is not so much the actual cutting of the metal as getting a clean chip, and an experienced lathe hand knows how to trim his tools in order to obtain a proper finish, thus destroying what would be observed under microscopical examination a complete series of spirals running the entire length of the shaft or journal. I believe that on the journals in question there was a series of spirals, and they naturally influenced the oil as soon as the shaft had bedded itself in the bearings.

It would be interesting to me, and no doubt to other readers, if the correspondent would fill both journals up to the centers, not from one end to the other, plug the holes up that communicate to each of the chambers, and let us know the result of the experiment.

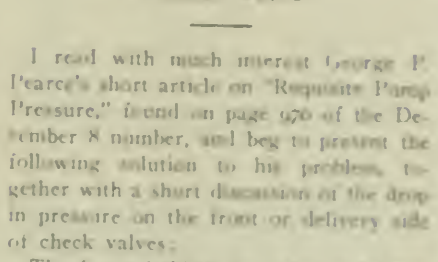
HORATIO W. HUTTON.

Glasgow, Scotland.

Pressure Required to Lift a Check Valve

I read with much interest George P. Pearce's short article on "Requisite Pump Pressure," found on page 970 of the December 8 number, and beg to present the following solution to his problem, together with a short discussion of the drop in pressure on the front or delivery side of check valves.

The forces holding the valve to its seat are the pressure per square inch into the



CONICAL OR PUPPET DOUBLE-SEATED BALANCING VALVE

area of the valve plus the weight of the valve, or in this case:

$$100 \times 19.63 + 5 = 1968$$

pounds. The force lifting the valve is the pressure per square inch beneath it into the area upon which that pressure acts. The area of seven 1-inch holes is 5.5 square inches; thus

$$1968 = 5.5 \times pressure$$

and

$$pressure = \frac{1968}{5.5} = 358$$

pounds.

This, of course, assumes that the valve cover makes perfect contact with its seat and prevents the fluid from the delivery side getting between the valve and its seat, which requires a perfectly tight-ground joint.

It is very evident in this case that if there were a gage placed on both the receiving and delivery sides of the check valve, there would be a drop in pressure after the valve opened from 358 pounds on the delivery side to 100 pounds on that of the receiving side. This would be true only provided that the pressure on the receiving side was due to a volume of fluid free to flow out and thus make room for the incoming fluid.

If the pipe conveying the fluid away from the receiving side were small compared with the size of the pipe and size of cylinder, I say the pump cylinder, on the delivery side of the valve, then the pressure on the receiving side would rise due to fluid friction in the discharge pipe, while the admission pressure would fall until the two were equalized, and then they would both continue to fall until the pressure at the valve was that due to the static head of fluid on the valve, when the valve would close due to the tendency of the fluid to flow back into the pump cylinders.

The trouble here is that the ratio of the area of the admission or delivery side of the valve to the area of the discharge or receiver side is too small.

George H. Anderson is correct in the statement that the total pressure P on the discharge or receiver side (back side) of a check valve is equal to the area of the passage plus the area of the seat multiplied by the pressure per unit area, while the total pressure P_1 on the admission or receiver side (front side) is equal to the area of the passage multiplied by the pressure per unit area. This, of course, assumes a balanced valve; the weight of the valve would increase the pressure on whichever side had to lift it.

The expression "area of the seat" should be modified to read the projected area of the seat on a plane parallel to the plane on which the area of the passage is measured.

Referring to the accompanying drawing, the area of the passage is the area of the circle, whose diameter is d_1, while the area of the seat is equal the area of the annular ring, whose outside diameter is d and whose inside diameter is d_1.

With correctly designed valves and ports having proper ratios of seat area to passage area, there ought not to be variations in pressures which would be perceptible on the ordinary gage.

In this connection it would be interesting to hear from someone who has spent considerable time in the design and operation of valves used for such a class of service.

The drawing shows a diagrammatic sketch of a conical or puppet double-seat valve which may be so proportioned that the pressure on the front side may be equal to that on the back at the moment of opening.

This is accomplished by bringing the fluid in contact with a recess in the valve as shown at aa. The fluid is led into this recess through the ports bb.

It is evident that if the area of this annular space, represented by $0.7854 (d_1^2 - d_3^2)$, be equal to the area of the annular $(d^2 - d_2^2)$, the valve will open when the pressure per unit area on the front is equal to the pressure per unit area on the back, since the areas exposed to the action of the fluid pressure are equal on both sides.

For valves having a circular cross section, the pressures will be equal on both sides at the moment of opening (neglecting the weight of the valve), when the valve is proportioned as expressed by the following equation:

$$d_2 = d_1^2 + d_3^2 - d_2^2$$

Practical Hygrometers

The practical hygrometer described by J. J. O'Brien in the issue of December 29, will, as he says, "be accurate enough for all practical purposes;" but it will tell very little to the observer except that the air is more or less moist at one time than another. To obtain the percentage of humidity in the air by means of the instrument described, a set of tables is needed.

Such tables may be obtained by writing to the United States Department of Agriculture, Weather Bureau, Washington, D. C., inclosing ten cents (the cost of the tables) and asking for "Psychrometric Tables W. B. 235." These tables give considerable very useful information, including the methods of obtaining the formulas, and the use of various kinds of hygrometer. The hygrometer should be hung in a moving current of air.

As an illustration of the need of tables when using the apparatus in question, showing that the difference in temperature between the thermometers is not the only factor to be taken into consideration, if the barometer stands at 30 inches, the temperature of the air is 32 degrees Fahrenheit, and the difference between the wet and dry thermometers is 10 degrees Fahrenheit, then the relative humidity of the air is 2 per cent.

With the air temperature at 80 degrees Fahrenheit and a difference of 10 degrees Fahrenheit between the thermometers, the relative humidity is 61 per cent., a very different figure. The tables also give vapor pressure, and temperature of the dewpoint.

J. G. Ould.

Brooklyn, N. Y.

Indicating Engines

Having two weeks off recently, I decided to try engine indicating. I first called at a lumber mill where there was a Corliss engine rated at 100 horsepower. The superintendent did not think it worth while to bother, but when I told him that I would charge him nothing if the valves were found to be properly set, he agreed. Fig. 1 shows the manner in which the valves were operating.

I next called at a factory where a high-speed automatic engine was in use. The engine seemed to be running nicely, with the exception of a knock in the steam chest whenever the load changed very much. Both the superintendent and engineer were anxious to have the engine indicated; Fig. 2 shows the steam distribution. As will be seen, one end of the cylinder is developing all the power, and the other end is doing negative work. At *CA* is the expansion line and *CBA* are exhaust and compression lines.

The valve did not open to admit steam to this end of the cylinder. The exhaust valve opened at *A*, however, and exhaust steam entered. When the exhaust valve closed at *B* the steam was compressed.

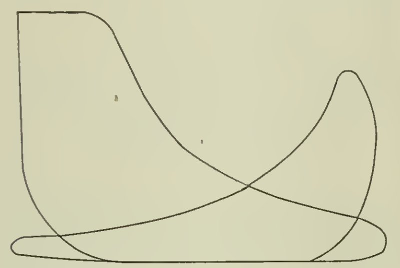

FIG. 1

The expansion line *CA* would lie directly on the exhaust and compression line were it not for the cylinder condensation but, owing to the little steam that does get in being condensed, a partial vacuum is formed in this end of the cylinder, so that the expansion line falls below the atmospheric line.

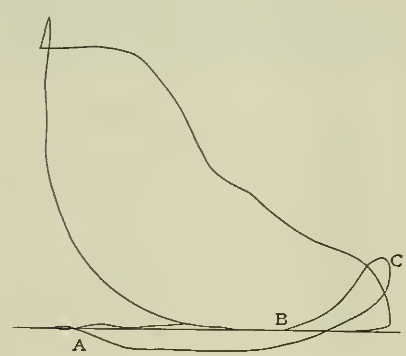

FIG. 2

This engine had been running so long this way that a shoulder was worn on the valve seat, and the valve could not be properly set until the seat was planed off. This explained the knock in the steam chest when the load changed.

I called on another engineer and was treated to a discourse on the slide-valve

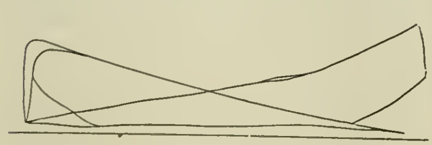

FIG. 3

engine and power-plant operation in general. He wound up by saying that he had been "running engines for 40 years" and had had charge of that particular engine for 12 years.

The president of the company employed me to indicate the engine. Fig. 3 shows what I found. The pencil was held on the drum for three revolutions when the diagram at the left was taken. There was about ¼ inch lost motion in the valve gear; thus, the points of steam distribution were not constant but varied for different strokes. The point of cutoff was varied so that one end of the cylinder would be carrying most of the load during one revolution; then, again, the other would carry the most. This card also shows how the compression and admission varied.

Out of twelve engines I found only one running with proper steam distribution.

Ray L. Rayburn.

Decatur, Ill.

Central Valve Engines

In a recent issue, J. J. Stafford contributes a description of "central-valve engines," which title, by the way, is a misnomer, as far as the term is understood in England, as the engine fitted with the valve gear which he describes is one of numerous types of high-speed, inclosed, double-acting engine. The term "central-valve engine" applies to a special and altogether different class of single-acting engine, in which type the piston rods are hollow and fitted with steam ports, the valves sliding up and down inside the piston rods, actuated by an eccentric in the center of the crank pin; there being two connecting rods, one on each end of the crank pin, which are worked from a long crosshead; or, in some sizes, from two short gudgeon pins, the whole arrangement forming a very interesting and economical combination.

It is not, however, my main object to point out the misleading definition, but to show that, even if Mr. Stafford is running several sets of high-speed engines, he is evidently not conversant with the most elementary principles of valve setting, as covering the simplest slide-valve engines.

His sketch shows that the two pistons are at the ends of their respective strokes, though how they have got there is a more difficult matter to arrive at, seeing that the lower high-pressure and the upper low-pressure ports are wide open for the admission of steam. He says: "In the position shown the high-pressure piston is at the bottom of the stroke, and the valve has just opened to admit steam to that end of the cylinder." I agree that "the valve has just opened to admit steam," with a vengeance. It cannot open any farther, because the piston valve is almost in its lowest position, and any farther movement of the eccentric will be toward cutting off the steam, before the piston gets far on its way, and the steam in the lower end of the high-pressure cylinder will be on its way to the exhaust, or receiver, before the up-stroke is anywhere near completion.

It is quite sufficient to deal with the high-pressure side alone, in considering the relative positions of the high-pressure crank and the eccentric (the position of the latter being assumed from the position of the valve as shown). The crank is on the bottom center, and the valve is at the bottom of its travel; therefore, if we imagine a line drawn through the center of the connecting rod and crank pin, that line would be coincident with the center line of the eccentric in its lower position, a peculiar combination, to say the least, and a scarcely workable one.

In the ordinary slide-valve engine, admitting steam to the cylinder from the "outer" edges of the valve, the eccentric is set at 90 degrees, plus the angle of advance, in advance of the crank, but in the class of valve under discussion, which admits high-pressure steam on the *inner* edges of the valve faces, the position of the eccentric is behind that of the high-pressure crank, or, say, 180 degrees from the position required in an ordinary slide-valve engine to run in the same direction. From this it will be seen, on examining Mr. Stafford's sketch, that the top edge of the ring *D*, shown in his Fig. 2, should be just below the top edge of the bottom high-pressure port, thus giving an amount of opening equal *only* to the desired lead for that particular size of engine, instead of giving full port opening in such a position of the piston as shown in the sketch referred to.

In conclusion, I would point out that the relative positions of the low-pressure crank and the eccentric (common to both cranks) are the same as in the ordinary slide-valve engine, and as Mr. Stafford rightly explains, the steam passes through the inside of the valve and over the outer edges of the valve faces, or rings, *A* and *B*, in his sketch.

Manchester, England.

Introducing Steam into Heating Coils

I have charge of a heating and ventilating plant. In the fan discharge there was originally 6400 feet of 1-inch pipe, through which the exhaust steam of a 9x16-inch engine exhausted, the exhaust inlets being along one end of the coils. While handling the maximum quantity of air the end of the coils farthest from the inlet remained quite cool, while the end next to the inlet had a temperature of 130 degrees Fahrenheit.

It happened that on the side of the plenum chamber where the cold air entered, there was one room in particular where the cold air came in underneath and, the building being constructed of concrete, the floor of that room was always cold. There were also in the room a glass skylight, four large windows and four partially glass doors, while about one-third of the partition wall was glass. The occupants of this room complained at various times about it being cooler than the other rooms, which were all heated from the same plenum chamber.

The coils were put together with right-and-left couplings, 9 feet high, and inclosed in a casing of No. 20 sheet steel, with folded seams, riveted together. To take the two coils out, turn them around and introduce exhaust steam from the other side would cost about $75.

The following method was used. The casing was cut about 1 foot high and the

HOW THE JOINT WAS MADE

[illegible]

removed, so that steam at any pressure desired could be admitted and an equal temperature in both ends of the plenum chamber obtained.

[illegible]

Seattle, Wash.

Commutator Troubles

Referring to the inquiry of [illegible], concerning a commutator trouble, I would state that there are numerous causes for sparking brushes and commutators. It is sometimes due to poor machine design, and in such cases cannot be remedied by the operator.

[illegible]

Quincy, Mass.

[illegible]

and give the commutator a good sandpapering in order to remove any roughness, and fit the brushes to the commutator by drawing a piece of sandpaper back and forward under the face of each brush. Start up the machine and wipe a little dynamo oil on the commutator; if possible, run the machine without load for a few hours, wiping a little oil on the commutator occasionally in order to get a gloss.

H. Jahnke.

Milwaukee, Wis.

I believe the trouble is due either to overload, which causes the machine to heat up, or to a dirty commutator and brushes. Carbon brushes produce a coating on the commutator which insulates and blackens it in spots. This film is liable to mix with the carbon dust, coating the brushes with a nonconducting, sticky substance.

Vibration is another cause of sparking, and a poor foundation will cause the vibration. Belt slipping will also cause sparking, as will weak fields or a ground, and high or low bars will also cause this trouble.

Francis J. Doyle.

Benson, Minn.

The trouble with Mr. Baker's commutator is that it is not even. I advise him to turn it off and then sandpaper it. The brushes should be adjusted to the load, which will often stop the sparking. A little sandpapering of the commutator while running will, as a rule, keep it in good condition. I also find that a little vaseline used on a commutator keeps it in a smooth, glassy condition.

Why not try a set of graphite brushes in place of the carbon brushes? I find they give good results.

Maurice W. Campbell.

Brooklyn, N. Y.

I believe Mr. Baker's trouble is due to various causes, such as improper setting of brushes, uneven tension, poor connection between the brush holder and leads, but probably the real trouble is in the commutator.

I have found most of such trouble to be caused by high or flat bars. If the commutator is badly burned on one bar, it indicates an open coil.

Paterson, N. J.

A Chronograph

All specifications for steam engines which are to be used as prime movers for electric generators contain a paragraph stating the allowable variation in angular velocity of the revolving parts. This may or may not be lived up to by the builder, and can only be determined by actual test. The following is the description of a chronograph which has been used for this purpose with excellent results.

This instrument consists of a hollow drum made of an alloy of 75 per cent. aluminum and 25 per cent. zinc fastened to a spider and suitably mounted on a bedplate of the same material. The drum is connected to a clock and governor by gears, as is also the feed screw, on which is mounted a tuning fork vibrating 100 times per second. The ratio of the gears and the feed screw is such that the carriage moves about half an inch for each revolution of the drum. Near the end of the tuning fork is mounted a small magnet which keeps the fork in vibration. A general idea of the arrangement of the chronograph may be obtained from Figs. 1 and 2.

When any engine is to be tested six or eight small holes are drilled and tapped at equal distances on the edge of the rim of the flywheel, into which are screwed steel pins about 3 inches long. The chronograph is connected as shown in Fig. 3. A piece of blueprint paper is placed on the drum and the pointer at the end of the fork draws a continuous record, as shown in Fig. 4. A brass nozzle is so placed that a jet of salt water issuing from it will strike each pin in turn, closing the condenser circuit, as shown in Fig. 3, and in discharging through the drum make a spot on the record. After the record has been taken it is a very easy matter to determine the variation in the velocity of the flywheel by comparing the space in time between the spots on the record.

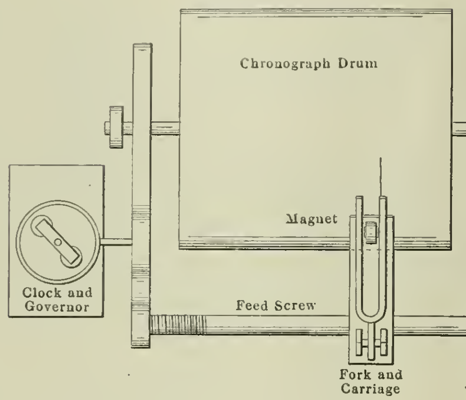

FIG. 1

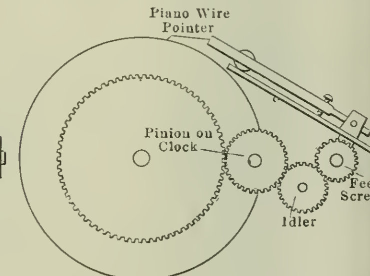

FIG. 2

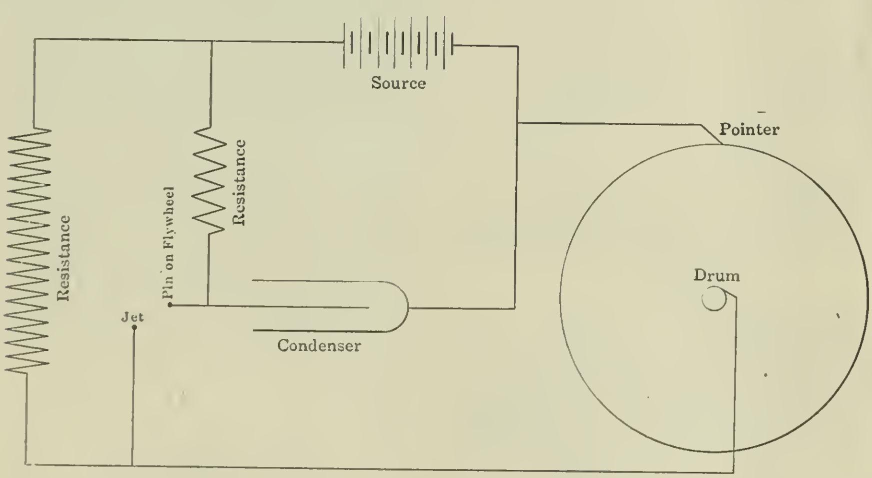

FIG. 3. DETAIL OF CONNECTIONS

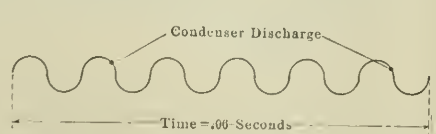

FIG. 4

Rope Drive for Governors

In an article in the December 8 issue, by Cornelius T. Myers, is shown a rope drive for governors. It seems to me that its only advantage is the reduced liability of the drive breaking. If the belt shown in Fig. 1 slips, it must be due to looseness of the belt or to "freezing" of the governor.

If the safety stop is adjusted so as to operate before the idler reaches the lower part of the belt, provided the upper part is the slack side, there can be no danger of slipping. If the governor "freezes," then the rope will either slip or break something.

It looks to me as if ball or roller bearings would serve a useful purpose in governor design to eliminate friction.

Berlin, Can.

Mr. Sheehan's Motor Trouble

I have read with a great deal of interest the description by Thomas Sheehan, on page 1011 of the December 15 issue, of a peculiar case of trouble which happened with two compound-wound 250-kilowatt General Electric dynamos, one of which was driven as a generator by a water wheel, while the other was operating as a motor in a mill about half a mile away. The statement that the meters were reversed gives a clue to work from right away. This shows that the polarity of the generator had been reversed by the accident, which could have been accomplished in any one of three ways: By reversing the direction of rotation and the connections of the shunt- and series-field windings, by shifting the brushes back the distance of the pole pitch and keeping the direction of rotation the same, or by reversing the polarity of the field magnet without changing the direction of rotation or the connections of shunt- and series-field windings.

The first two methods resemble each other in that the magnetic flux traverses the magnetic circuit in the same direction in both cases, that is the polarity of the field remains unchanged. It is evident that the polarity of the machine in the present case was not reversed by either of the first two methods, which leaves only the hypothesis that it was reversed by reversing the polarity of the field magnet, which was doubtless accomplished in the following manner:

The connections of the machines are shown diagrammatically in Fig. 1, both the generator and motor-field windings being connected differentially, that is, so that the series-field winding opposed the magnetizing effect of the shunt winding, which has the effect of weakening the field strength as the load current increases.

When the beater was thrown on and pulled the speed of the motor down to a low value this caused a heavy current to flow through both machines, and this current flowing through the series-field windings and aided by the armature reaction due to the large current in the armatures, reduced the field strength of both machines to a very low value. The line current rose to such a value that the series-field winding of the generator completely neutralized the shunt-field winding and reduced the generator voltage almost to nothing, the voltage being merely that due to residual magnetism in the iron.

The rheostats in the shunt-field circuits of the machines were evidently adjusted so that the shunt-field excitation of the generator was considerably stronger than that of the motor, and assuming that the series-field excitation of the two machines was equal for any given current, the ratio of the strength of the shunt winding to that of the series winding was greater in the generator than in the motor. This being true, when the line current had increased sufficiently to neutralize the shunt winding of the generator, the shunt winding of the motor was more than neutralized and the polarity of its field magnet was reversed and built up in the opposite direction by the series winding.

The motor armature was still revolving with considerable inertia and built up a generator electromotive force with the

Fig. 1

polarity at its terminals reversed, but with the current flowing through the circuit in the same direction as before. This is all that was needed to overcome the residual magnetism of the generator and reverse the polarity of its field magnet and, consequently, that of the machine terminals.

As soon as the motor began to act as a generator it slowed down and soon stopped, while the generator, being driven by the water wheel, built up to normal voltage of reversed polarity, which left the motor armature short-circuited across the generator terminals as indicated in Fig. 2.

It is evident that the current in the line and series-field winding of the motor rose to a large value instantaneously, while the current in the shunt field came up very slowly, due to inductance (or not at all if the field rheostat was equipped with a no-voltage release), hence it is evident that the field of the motor was reversed by the current in the series winding and was also weak, while the

Fig. 2

polarity at the terminals was reversed, which would cause the motor to start backward at a high rate of speed with very poor commutation due to the large armature current and the weak field. Opening the line switch caused the motor to come to a standstill, and if the shunt field was excited, as it should have been, before the armature circuit was closed, the machine would start up in the right direction, but the meters would be reversed, due to the reversed polarity of the generator.

From the foregoing analysis it is evident that the field windings should be changed to a straight compound connection instead of the differential connection, or the same trouble will occur again.

E. C. Hales.

Schenectady, N. Y.

In regard to Mr. Sheehan's motor trouble, I would say that according to the arrangement of starting, there is no governor on the water wheels and the gates are throttled for a given load.

When the large beater was thrown on the probabilities are that the gates were not open far enough for the generator to supply the required amount of current to the motor to carry the load, and the motor was brought to a standstill. This practically caused a short-circuit on the generator, still further reducing its speed and voltage. This low voltage at the generator reduced the shunt-field current and left the fields in an unstable condition. Then, the large armature reaction, caused by the short-circuit current flowing in the armature, reversed the field magnetism of the generator, causing the reversal of polarity which is noted by the action of the meters.

The reason the motor started off in the opposite direction when the beater was thrown off is probably because the motor was differentially wound, and when the motor was almost stopped, and still connected to the line, the current circulating through the series field and armature was greatly in excess of normal, and the magnetic field set up by the series field overcame the weak shunt fields. They were weak on account of the low voltage at the motor, and the required field current was not sent through, thus causing the direction of rotation to be reversed. The excessive speed is due to the weak field.

It is natural that the motor should start up in the right direction after the shutdown, because on starting everything was in normal condition and the shunt field fully excited before the current was applied to the armature. If the line current is reversed, as shown by the meters, it will not change the direction of rotation of any direct-current motor. It would be advisable to have the fields of the motor connected up cumulatively and also recharge the shunt fields of the generator back to their proper polarity.

[illegible]

[illegible]

With reference to the experience of Thomas Sheehan, described on page 1011 of the December 15 number, I should like to offer the following explanation:

If the field windings were connected up when the machines were shipped by the manufacturers, they were probably arranged for cumulative compounding, that is, the shunt and series fields assisting each other. When such a machine is run as a motor without changing the field connections it will operate as a differential compound motor, the shunt and series fields opposing each other, because the relative direction of current in the series field has been reversed.

When the motor was stalled by the overload, there was, momentarily, an excessive current through the armature and the series field. This produced an excessive magnetomotive force opposing the shunt-field magnetomotive, and must have overpowered it, thereby reversing the residual. The reversed field would cause the motor to reverse its direction of rotation, which condition would endure until the shunt field again established the correct polarity. The weakening of the field on account of the differential action would account for the high speed.

SELBY HAAR.

Schenectady, N. Y.

It is my impression from reading Mr. Sheehan's letter that when used as a motor the machine's series fields were connected as they were originally, when the machine was to be used as a generator, with the result that when the machine was stalled the very heavy rush of current through the series fields was sufficient to overpower the shunt.

The voltage had probably dropped considerably at the same time, so that when the clutch was thrown off, the series field predominated, and the motor then acted as a series motor, reversed and tended to run away. Opening the circuit under heavy load and low voltage reversed the generator so that on starting again the motor operated correctly, the instruments, however, being reversed. It would be interesting to know what did happen at the generator end.

HENRY D. JACKSON.

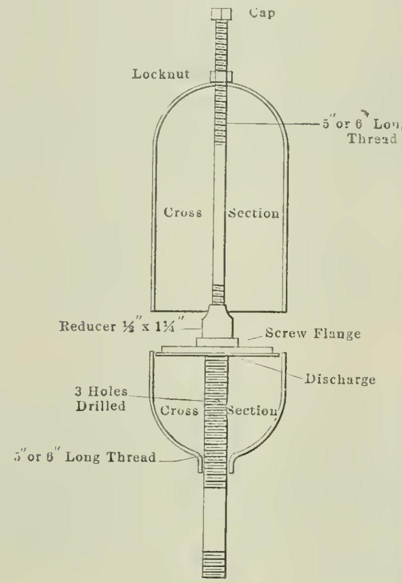
Boston, Mass.

Whistle Made from a Mercury Flask

The accompanying illustration shows a whistle made from a mercury flask. The flask was cut in half, about 3 inches from the filling plug, and tapped at the filling plug for a 1¼-inch pipe. A piece of 1¼-inch pipe, about 10 inches long, was cut with an ordinary thread on one end and on the other end a long thread about 5 inches long, and screwed in the smaller half of the mercury flask.

A disk was cut from a sheet of ⅛-inch copper plate, $\frac{1}{32}$ inch less than the inside diameter of the flask, and a hole cut in the center so as easily to slip over the 1¼-inch pipe. A 1¼-inch screw flange was riveted to the copper disk and screwed on the end of the pipe flush with the small half of the mercury flask. A ½x¼-inch reducer was made a locknut to keep the disk from working loose. The protruding thread was cut off flush with the reducer.

A piece of ½-inch pipe, 13 inches long, was cut with an ordinary thread on one end, and a thread 6 inches long on the other end, and screwed in the reducer. The larger half of the flask was tapped for a ½-inch hole and a ½-inch iron pipe screwed into it. This was screwed onto the 6-inch thread the required distance to



SECTION THROUGH THE WHISTLE

obtain the tone of the whistle and locked with a ½-inch locknut. The other end of the ½-inch pipe was capped.

A. C. HARRISON.

Jersey City, N. J.

An Error in Figures

In reply to the letter written by W. E. Sargent, and published on page 963 of the December 8 issue, I would say in defense of the N. A. S. E. that since Mr. Sargent got his information from the *Boston Globe,* I would much rather believe that the reporter for the *Globe* erred in his report, than to believe that Mr. Sargent was right, as per his formula for a 150-horsepower engine, using 30 pounds of water per horsepower-hour, running 10 hours per day, steam costing $15 per 1000 pounds, or a total of $675,000 per day.

I would suggest the following formula for Mr. Sargent:

$$\frac{150 \times 30}{1000} \times 10 \times 15 = \$675,$$

which would be an unreasonably high cost for power.

I would further add that in a locality where fairly good steam coal sells for $4.50 per ton, figuring about 7 pounds of water per pound of coal, this problem would figure out as follows:

$$\frac{150 \times 30}{1000} \times 10 \times 0.32 = \$14.40$$

per day.

From this result I would rather believe that the Boston association that gave the reporter the estimate on power cost, gave it as from 0.15 to 0.30 per 1000 pounds of steam, rather than from $1.50 to $3, which mistake could easily be made by misplacing the decimal.

C. G. SIGWALD.

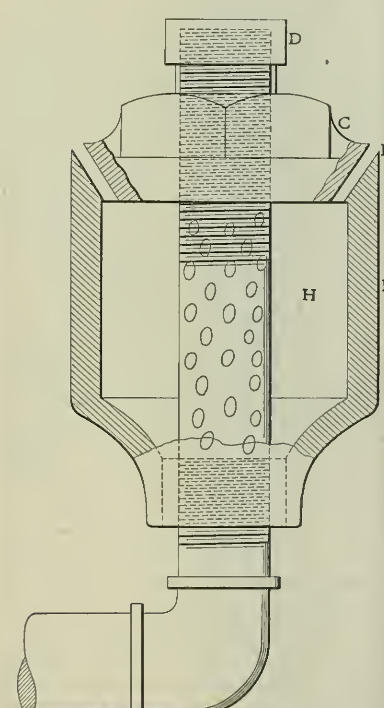
Minneapolis, Minn.

Homemade Blower Head

Herewith is a description of a blower head which I used in the stack of a 60-horsepower return-tubular boiler.

To make it I used a 2x¾-inch reducing coupling, turned out as shown at *B*. A short piece of ¾-inch steam pipe *A*, so threaded as to reach entirely through the coupling 1½ inches at the top, was obtained; also a reducing bushing turned down to cone shape as at *C*, and a ¾-inch pipe cap *D*.

The ¾-inch pipe was drilled with twenty ¼-inch holes, as at *H*, for the steam to pass to the body part of the coupling. The reducing bushing was screwed on, as shown, until the space *E* was $\frac{1}{32}$-inch wide.



HOMEMADE BLOWER HEAD

The idea is that the steam coming out in funnel shape will catch the entire column of air inside the stack and force it out, where a simple piece of pipe would only set a core of air in motion in the center of the stack.

HERMAN E. KING.

Columbia, S. C.

A Concrete Feed-Water Storage Tank

Why Such a Tank Is the Most Serviceable; Plain Directions for Building One; Used for Water Softening, Also, with the Lime Process

BY WARREN H. MILLER

Whenever a power plant uses city water, or, in fact, any source of feed water other than the direct suction of its own feed pumps from some natural supply on the ground, this feed-water supply at once becomes the most vulnerable point in the power system. Stoppage of this supply ties up everything. It is always sudden; it seldom lasts long; but in the short hour or so that it does last, there is nothing for it but to bank fires and shut off the steam all over the plant. Those who have managed large steam distribution systems do not need to be reminded of what a dangerous, uncertain business starting all this up again is.

If it is the city water you are dependent upon, your first notice is usually of the man with the monkey wrench, who announces that your main is going to be shut off in half an hour to make some change five blocks up the street. Or else it is a telephone call, to the effect that a main has burst and your main will be out of business until the street is dug up and the thing repaired.

If you pump your own feed water from a well your shrift is likely to be still shorter. The well-pump steam valve sticks, and you have precisely the capacity of the small storage tank to run your boilers on. In fact, it is absolutely essential to provide three or four hours' storage capacity for boiler-feed water. You must do this cheaply, and not use up any valuable building space, nor get too far from the power plant.

A cylindrical iron tank possesses a number of disadvantages. It holds little water for the land it occupies; it is expensive to buy and have delivered on the ground, besides requiring to be assembled on the foundation; it carries a depreciation of about 10 per cent. per annum and you can count on cutting it up for junk in fifteen years; it requires massive underpinning, unless the corner of some brick firewall is handy to the power plant, and heavy foundations if set on the ground. The cypress-stave tank is better, but has the same objections as to depreciation of iron work, area of floor space, etc.

Rectangular Concrete Tanks Best

On the whole, the rectangular reinforced-concrete tank offers the best proposition. It is easy to find ground space for it, in some angle around the power-house chimney, for example. It has no depreciation and requires no repairs. It costs hardly more than the foundations for an iron or wood tank. And at about the time you are thinking of replacing the latter because of old age, the concrete tank will still be gradually approaching its maximum strength—which is after the fashion of an asymptotic curve, as the mathematicians would put it.

The most economical way to get the thing up is to put most of the tank underground and leave not more than 6 or 8 feet above ground to resist water stresses. These mount up surprisingly with the height. At 6 feet the point of maximum pressure will be 432 pounds per square

FIG. 1

foot at ground level. It is entirely permissible to neglect the water pressure below ground. Even in poor soil, the resisting capacity of the earth surrounding the tank walls below ground can be taken at two tons per square foot, precisely as in foundations.

A pit is first dug, with plumb sides equal to the outside dimensions of the tank, and a footing or floor of concrete, about 9 inches thick, laid down. Next a box form of the inside dimensions of the tank is set up, and the space between it and the pit walls filled with concrete up to a foot below ground level. The overlapping rods for the above-ground section can now be set in place, and the work poured to ground level, securing the rods in position.

The design shown for the portion above ground, Fig. 1, makes a pleasing, strong, and economical construction. The pilasters are figured as beams to carry the whole load of the panels, and reinforced accordingly. The panels are treated as floor slabs figured on the pressure of water per square foot at ground level.

Constructing the Tank

The first carpentry work will be to set up the outside forms, Fig. 2, and nail the expanded metal to them, [illegible] strips of [illegible] flat strip steel being used to hold them off the surface of the forms. Another scheme is to drive two nails crossing at the intersection of the diamond meshes of the expanded metal. A single nail driven at the proper slant will also serve to hold the reinforcement about an inch off the forms, but is weak and liable to come out in the ramming and placing of the concrete. It is mentioned here because carpenters are too apt to discover this method themselves, and to work it with enthusiasm as being the easiest possible method.

A dense, impervious, rather [illegible] concrete should be used. The 1:2:4 mixture gave very good results in the tank illustrated. It will have no bad spots in it, nor will it leak or sweat. Rock concreting is not permissible. Remember that you are pouring into a thin shell, only 4 inches wide including the expanded metal. The actual space in which to pour is only 4 inches. Rock is sure to bunch and arch. [illegible] the expanded metal [illegible] the form. Of course, before pouring, the [illegible] be [illegible] in the lower section and raked to [illegible] the outside forms and the sheets of expanded metal which reinforce the [illegible] should be placed lapping down a foot or so into the wall forms; also the longitudinal reinforcing rods of the beams, which is figured as a grand beam like the pilasters.

[illegible]

[illegible]

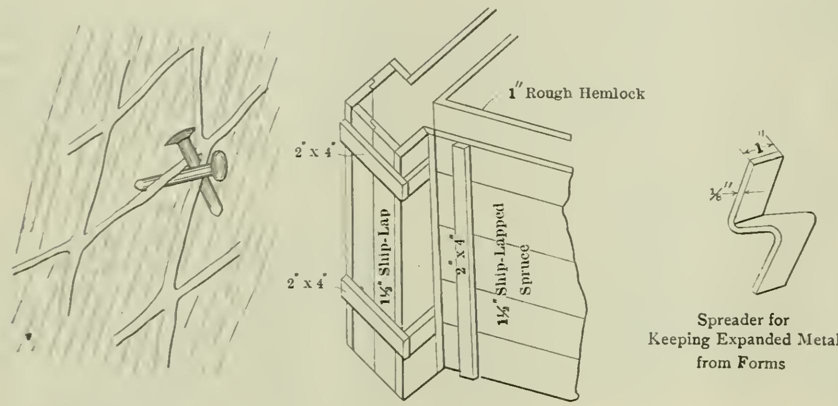
anthracite-cinder filling. The city water was led into it at ground level from a spur of the suction piping. When using the tank water, the meter valve was closed and the tank valve opened, when the feed-pump would suck it back through the same pipe.

It often occurs that there is exhaust steam. not otherwise condensable, which may be led into the feed-water tank. If a tee is left on the main exhaust pipe, and is well worth while, being inexpensive and in no sense a nuisance.

Tank Suitable for Water Softening, Also

A farther use for this tank is for water softening where the lime process is used. There is plenty of depth for settlement, and the large 24x24-inch manhole in the ceiling gives facility for handling the sludge. If boiler compounds are used, was charged with its quota of compound. To do this, the drip in the bottom of the charger was opened, and the feed water drained out of it. It was then filled by way of the funnel at the top with a saturated solution of the compound. The connecting nipple valves were then opened and the main feed gate shut, thus forcing the incoming feed water to pass through the charger driving along the compound before it. As only one set of boiler checks was left open, that particular boiler received the total charge intended for it.

The actual cost of the feed-water storage tank described was $482.26; the iron tank which it replaced cost $648.68, including $120.56 for a foundation of 10-inch I-beams cut into brick walls across a 14-foot alley between two buildings. This is the cheapest possible foundation. Supposing that the iron tank were to be placed on concrete piers on the site of the present tank, the tank being 12x12 feet, five piers would be required besides the footing. With the top of the piers 2 feet above grade and the bottom of the footings 4 feet below, the estimated cost of this foundation would be about $140. As the tank itself cost $528.12, set up, to replace the concrete storage tank with a

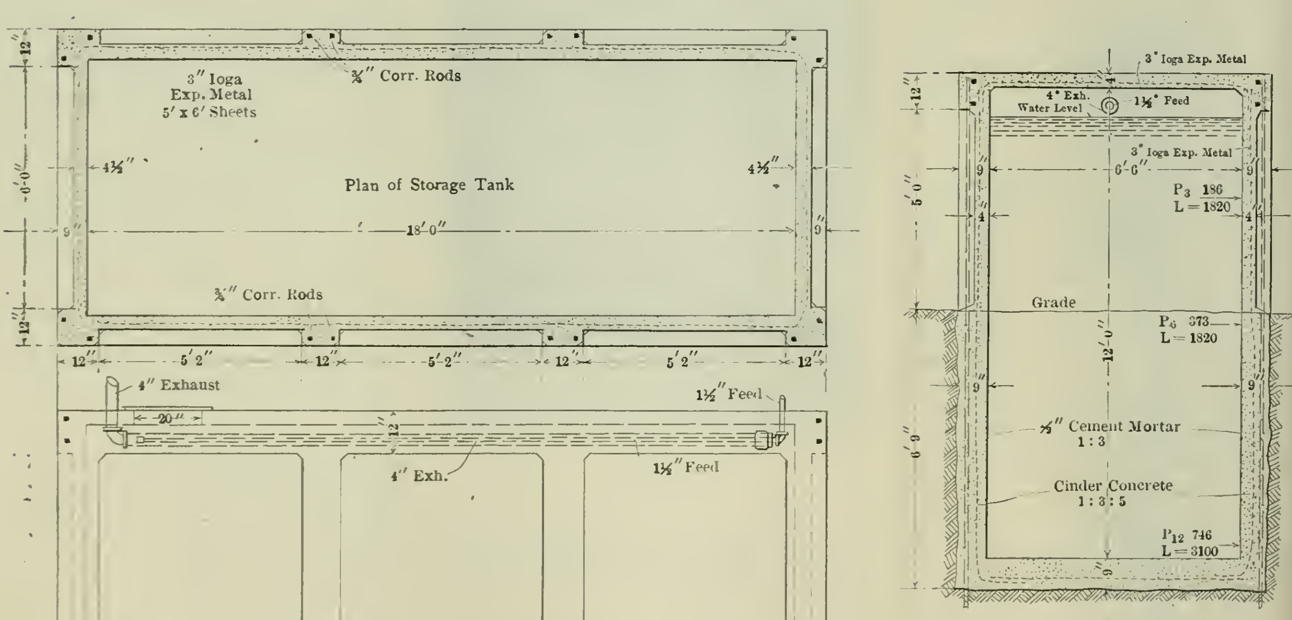


Crossed Nail Spreader

Sketch of Forms

Spreader for Keeping Expanded Metal from Forms

FIG. 2



Side Elevation

Cross-Section

FIG. 3

a suitable pipe led off to the tanks, much of this steam will be condensed and give a preliminary heating to the feed water. This pipe should run the length of the tank just above the water. Into the opposite end enters the water-supply pipe, about 1½ inches in size, and perforated all along the top with ⅜-inch holes. A large surface of cold, flowing water is thus exposed to the incoming steam, and a quantity of heat interchanged. This economy the writer prefers to introduce the charge directly into the feed line. For that purpose, a 4-inch nipple, capped at both ends, exactly held a charge for one boiler. This was by-passed around the main feed-line gate valve by attaching it above and below with ¾-inch nipples with a ¾-inch union and valve in each nipple. A drip valve was put into the bottom cap, and a feed valve and funnel tapped into the top. Just after blowing down, each boiler in turn steel one on the same site would cost $668.12. The cubic contents were identical.

When the terminal pressure of an engine cylinder is practically equal to the back pressure, as in some compound engines, the mean effective pressure formula reduces to

$$p_m = p_b \log R,$$

p_b being the back pressure.

Electric Dynamometers

By G. Everett Quick

Motors have often been rated from so-called power determinations in which the power was absorbed by crude devices or standard machines giving merely an estimated value, subject to wide variations. A true test worthy of the name, requires some means of loading by which observations may be made for accurately computing the power developed. The apparatus for doing this is called an "absorption dynamometer," while a transmission dynamometer is an apparatus by means of which the mechanical power delivered by one machine to another may be measured.

The simplest type of absorption dynamometer is the friction brake, which is made in various forms. In all forms of this brake, the force opposing rotation is obtained by the friction of a revolving pulley with a strap, disk, or wooden arm adjustably clamped to it. If these are clamped to the pulley and allowed to revolve freely with it, the load is zero, but if held stationary, the weight or spring required to hold the brake from revolving is a direct measure of the power absorbed by the friction. Fig. 1 shows an outline sketch of a prony brake, in which A is the friction wheel, L the horizontal distance of the weight from the center of the wheel, which is the radius of the circle which would be described by the suspended weight if it were allowed to revolve with the friction pulley. The imaginary speed, in feet per minute, which this weight would attain under these conditions, multiplied by the weight opposing this rotation, gives the power absorbed in foot-pounds per minute. The imaginary speed is obtained by multiplying the length L of the arm by 6.2832 and multiplying this product by the revolutions per minute made by the wheel A. In short,

6.2832 × *Rev. per min.* × *Arm length* × *Weight* = *Foot-pounds per minute*,

and

$$\frac{\textit{Foot-pounds per min.}}{33{,}000} = \textit{Horsepower}$$

By the use of a chart similar to that shown in Fig. 2, separate calculations for each reading may be avoided. A chart for each length of brake arm is required.

Electric Dynamometers

The well known prony brake is still used in the great majority of tests, and on account of its simplicity and low initial cost, and in spite of its inherent defects, it will no doubt always be widely used. However, other types, such as the Alden brake and the electric dynamometer have been developed which are practically free from the erratic and excessive vibrations characteristic of the prony brake, and mechanical power absorbed by these types may be accurately measured within a fraction of a per cent. Furthermore, the two classes of apparatus mentioned are not only used for loading small units, but may be made in single units capable of absorbing far more power than can be satisfactorily absorbed by a single prony brake.

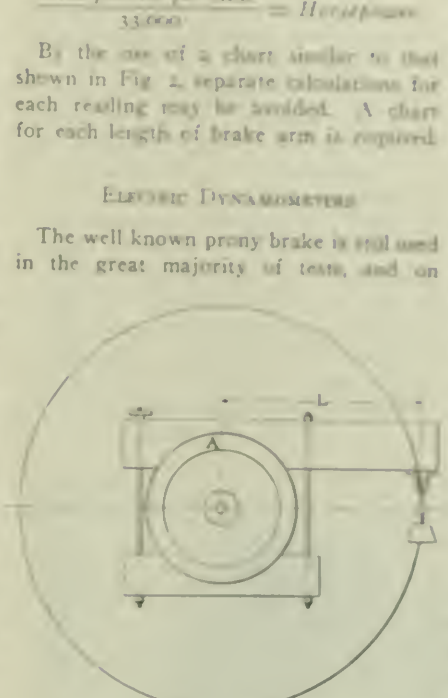


FIG. 1. SIMPLE PRONY BRAKE

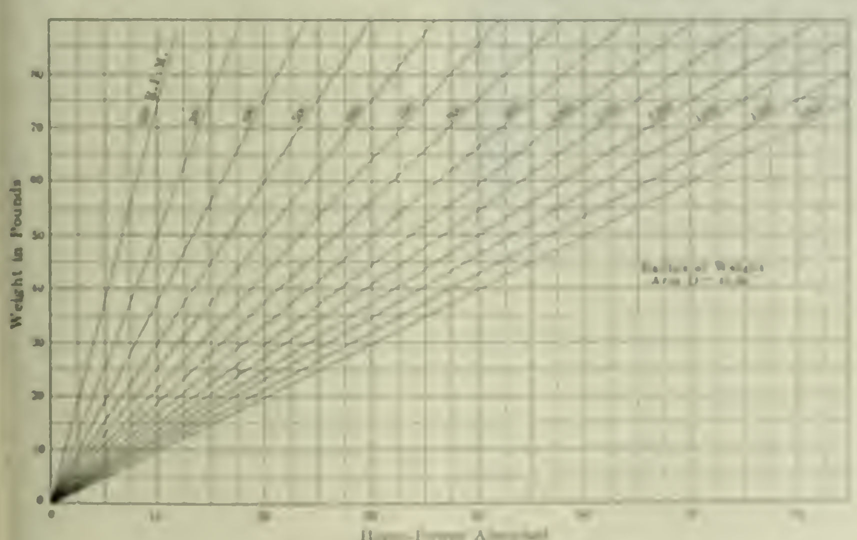

FIG. 2. REFERENCE CURVES FOR DYNAMOMETER

In all types of electric dynamometer, an electric generator, usually a direct-current machine, transforms most of the mechanical energy of the test motor into electrical energy, which in turn is dissipated as heat in an external circuit, or in the armature itself. Under certain conditions, the power ordinarily wasted in rheostats may supply useful power to other circuits.

The best known type of electric dynamometer, and in fact the only one which has been extensively used, is the standard electric interchangeable motor or generator connected by belt or flexible coupling to the test motor. When used to load motors of widely varying speed, the belt drive with different pulley ratios is necessary. Since the power absorbed is measured by the generator output in electrical units, the variable losses of the driving belt and armature resistance make a calibration curve very uncertain. With direct drive the curve is more reliable, although subject to variations due to the variable resistance of the generator conductors. The electric output and consequently the load on the motor, is controlled by passing the electric current through an adjustable rheostat. For small capacities a metallic rheostat, usually of the iron "grid" type, may be used, but for medium and large capacities the well known water rheostat is more practicable.

The so-called "cradle" dynamometer differs essentially from the above only by suspending and balancing the field frame of the generator on knife-edges or frictionless bearings and measuring the power by the torque between the field magnets and the revolving armature. It affords an easy, accurate and efficient means of obtaining instantaneous readings of the brake horsepower of an engine and also of putting full load on it for a continuous running test without excessive heating of the dynamometer. It may be used as a transmission dynamometer to give instantaneous indication of the power required to operate any particular machine by noting the pounds pull exerted at the end of the weight lever and the speed of the rotating armature. It affords a simple and accurate method for determining the horsepower required to operate the machines without the necessity of calculating efficiencies, reading electrical instruments, etc., as would be required with the usual method of testing with a standard electric motor. Owing to the simplicity of apparatus and calculations, the test may be made by comparatively inexperienced attendants.

The general arrangement of the electric dynamometer as manufactured by the Sprague Electric Company is shown in Fig. 3. The machine consists of a specially constructed direct-current generator of the familiar standard-yoke type, with compensating poles. The stationary part is supported on ball bearings in each a manner as to permit the field magnet to oscillate about the armature, remaining concentric, of course, in order that it may revolve freely under all conditions. Two arms extend horizontally from opposite sides of the field-magnet frame to which they are rigidly secured. The short arm or balance lever contains an adjustable weight to balance the complete dynamometer on its bearings. The long arm or weight lever is provided at its outer end with a hanger similar to that on an ordinary platform scale, on which slotted weights may be placed, or if preferred a spring scale may be used for measuring the pull exerted at the end of the lever when the dynamometer is in operation.

The torque exerted by the revolving armature on the field magnet tends to carry the frame around with the armature, and this torque acts in a similar manner to that of the frictional resistance of the friction brake, but without the objectionable vibrations.

Although the electric dynamometer is used more for absorbing a known mechanical power, it can also be employed as a combined motor and indicator, driving a machine and at the same time measuring the power required to do it, thereby serving as a simple transmission dynamometer.

The current for driving is obtained from any direct-current circuit of suitable voltage. The commutating poles afford a very wide range of speed control by varying the field strength with the rheostat connected in the shunt-field circuit of the machine.

Owing to the fact that this dynamometer can be used regularly as a power motor for driving shop equipment, comparatively little added capital is required to avail oneself of such a test outfit.

Eddy Current Dynamometer

A special form of electric dynamometer is the so-called eddy-current brake, which meets with a somewhat limited use as an absorption dynamometer for comparatively small powers when a continuous load is required. The field-magnet yoke and attachments are constructed and balanced essentially the same as in the previous type, although the field excitation must be obtained from a separate source. The armature, instead of having the customary winding and commutator with connections to an external circuit, is made up of copper disks or other short-circuited conductors in which currents are set up by rotation with the field and the heat thereby generated is dissipated to the atmosphere by radiation and connection without recourse to an external rheostat. However, a small rheostat is required in the field circuit for regulating the strength of the field magnet, and consequently the load absorbed.

The rotor of this dynamometer is very rigid and is not subject to electrical breakdown; there being no armature wiring, commutator or external circuit, the initial cost is less than that of the dynamo type. Obviously, the capacity of this type is limited to small powers as only a limited amount of energy can be dissipated in the form of heat by air cooling. However, the temperature of the rotor may be allowed to reach a much higher value than that allowed in the dynamo, since no combustible material need be used in its construction.

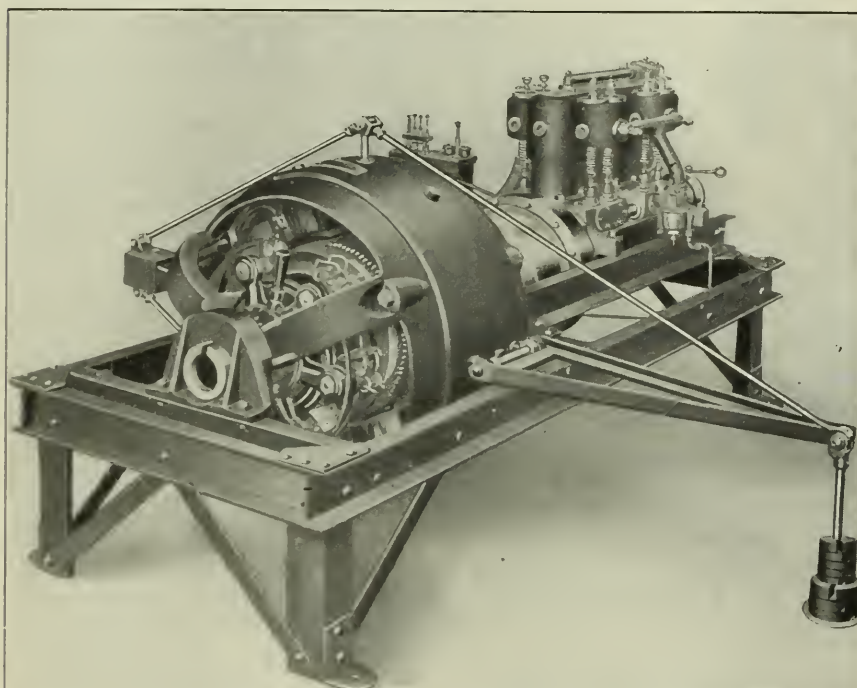

FIG. 3. ELECTRIC DYNAMOMETER COUPLED TO AN AUTOMOBILE ENGINE

Compound Cylinder Ratios for Equal Work

In the following is shown, step by step, the derivation of the formula by which was prepared the table of cylinder ratios, on page 215 of this number:

Let I = Initial pressure absolute,
t = Terminal pressure absolute,
b = Back pressure absolute,
R = Ratio total expansion,
r = Volumetric ratio of cylinders,
$M.P.$ = Mean pressure,
$M.E.P.$ = Mean effective pressure.

$$R : 1 + \log_\varepsilon R :: I : M.P.$$

$$M.P. = \frac{I\,(1 + \log_\varepsilon R)}{R} = \frac{I}{R}\,(1 + \log_\varepsilon R). \qquad (1)$$

But $\frac{I}{R} = t$ and

$$M.P. = t\,(1 + \log_\varepsilon R). \qquad (2)$$

$$M.E.P. = M.P. - b.$$

So that

$$M.E.P. = t\,(1 + \log_\varepsilon R) - b \qquad (3)$$

If the work is to be equally divided the mean effective pressure in the low-pressure cylinder will be

$$M.E.P._l = \frac{t\,(1 + \log_\varepsilon R) - b}{2} \qquad (4)$$

and the *mean* pressure in that cylinder

$$M.P._l = \frac{t\,(H \log_\varepsilon R) - b}{2} + b. \qquad (5)$$

By transposing formula (2) it is seen that

$$\log_\varepsilon R = \frac{M.P.}{t} - 1. \qquad (6)$$

Substituting for $M.P.$ the value given by formula (5) the $\log_\varepsilon$ of the ratio of expansion in the low-pressure cylinder (which is the same as the volumetric ratios of the cylinders, for the contents of the high- are expanded to the volume of the low-) is found to be

$$\log_\varepsilon r = \frac{\frac{t\,(1 + \log_\varepsilon R) - b}{2} + b}{t} - 1 =$$

$$\log_\varepsilon r = \frac{\log_\varepsilon R + \frac{b}{t} - 1}{2} \qquad (7)$$

when $\frac{b}{t} = 1$, i.e., when the diagram ends in a point this reduces to

$$\log_\varepsilon r = \frac{\log_\varepsilon R}{2}, \qquad (8)$$

and since halving a logarithm gives the logarithm of the square root, formula (8) simply means that for the condition cited

$$r = \sqrt{R}.$$

Heat in Steam

By Joseph H. Hart

The question of the amount of heat in steam under various operating conditions, the quantity of this heat available for transformation into work and the various relations of this heat quantity which produce condensation and superheating and other equally important changes in the steam content is a question of the greatest importance not only to the designing engineer, but to the operating and stationary engineer as well. As a general thing almost every man familiar at all with the operation of steam engines has a little information in regard to the subject of heat units and a number of heat changes and the amount of heat available under certain circumstances, but in regard to all the heat relations possible in steam under various conditions of operation they are not familiar. Thus such statements as the one that the quantity of heat in steam is approximately the same independent of its temperature is one not easily understood. Again, the statement that the specific heat of saturated steam is negative leads to an interesting situation and one not clearly understood by the average operator. These two examples will serve to illustrate the type of difficulties which arise, and it is the object of this article more fully to explain the connection of heat and steam, the variation of amount with temperature and the variability of the quantity available for transformation into work under various standard conditions and the causes of steam condensation under conditions not clearly understood.

Thus it is assumed that the average engineer or reader of this article is more or less familiar with the definitions of specific heat and latent heat and has a clear conception of what is known as heat quantity. Specific heat is defined as the quantity of heat required to heat one pound of material one degree Fahrenheit, measured in B.t.u., where a B.t.u. is the quantity of heat required to raise one pound of water one degree Fahrenheit. This heat quantity is referred to heat held by water under varying conditions, and the specific heat is often defined as the ratio of the heat under certain circumstances to that in an equivalent mass of water under the same circumstances. Latent heat is defined as the quantity of heat required to change the state of a body without change in temperature, and it is generally known that this latent heat is given out in condensation or solidification, but absorbed in liquefaction or vaporization. However, this definition is not general enough and often leads to considerable ambiguity, whereas a broader statement of the case would explain many difficult facts as they arise and will not complicate the conditions at the outset in any respect.

Latent Heat Potential Energy

A rise in temperature of a body is nothing more or less than an increase in the kinetic energy of the molecules. The temperature of a body measured by the absolute scale is directly proportional to the mean kinetic energy of the molecules, and these can best be regarded as little bullets flying around through space, in the case of a gas, and producing pressure by their multitudinous bombardments. In a liquid they are fastened together by some unknown bonds, probably similar to gravitation, but still free enough to possess a certain free path and hence capable of possessing kinetic energy. Thus, when a pound of water is heated one degree, a portion of the heat or energy, is used to raise the kinetic energy of the molecules and a portion used to cause expansion or a stretching of the bonds which tie the molecules together. Latent heat is in reality potential energy of the molecules or energy of position and the molecules of water changed into steam possess potential energy of position in exactly the manner that a ball thrown above the surface of the earth, until it escapes the influence of gravitation, possesses energy of position. The molecules of steam have possessed at one time sufficient kinetic energy to rise from the surface of the water due to their motion against the force of cohesion, losing a portion of their velocity exactly as a ball thrown into the air does in rising higher and higher.

When water is heated one degree, a certain amount of heat or energy is used in raising the temperature or kinetic energy of the molecules of the water, and a small fractional part is used up in producing the change of relative position and is apparent as potential energy. The molecules have a variable speed ranging over several thousand per second, and the average or mean velocity or energy only is considered. When the water gets to the boiling point some of the molecules possess sufficient speed to rise high enough above the mass of liquid to become practically free from their attractive power and they lose during this maneuver a large amount of their kinetic energy, possessing after separation approximately the same average kinetic energy as the average molecule in the liquid. The removal of the high-speed molecules causes a diminution in the average speed of the remainder, and hence a fall in temperature unless heat is supplied. This supply in reality is the latent heat of steam. After the water is changed to steam the steam then possesses practically nothing but specific heat, or further increase in temperature means an addition only to the kinetic energy of the molecule. This is actually the case in what is known as superheated steam, in which case the steam behaves as a perfect gas and obeys Boyle's law and Charles' law absolutely.

What Happens if the Pressure Above the Steam is Increased

If the pressure above the water is increased, with less space the molecules are crowded together and a great many more collisions occur among the molecules endeavoring to escape from the surface of the water, and thus a larger kinetic energy per molecule must exist for the evaporation to go on, or simply that the temperature must rise before evaporation occurs. This is the reason for the rise in temperature of the boiling point with increase in steam pressure. The molecules, however, lose a smaller percentage of their kinetic energy in escaping from the water and attaining their position with its corresponding potential energy as steam, and hence the latent heat or quantity of heat used up in potential energy is diminished, and hence the further phenomenon of a fall in latent heat of vaporization with rise in temperature of the boiling point. The fall in latent heat or potential energy required compensates largely for the increase in apparent heat or kinetic energy, so that the total heat in the steam is the same as the potential energy of position of the molecules plus their kinetic energy or energy of motion. The latter undoubtedly varies with rise in temperature, but the specific heat of steam at that temperature, or the quantity of energy required to raise the kinetic energy of the molecules the fractional amount required per degree, is so small a percentage of the total energy involved that it is often neglected.

It is possible under some circumstances at least theoretically to increase the pressure on steam to a sufficient extent to eliminate the latent heat of position entirely. If the molecules are sufficiently packed to prevent separation from the liquid, the energy of position practically disappears and the molecules increase their kinetic energy only, and this phenomenon occurs at what is known as the critical temperature, pressure and volume respectively.

Action of Steam in Contact with Water

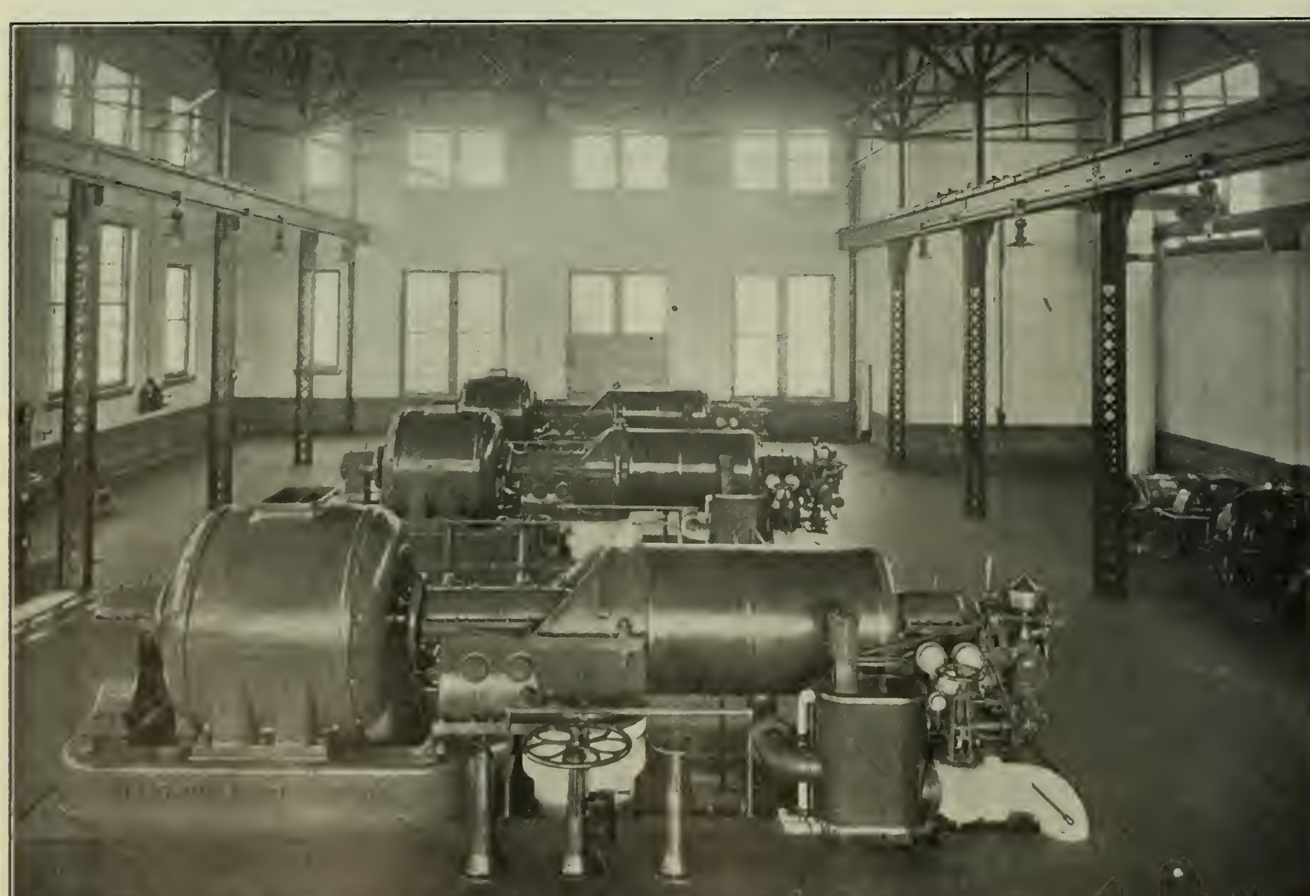
Steam in contact with water possesses anomalous behavior under varying conditions. The number of molecules in a given volume of steam at a given pressure, if the steam is saturated, that is at the temperature of the water in contact with it, is a certain definite quantity which [illegible] under [illegible] conditions. The best explanation of the phenomenon here is that there are as many molecules in the steam that [illegible] arise from the water and [illegible] from the steam into the water and are condensed as lose their energy of position and acquire an increased energy of motion due to the pressure exerted upon them. The molecules in the steam and water possess the same average kinetic energy. Since the same temperature, and only a certain number can exist in the steam, and the transfer of molecules to the steam from the water with the consequent loss in kinetic energy and production of potential energy of position, is exactly counterbalanced by the number of molecules of steam transferred from the steam to the water with their consequent loss of potential energy of position and equivalent rise in kinetic energy. Any increase in pressure on the steam or diminution in the volume of the same results in a crowding of the molecules from the steam into the water, with a corresponding increase in the average kinetic energy or temperature of the water and of the steam as well, since there are then less molecules in the steam and less potential energy in the system, with an increase in the average kinetic energy of all the molecules. This condition explains in reality what is known as the negative specific heat of saturated steam.

When steam in contact with water is heated one degree, the kinetic energy of the entire mass of molecules in both the water and steam is increased a certain definite percentage depending upon the absolute temperature of the system. The increase in kinetic energy of the molecules in the steam results in an increased pressure which means that a number of the molecules are transferred automatically to the water and give up their latent heat of position, which energy is apparent in increased average kinetic energy of the molecules. This energy results in a further rise in temperature. Hence when heat is added to a mixture of water and steam, or what is known as saturated steam, the amount of steam actually diminishes in quantity as determined by weight. The temperature of the water is raised a much larger amount than the heat put in would warrant according to the specific heat of the water, and the extra heat that is evolved in increased rise in temperature of the water and steam comes from the latent heat of condensation of the fractional part of the steam which disappears. Hence arises the statement of the negative specific heat or the production of heat with rise in temperature of saturated steam.

Cause of Much Difficulty in Design and Operation

This anomalous behavior of steam in contact with water is the cause of much difficulty in steam design and operation. Saturated steam, that is, steam in connection with the water in the boiler, changes in amount with every variation in pressure and volume of the same and does not behave as a normal perfect gas would under the circumstances. Thus with saturated steam entering the cylinder of a steam engine, the increase in volume which results from expansion in the cylinder and the transfer of a portion of the kinetic energy of the molecules into energy of the piston, results in a diminution in the kinetic energy of the molecules sufficient to cause a portion of the steam to change into water and to give up its latent heat, in order to maintain the temperature normal for saturated steam at this pressure and temperature. Hence, the phenomenon of cylinder condensation which is augmented greatly by the further radiation of heat through the walls.

Sufficient has been shown to warrant the statement that the behavior of steam under all conditions of operation and theory is a purely mechanical one, and the transfers of kinetic to potential energy and *vice versa* are responsible for all the anomalous conditions existing in the utilization of steam. Any difficulty or misconception or ambiguity that arises in the utilization of steam can be explained and clearly understood by a reference to the kinetic and potential energy of the molecules. This latter conception, known as the kinetic theory of gases, is the basis of thermodynamics and has suggested many possible developments of a mechanical nature which are used in practical applications to eliminate the more serious difficulties in power production in this field.



THREE ALLIS-CHALMERS STEAM TURBINES AND GENERATORS, EACH 750-KILOWATT 3-PHASE 60-CYCLE 2300-VOLT, INSTALLED IN THE NEW POWER PLANT OF THE PACIFIC MILLS, LAWRENCE, MASS.

Heat Losses in an Electric Power Station

At a recent meeting of the Institution of Civil Engineers, a paper was read on "An Investigation of the Heat Losses in an Electric Power Station," by F. H. Corson, of which the following is an abstract:

An inquiry, originating from Blackburn, in 1903, showed that the average coal consumption of 34 principal generating stations of the United Kingdom was about 7.7 pounds per unit generated. The figures ranged from 3.6 pounds to 15 pounds, Blackburn standing at 10 pounds. Rough tests on the various sections of the plant resulted in considerable rearrangement. The steam-pipe system was overhauled and more effectively drained, and steam separators and driers were in consequence dispensed with. Engine stop valves were, where possible, attached directly to the main steam pipes. The steam ring was discarded, and generally the effective heat-radiating surface was greatly diminished. Better-fitting boiler dampers were provided, the condition of the brickwork was improved, and the whole process of combustion was more thoroughly controlled by the institution of flue-gas analysis. These and similar alterations occupied about three years, and the fuel consumption fell during that time to about six pounds of the same coal per average unit generated, a reduction of 40 per cent. Further progress being imperative, it was decided to conduct tests covering the whole operation of the works, viewing the losses peculiar to each part of the plant in their relationship to each other and to the whole; and arrangements were made, and apparatus devised, for their prosecution. After isolated trials of the various types of apparatus had proved their reliability, simultaneous tests were arranged, of a duration long enough to embrace all conditions of operation met with in routine work.

The Blackburn undertaking comprises two adjoining stations of 2300 kilowatts capacity each, containing 12 mechanically fired Lancashire boilers, six fitted with superheaters; 15 high-speed engines driving generators from 60 to 775 kilowatts in size, controlled from three switchboards; steam piping 3 to 14 inches in diameter; ejector and jet condensers fed from an overhead water tank above the boiler house; low-speed steam-driven feed pumps; four batteries of economizers totaling 1504 tubes; two chimneys, 130 and 250 feet high, respectively. The test has covered during 168 consecutive hours the combustion of about 230 tons of coal, the evaporation of 3.176 million pounds of water, and the generation of 99,209 electrical units. The net results show a consumption of 5.15 pounds of coal, and a total evaporation of 33.9 pounds of water per average unit.—*Mechanical Engineer.*

Purchasing and Burning of Coal

By H. W. Richardson

The purchasing of coal for power plants of any great size should receive a great deal of consideration, as the economy of the plant depends much on the quality of the fuel which is burned. In not a few large concerns all coal is purchased by the company's purchasing agent, who in most cases does not understand the peculiar characteristics of coal and seldom, if ever, does he consult his engineer before making a purchase.

All coal companies sell the very best fuel obtainable, according to their agents, and the man who can show the purchasing agent a coal which is of high B.t.u. value and at a low price will invariably obtain the contract. The coal is then sent to the power plant and the engineer's troubles begin. The purchaser of the fuel understands that the coal contains a great many heat units, but he is generally ignorant of the conditions under which the coal is to be burned. What I wish to make plain is that the B.t.u. value does not show that the coal is just what is wanted for any particular plant. Every plant is, of course, equipped with certain grates or stokers, and these furnaces may be adapted to some fuels, but will not burn other grades economically.

The B.t.u. value of coal is determined principally by the amount of ash. One coal may show by analysis 15 per cent. volatile, 75 per cent. fixed carbon and 10 per cent. ash; another coal will show 25 per cent. volatile, 65 per cent. fixed carbon and 10 per cent. ash. The B.t.u. value of these two coals will be the same, but they do not burn equally under the same conditions. For a poor furnace the high volatile coal is unsuitable, and in many installations no adjustments are possible that will better the results. In this case, if a low volatile coal is tried, it will often solve the difficulty.

The coal dealer explains to the purchasing agent that his coal is high in heat value and offers it at a good figure, which will invariably attract the purchasing agent and cause him to purchase a large amount. He does not understand furnace peculiarities and it is then up to the engineer to burn the coal, and if results are not forthcoming he is sure to meet with severe criticism. In a particular case where conditions were as stated above, the excess amount of cheap fuel burned made it in reality quite expensive, simply because the fuel was not adapted to the plant. The adaptability of the coal is more necessary in stoker plants than in hand-fired plants. In practically all stoker furnaces it is absolutely impossible to use one fuel. Some fuels even among those of high heat values, will not burn properly unless they can be worked and stirred up frequently.

To determine which coal is adapted for a particular plant, most engineers will agree that it is good practice to sample and analyze all cargoes received. This procedure is proper to pursue in order that the purchaser may be assured that he is receiving coal of the quality he desires and it will determine whether or not the coal dealer is fulfilling his obligations. Simply knowing the B.t.u. value of the coal, however, is not an assurance that it is the coal wanted. To determine this it is necessary actually to burn the coal and carefully observe the evaporation of the boilers. It is preferable to make tests on all of the boilers, as merely trying the coal under one will not give general results. That these observations may be taken with any degree of accuracy, it is preferable to weigh the coal and use a meter of some kind in the boiler-feed line. If only the weight of the coal consumed had been determined, the economy can be checked quite closely by noting the wattmeter readings and obtaining the pounds of coal per kilowatt-hour. It is thus easy to determine the grade of fuel which will burn with the best economy in the plant, and all that remains to do is to analyze all coal of this grade that is received on any contract to make sure that the coal in each cargo is of the same quality.

The majority of engineers are not familiar with the sampling and the analysis of coal. It is generally considered that this is something beyond them and requiring the skill of a chemist. This is a wrong impression, as any engineer of ordinary intelligence can analyze his own coal. Two forms of analysis are made, one called the ultimate, which requires a chemist, as it determines all the different chemical elements. This is not of any great value to the engineer. The other form is the proximate analysis. This gives the percentages of volatile combustible, fixed carbon and ash, which are in fact the only elements which interest the average engineer, excepting sulphur, the percentage of which he can also easily obtain. All that are necessary to perform the proximate analysis are a platinum crucible, a set of balances, a bunsen burner and an assayer's muffle. As a general rule the coal dealer will be more careful in the selection of the coal if he is aware that an inspection is to be made.

Analysis of the flue gases must also be made. In plants of great magnitude the installation of a CO_2 recorder is the proper idea, but in smaller plants the management is generally adverse to the purchasing of expensive instruments. In this case the engineer can procure an Orsat apparatus, which is inexpensive and requires not a great amount of skill to operate. With this apparatus he can obtain the proper amount of air necessary to burn the coal economically and will get results which will enable him to increase the boiler efficiency.

There has been considerable agitation for the purchasing of coal on the B.t.u. basis, which is all right as far as it goes, but the best method is to find the proper coal and then contract for this particular grade and obtain it as long as possible, for generally if too many requisites are demanded for a particular coal the coal dealer will state his particular price, and in the end but little is gained.

Pipe Sizes Without Figures

By J. E. Bates

Frequently an inquiry or discussion is seen in the correspondence columns of mechanical journals as to how to get the proper size of a single pipe that will be required to carry the same volume as two or more pipes, and while it can be figured out very readily by getting the area of the pipes, there is a much quicker way of getting the same results which has the advantage of requiring no more knowledge than the ability to read correctly the figures on a rule.

Suppose there are an engine and pump to connect up and it is desired to know what size of pipe will be ample for both. Take a steel square or any true right angle and lay off the diameters of the pipes on the legs of the square; then measure across from the points representing these diameters, and this will be the diameter of pipe wanted.

Suppose the steam inlet to the engine is 3 inches and that on the pump 1½ inches; then the distance from the end of the 3-inch mark, Fig. 1, to the end of the 1½-inch mark would be about 3⅜ inches. which would mean the nearest commercial size, or a 3½-inch pipe. This is simply the solution of a right-angled triangle, in

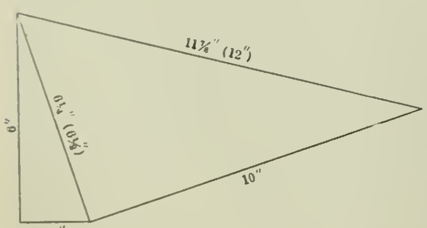


FIG. 4

which the diameter obtained is the hypotenuse.

Taking another case, suppose we have an engine with a 4-inch steam inlet, another engine with a 2½-inch steam inlet and a pump with a 1¼-inch inlet. Then a right-angled triangle, Fig. 2, with a base of 1¼ inches and a hight of 2½ inches, will have a hypotenuse about 2¾ inches long. Now take this resulting hypotenuse and use it as a base for another triangle, the hight of which will be equal to the inlet diameter of the other engine. The result obtained is 4⅞ inches, or a 5-inch pipe. This will mean that a 5-inch pipe will be run from the boiler to the 4-inch connection. a 3-inch pipe from there to the other engine, and a 1¼-inch pipe to the pump, assuming that the pump is farthest away from the boiler. If the engine with the 2½-inch opening is farthest from the boiler. the pump next and the engine with a 4-inch inlet nearest, it would require a 5-inch pipe from

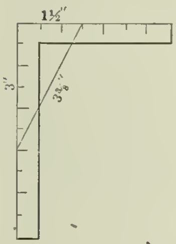

FIG. 1

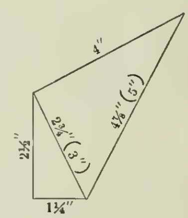

FIG. 2

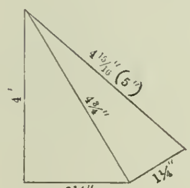

FIG. 3

the boiler to the 4-inch outlet, a 3-inch pipe on to the pump outlet and a 2½-inch to the other engine.

Taking it another way, if the engine with the 4-inch inlet was farthest from the boilers, the 2½-inch connection next and the pump nearest, the problem would be as represented in Fig. 3. In this event there would be a 5-inch pipe from the boilers to the smaller engine, with a 1¼-inch outlet to the pump and a 4-inch pipe on to the larger engine.

As a proof, the area of a pipe is the square of its diameter in inches times 0.7854, or to express it in a formula, where d represents diameter in inches, we have:

$$d^2 \times 0.7854 = A.$$

The area of an 1¼-inch pipe is 1.227 square inches; of a 2½-inch pipe, 4.908 square inches; of a 4-inch pipe, 12.566 square inches. The sum of these areas gives a total for the three pipes of 18.70 square inches. The area of a 5-inch pipe is 19.635 square inches, which is the nearest size.

Suppose the pipes are 10, 6 and 2 inches, respectively, the problem would work out as in Fig. 4, and a 12-inch pipe would be required. Reducing this to figures as a check, we obtain:

	Square Inches.
Area of 10-inch pipe	78.54
Area of 6-inch pipe	28.27
Area of 2-inch pipe	3.14
Total	109.95
Area of 12-inch pipe	113.10

To find the size of pipe required for any number of openings, begin at the opening farthest from the boiler and work toward the boiler. Suppose there are five different steam inlets to pipe to, which may be numbered 1, 2, 3, 4 and 5, No. 1 representing the opening nearest the boiler and the others numbering consecutively as to their relative distances from the boiler. For sizes take No. 1 to be 3½ inches in diameter; No. 2, 5 inches; No. 3, 2 inches; No. 4, 2½ inches; No. 5, 6 inches.

Beginning with opening No. 5 as the base and opening No. 4 as the hight, a hypotenuse of 6 7/16 inches is obtained. This would mean the use of a 6½-inch pipe between No. 3 and No. 4 openings, and a 6-inch pipe between No. 4 and No. 5 openings, the diameter of the opening farthest from the boiler always determining the size of the pipe to use between it and the next steam outlet. Taking the hypotenuse already obtained as a base, draw another triangle, the hight of which will be determined by the diameter of No. 3, or 2 inches. A resulting hypotenuse of 6¾ inches is obtained, and this means a 7-inch pipe between No. 2 and No. 3. Taking this last hypotenuse as a base and opening No. 2 for the hight, a hypotenuse of 8⅜ inches is obtained, or an 8½-inch pipe between No. 1 and No. 2 openings. With the hypotenuse last obtained as a base and No. 1 opening as the hight, the final resultant is 9 1/16 inches, which will determine the size of pipe to run between No. 1 opening and the boilers, or practically a 9-inch pipe.

By computation the following areas are obtained:

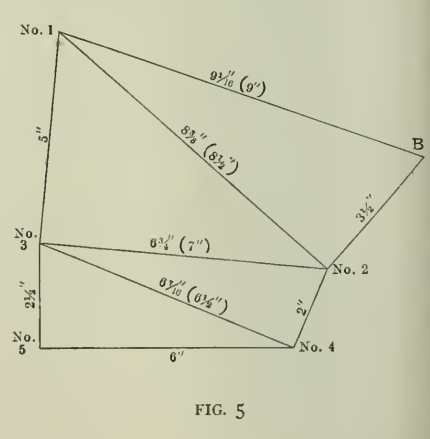

FIG. 5

	Square Inches
Area of No. 1 pipe	9.621
Area of No. 2 pipe	19.635
Area of No. 3 pipe	3.142
Area of No. 4 pipe	4.908
Area of No. 5 pipe	28.274
Total area	65.580
Area of 9-inch pipe	63.617

This is within 1.963 square inches of what the figures call for, which is certainly near enough for all practical purposes.

Cylinder Ratios for Compound Engines

The accompanying table gives the cylinder ratios which in two-stage compounds will produce an equal division of the work between the two cylinders, with no drop or free expansion in the receiver. It considers only the ideal diagram, unaffected by clearance, wire drawing, compression, etc.

Find the total ratio of expansion in the first column. If not given, it may be found by dividing the initial by the terminal pressure, both absolute.

Divide the back pressure by the terminal pressure, both absolute, and find the quotient at the head of the columns. If the terminal pressure is not given it may be found by dividing the initial by the ratio of expansion.

In the column at the head of which the quotient of the back pressure divided by the terminal pressure is found, and in the line opposite the given ratio of expansion, will be found the cylinder ratio which will produce an equal division of the load as represented by the ideal diagram.

EXAMPLE

What should be the ratio between the cylinders of a compound engine to work with an initial pressure of 120 pounds absolute, ten expansions and exhaust against an absolute back pressure of 3 pounds, in order that the work may be [illegible]

[illegible]

Cylinder Ratios for Compound Engines, with Equal Distribution of Load

(Column heading: Quotient of Back Pressure Divided by Terminal Pressure, Both Absolute.)

terminal is unity. The values in the body of the table are the volumetric ratios; the volume of the low-pressure cylinder divided by the volume of the high-. The second row of figures give the ratios of cylinder diameters when the strokes are the same. For example, in an engine using 13 expansions and with a back pressure one-half the terminal, the low-pressure cylinder must have 2.81 times the volume and 1.68 times the diameter of the high-. The derivation of the formula by which the table was computed is given in another column.

Marine Engines

About the reciprocating marine engine there is absolutely nothing new to record. The manufacture of such engines has become as simple and monotonous as the weaving of calico. Attention has been concentrated on the turbine. The position, so far as marine propulsion as a whole stands, has been made quite clear. The turbine, to be efficient, drives the propeller too fast for it to be efficient, except for speeds over 18 knots. Either the turbine must be sacrificed to the propeller, or the propeller to the turbine. It has come to be fully understood that the economy of the turbine lies at the low-pressure end. In the reciprocating engine steam cannot, as a rule, be expanded much below 7 pounds absolute in the low-pressure cylinder. This cuts off a large section of the toe of the diagram. But the turbine can work down to 1½ pounds absolute. The result is that, instead of exhausting direct from the low-pressure cylinder into the condenser, it is worth while to interpose a turbine and exhaust through it to a condenser fitted with special auxiliary air extractors. This turbine may be of fairly large diameter running at a reasonable speed. Three screws are then used to propel the ship. This system of propulsion has been for some time under discussion, and has at last been put to the test on a large scale. The first merchant steamer to be fitted is the "Otaki," the property of the New Zealand Shipping Company, Limited, London. The vessel was built by W. Denny Brothers, and engined by Denny & Co., Limited, Dumbarton. The "Otaki" is fitted with two sets of reciprocating engines in the wings, driving twin screws; between these two engines is interposed a low-pressure turbine of very large size, which drives a center screw. The turbine revolves only in the ahead direction, and change valves are fitted so that the steam may be either passed directly into the condenser or to the turbine. Hence in maneuvering the vessel becomes an ordinary twin-screw. The twin-screw engines are triple-expansion of the ordinary design, 24½, 39 and 58 by 39. The "Otaki" is virtually a sister ship to the "Orari," which was built and delivered in 1906 to the same company. The boiler installation is precisely the same as in the "Orari." The only alteration that was made by the builders was that the length was slightly increased to make up for the loss due to the three tunnels, as against two in the "Orari," and the stern post was so arranged that the third screw could be fitted in an aperture. The dimensions of the "Otaki" are 464x60x34 feet, or 4 feet 6 inches longer than the "Orari." Otherwise the vessels are the same. The economical results seem to be very good. During the trial trip of the ship, which were made in November, the consumption of water for all purposes came out at 12.3 pounds per indicated horsepower per hour, a consumption probably the best ever attained at sea.

The purpose of the combination we have just described is the attainment of the economy of fuel. It has not been adapted to get over the speed-efficiency trouble. During the last year a radically different scheme has attracted a good deal of attention. It is to let the turbine run at that number of revolutions which best suits it, and the propeller at its best speed, the reconciliation of conflicting conditions being effected by the interposition of transmission gear of some kind. When the screw propeller was first introduced it was found that it would have to be run too fast for the slowly revolving steam engines of those days. Therefore gearing was introduced, the screw making two or three turns for each one of the crank shaft. Now we find the conditions reversed, and it has been proposed to drive the screw by spur gearing. The circumstances are more favorable than those just mentioned, because a pinion will drive a spur wheel with less loss of power, less friction and vibration, than a spur wheel will drive a pinion. But electricity provides a better way out of the difficulty. The turbine drives a dynamo at one speed, and that drives motors at a much lower speed. All the arguments in favor of this plan were very ably set forth by W. P. Durtnall to the Institute of Marine Engineers on July 2 and dealt with in our impressions for July 24 and November 6.

Superheating enjoys a strictly qualified popularity. Used in moderation it promotes economy without drawbacks. Attempts to use very hot steam, however, have not been commercially successful. It would occupy far more space than we can spare to set forth the reasons why in any detail. Great benefit is obtained by drying the steam thoroughly in the superheater, and raising its temperature about 100 degrees in the valve chest above that normal to the pressure. With such steam, and a pressure of 160 pounds, and clearance reduced to a minimum, an indicated horsepower may be had for a pound of good coal per hour, and this may be regarded as the most that can be obtained from any commercial kind of steam engine whatever.—*The Engineer*, London.

Gas Power as an Aid to Electrical Industries

By Philip W. Robson

Most of the generating stations in our smaller towns find it difficult to show satisfactory financial results. This is not a prejudiced statement, for though personally I have long felt its truth, I am able to quote a prominent electrical engineer as its author. I refer to J. F. C. Snell, who dealt fully with this aspect of the matter in his paper read in the early part of last year before the Institution of Electrical Engineers. On account of their unsatisfactory financial position, Mr. Snell actually advised the entire elimination of independent electricity stations in the smaller towns in favor of central plants each supplying groups of towns. This drastic step is not at all necessary if gas power is adopted in lieu of steam, and this opinion is the result of the frequent opportunities I have had of making careful comparison in the actual running costs of the best steam engines as against gas engines. I will give one characteristic example of a new slow-speed vertical-mill steam engine fitted with surface condenser and all the latest steam-saving appliances:

COMPARATIVE COSTS.

	Steam.			Gas.		
Output of engine......	250 I.H.P.			250 I.H.P.		
Weekly working costs, 55 hours:						
Coal...............	£9	10	0	£	0	0
Coke...............	0	0	0	3	0	0
Wages..............	2	1	6	2	0	0
Oil................	1	5	0	0	6	0
Water..............	0	7	6	0	0	0
Sundries...........	0	15	2	0	5	9
	£13	19	2	£5	11	9
Weekly saving in favor of gas engines.......				8	7	5
Annual (52 weeks) saving in favor of gas engines............				435	5	8

In the above comparison both the steam engine and the gas engine are assumed to work on constant load, but in the case of the fluctuating load which is usually experienced in a generating station, the comparative saving would be still more in favor of the gas-power plant, while the standby losses with the latter would be practically negligible. For such reasons it is not too much to say that the running costs of a small station driven by gas engines will be only one-third of the present costs with a steam plant. In addition, it is not to be forgotten that with a gas-engine combination there is no boiler, and consequently no smoke, and few ashes, besides which the plant can be got on full load within 30 minutes from starting with everything cold.

It is pleasant to record that during the year several gas engines have been ordered for use in such generating stations, and I do not doubt that experience will justify a great extension of their adoption. I believe that gas power will prove to be the salvation of small stations.

LARGE UNITS FOR BIG STATIONS

The problem of large units is quite different. The large gas engine is still comparatively in its infancy, and the fiasco of the Johannesburg station is quite sufficient in itself to scare even bold minds from contemplating large gas units. Still progress is being maintained at a rapid rate, and an astonishing change of feeling has taken place in the year. In proof of this, the city of Birmingham is actually inviting proposals at the present time for 3000-kilowatt gas-driven sets. Confidence has been restored to a large extent by the organized visits which leading electrical engineers have paid to the Continent in the course of the year, when it was made possible for them to see many large engines successfully at work.

I think there is no doubt that the best types of large engine work well, and the fuel consumption is only about one half that of the best large steam engines, but in connection with their adoption I would like, if I may do so without being misunderstood, to utter a word of warning. There are two chief factors in making a new prime mover a success; it must first be made right, and it must afterward be worked right. Both require special knowledge, and, speaking from experience as an engine maker, I am bound to admit that I very often find our engines better looked after by the station engineers and attendants than by our own men. I think other engine makers will bear me out in this, and after all one of the essential elements in the successful application of gas power on a big scale in central stations is that station engineers shall in all cases be educated up to them. With this object in view I advise in such cases that a moderate-sized engine and gas plant be first installed, say a unit of from 400 to 500 horsepower. This would always be a useful set to have; it could work quite as economically as the larger units, and further would be an experimental set to make all concerned acquainted with the general behavior and management of gas units. The transition from this first set to a subsequent larger unit would be so easy and natural that there would be a complete absence of administrative anxiety.

Let me again emphasize that it is one of the features of gas power that units of 400 horsepower will work quite as economically as those of 2000 horsepower, so that apart from space consideration there is not at present a great gain in adopting the larger units.

STEAM TURBINES VERSUS GAS ENGINES

I am not aware of any reliable figures which will afford proper data for a comparison of the merits of the turbine with those of the large gas engine. There are frequently, however, special factors which must decide in favor of the latter. The turbine requires a high vacuum and consequently a lavish supply of cooling water for the condensing plant; the gas plant will work successfully with little water. Again, what is the cost of upkeep of these turbines? One hears rumors of the rapid disintegration of the blades, the renewal of which is a costly job, and there are many indications that the gas engine will not suffer from an upkeep comparison. Nor must it be forgotten that the only pressure in a gas-engine plant is that within the working cylinder. There are no high-pressure boilers, feed-heaters, feed and steam pipes, and all the other high-pressure fittings which are necessary in a modern steam plant. The absence of these is an important advantage.

THE USE OF BY-PRODUCT GASES

There has been a great extension during the year in the use of gas engines in conjunction with blast-furnace and coke-oven gases, which are by-products of the great iron works and collieries. In the majority of cases these engines drive dynamos, and the works are accordingly equipped for electric drive. This sphere of development is going to prove a most valuable and important one, not less for electrical engineers than for gas-engine builders. There are many inquiries out at the present time for engines and dynamos for this class of work, a great deal of which will be carried out in the course of the new year.

ISOLATED INSTALLATIONS

The past year has witnessed a continuance of the use of gas power in isolated plants. Particular location has little or no influence on the successful and economical working of gas engines and gas producers, and it is to them that the electrical engineer must turn to enable him to produce electricity with economy in such cases, especially in view of the growing tendency which exists to remove factories out of the large town areas. In addition to factories, there are asylums, schools, and large country houses which are gradually adopting gas power for generating electricity.

CONFLICTING INTERESTS

In those comparatively few districts where cheap current is available for power purposes from the public supply a feeling of competition undoubtedly exists between those interested in the sale of smaller gas engines and producers, and the electric supply. Whether it is really economically sound for the latter to sell current to power users at a price which cannot be remunerative, is a controversial subject beyond the scope of these remarks. I would, however, like to remind the electrical industries that the use of electrical energy in all isolated factories cannot be dispensed with, and hence if gas engines are put in, dynamos are also required. The electrical trades benefit here to at least an equal extent with the engine makers, and the attempts, often successful, which have been made in such cases to depreciate the use of gas engines, has also had the effect of shutting out an enormous number of contracts for dynamos and other equipment, to the serious disadvantage of the electric trade. This should be specially noted at present when many of the latter are unfortunately in a most depressed condition.—*The Electrical Times*, London.

New Swedish Peat Invention

In stating that considerable money has been expended on Dartmoor and the Great and Tregaron moors in England in attempts to convert peat into a marketable commodity on a large scale, Consul Joseph G. Stephens writes from Plymouth of a present apparently successful invention:

The peat is employed on the moor and its immediate vicinity as fuel, but the various processes hitherto tried with a view to adapting it for use as a fuel in rivalry of coal in the towns, or for putting it to other useful purposes, have hitherto ended in large losses. A new method is, however, being put forward according to a local journal under which, it is claimed, peat may become a very valuable commodity. The inventor is a Swedish scientist, who has been engaged in experiments for years and has now reached the stage when a large factory plant has been put in operation.

The process is very simple. The peat, as obtained from the bog, is first of all pulped into a homogeneous mass. It is then heated under pressure to a temperature above 150 degrees Centigrade, after which the water is pressed out by mechanical means. The residue is formed into briquets in the usual way. It is because of the heating of the mass to so high a temperature that the peat ceases to hold water in the same way as at lower temperatures. By mechanical methods it is almost impossible to eliminate water from peat at ordinary temperatures, but by this process beyond the important taken place quite easily. As to the commercial value of the peat briquets, it is claimed that 4 pounds will give as much heat as 4 or 5 pounds of good coal. It is held that the manufacture of fuel from peat by this process can be carried on commercially, may be sold near and that in the matter of price peat fuel would be much cheaper than coal.—*Monthly Consular and Trade Reports.*

The Technologic Branch of the United States Geological Survey is issuing, upon application, a copy of Bulletin [illegible] which has to do with the density of woods.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT McKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 *we printed and circulated* 1,836,000 *copies of* POWER.

Our circulation for December, 1908, *was (weekly and monthly)* 191,500.

January 5	46,000
January 12	38,000
January 19	38,000
January 26	38,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

Contents PAGE

Visiting

The engineer who has frequent opportunities to visit other plants than his own possesses a material advantage. To see other makes and types of apparatus, to exchange ideas with other engineers regarding methods and results, to discuss difficulties and swap experiences, can but make a man broader, better informed and capable of greater things.

Comparatively few engineers are so favored. The activity of the ordinary member of the craft is confined to a small sphere, and the condition that he shall be constantly within it is imperative. When he does get a day off he is naturally more inclined to spend it in some other way than in visiting other plants. And yet there are evenings when one might drop in at the power house or the electric-light station or some of the hotel and other plants which run at night.

Have you exhausted the possibilities for information of all the plants in your neighborhood?

Have you noticed that it is the man who devotes some of his spare time to visiting around in this way who gets on, and who is looked up to and sought when something of importance is up?

The next best thing to visiting oneself is being visited. An intelligent and interested caller can be made a fertile source of information, and in return for your courtesies to him will gladly be drawn upon for any knowledge which he may possess about the things in which you are especially interested. The men who knew two or three things about engineering and hugged them to themselves, have been swept aside (they never were engineers) by men who by a free exchange of knowledge have learned more in weeks than the niggards would acquire in a lifetime.

And finally for the man who has neither the chance to make visits to nor receive visits from his kind there is the weekly or monthly arrival of his technical paper. Here he will find accounts of the visits of the editors to different remarkable and interesting plants. Photographs of the different features of the plant will be reproduced, so that the reader who follows the article closely and intelligently may know how the plant looks and how it is put together almost as well as though he had been over it himself. These articles are not simple enumerations and catalog descriptions of the proprietary articles and machinery which go to make up a power plant, but seek to answer the questions that an intelligent engineer would ask and to point out the things which would interest and attract him if he were visiting the plant himself. In your paper also those who have had exceptional opportunities for observation or have devoted study and thought to some particular subject come to talk to you upon the things with which they are especially qualified to deal, and if you do not catch their meaning and require some point straightened out, they or the editors are always glad to be called upon for an explanation. If you do not agree with them, there are the correspondence columns where you can argue it out with them and other contributors to your own satisfaction, besides making a little cigar or book money by your trouble.

The next time you have a caller, try to make it worth his while to have called, and do not let him go until you have profited by all that he is able and willing to tell you.

And the next time your paper comes see if you have been getting out of it all the good which it is capable and willing to do you.

Failure of a Butt Joint

On another page of this issue will be found a description of the failure of a triple-riveted butt double-strapped boiler seam. (Two other similar cases are known to the writer of the article.) From the description of this failure it would appear that it was caused by an action similar to that supposed to produce a like defect in the lap form of seam. It has generally been assumed that this defect in the lap seam was caused by the ends of the sheets being out of line, and the circumferential stresses produced by internal pressure causing the plates to bend along the outer line of rivet heads, this action being repeated with each change or pulsation in the steam pressure.

While this explanation is doubtless in the main correct, it does not explain why these lap cracks invariably start on the under side of the outer lapping sheet and never on the top of the under lapping sheet. As far as the foregoing theory of their formation is concerned, they should be as likely to occur on one side of the lap as the other. It is not impossible that the form of the seam is not the only factor to be held responsible when failure occurs to a lap joint.

While the record of a single failure of the butt form of joint would not justify speculation as to the probability of other failures of a similar character, it does not require a great stretch of the imagination to picture this type of joint being made so that the true cylindrical form of the boiler would not be maintained at the joint, and as a consequence bending of the sheet might take place in operation.

It has been previously suggested in these columns that there is an apparent need for further investigation of riveted joints and it would seem that there is an interesting and profitable field of investigation open to some institution of learning, to determine by actual experiment on boilers under pressure just how deformation occurs at the seams when made true to form and otherwise.

The State of Massachusetts is spending, directly and indirectly, a vast sum of money annually in an endeavor to insure as far as possible that steam boilers in its bounds be immune from explosion. Why would not a careful investigation of what actually happens to boiler joints under working conditions be of advantage in accomplishing the desired result?

If maintaining the true cylindrical form of the shell at a butt-strapped seam is of equal importance to the type of joint in rendering it safe for continued use, the sooner the facts are known the better. Safety of boiler construction is of the greatest importance to the public, and no feature should be guessed at or surmised that will admit of direct proof by experiment. The number of extremely dangerous cracks that have recently been discovered in boilers, before they have actually caused explosions, would seem to point to a need for a periodical examination of old boilers under hydrostatic pressure, with all the longitudinal seams uncovered so that every facility may be afforded to detect such defects.

The fact that the boiler did not explode is evidently due to the fact that the sheet, although split nearly across, was retained in position by being riveted to the flange of the head on one side and to the round sheet on the other.

The Actual Cost of Power

In the great majority of cases where power costs are figured from the records of operating plants, the total expense per horsepower or per kilowatt-hour is calculated without taking into account the fixed charges of the installation. It is usually sufficient from the point of view of the plant operator to determine what his power costs him month by month, as manufactured under the local conditions of his station. He can ordinarily do little or nothing to reduce the fixed charges, except by properly maintaining the plant to offset its depreciation; the operating costs, pure and simple, are the facts he must deal with, and upon which he must base his work in the interests of economical production.

It is important for the engineer to be able to figure power costs including the fixed charges, however, when occasion arises, and to appreciate the influence of the annual interest, depreciation, insurance and taxes on the unit cost of power produced. It is evident that the greater the output that can be obtained in a plant, the less will be the fixed or annual charges per unit. In some cases these charges are quite high, in others low. An example of what power actually costs in a modern oil-engine station in the past year may be cited. This station contained two American Diesel engines of 225 horsepower each, with triple 16x24-inch cylinders, direct-connected to alternators running 164 revolutions per minute.

The total cost of the station was about $105,000, or $234 per horsepower of normal rating. The manufacturing cost of the plant was made up of the following items: Fuel oil, $3,160; water, $88; oil and waste, $247; wages, $3,913; station repairs, $5; oil-plant repairs, $663; electric-plant repairs, $73; total, $8,149. The energy delivered at the switchboard was 817,000 kilowatt-hours. The operating cost was thus about 1 cent per kilowatt-hour. The total cost of the power, however, included the interest on the total cost of the plant, assumed as six per cent., depreciation, taken at seven per cent., taxes, one per cent., insurance, one per cent., total fixed charges, fifteen per cent. The plant cost was made up of: building, $39,288; real estate, $17,057; oil plant, $38,500 ($85.50 per horsepower); electric plant, $9,500. The total fixed charges were, therefore, fifteen per cent. of $105,000, or about $15,700 per year. The manufacturing cost at the station per kilowatt-hour figures about half the fixed charges per kilowatt-hour, the latter coming to about 1.92 cents. Thus the total cost of producing power in this plant is not far from 2.92 cents per unit generated, and the influence of the initial investment in the station becomes clearly important.

In making the choice of station equipment, it is, of course, necessary to consider the features of operating convenience and reliability, safety, probability of heavy repairs, overload capacity, the reliability of the makers, the accessibility of the equipment for repairs and adjustment and similar points, in addition to the simple question of cost. The economy of production may be excellent, as in the case illustrated, oil costing from 3 to 4 cents per gallon; the repairs are far from alarming, also; but the initial cost of the station is high. It must be borne in mind, in considering a case of this kind, that the load factor of the plant exerts a powerful influence on the ultimate economy of production. The output of the station for the year was about one-third its maximum possible output for a three-hundred-day year at full load for twenty-four hours. If the company succeeds in increasing the load on the plant, the cost per kilowatt-hour due to the fixed charges will rapidly go down. If the plant could be operated at full load for every business day of the year, doubtless impracticable under the local conditions, but sometimes feasible with electrochemical loads, the fixed cost per kilowatt-hour would drop to about 0.7 cent, and it is probable that a load nearer the machinery rating would result in still better fuel economy, probably carrying the total cost of power production down to 1.5 cents at the most.

A moderate initial cost of plant is exceedingly important if it can be obtained, but in cases where it is high it will not do to assume that it will not pay to install expensive apparatus, provided the operating economy and service reliability are all that could be desired. The point is, not to overlook the fixed charges in making estimates of the values of different equipments.

Furnace Arches

It has been said, and rightly, that in the future the greatest economy to be made in the steam plant will be in the boiler room, rather than in the engines, which have arrived at a fair state of perfection. Stress has lately been laid upon the matter of preserving the coal supply, but even setting aside the fact that this is desirable, the standpoint of economy in dollars and cents demands not only that the furnace of a boiler shall be constructed so that the coal will be burned to the best advantage, but that a low grade of cheap fuel can be burned successfully.

That the down-draft furnace is the best type, so far as known, is a matter of fact, and that it has not become more popular is not that its merits have not been recognized, but that in most cases the necessary space for its installation is lacking. The down-draft furnace is efficient because in it the gases are heated to a temperature sufficient to cause their consumption before reaching the cooling surfaces of the boiler tubes or shell, as the case may be; the top of the lower grate, which is constructed of [illegible], bringing about this result. This idea is being carried out in the shape of brick arches in the ordinary furnace, which gives the same economical result regarding the consumption of gases freed from the fuel.

The brick arch is a fuel saver not only because it consumes the gases liberated from the coal, but because it produces a longer flame than obtained in furnaces not so designed, thus making the heating surface of the boiler more efficient. A furnace having the lowest temperature will have the highest amount of CO, due to imperfect combustion, and tests have been made with furnaces with and without the fire-brick arch which have resulted in a saving of more than fourteen per cent. in CO over the furnace not fitted with the brick arch.

The matter of burning the smaller sizes of coal is becoming of considerable importance and the brick arch plays no small part in its consumption, especially in cities where a smoke ordinance prohibits the making of smoke to any great extent.

It is necessary to take into consideration that the [illegible] furnace, at the rate of about [illegible] per cent. This includes the heat escaping out of the stack, radiation from the boiler and setting, which may be greatly varied depending upon the manner in which the brick-work is kept in repair, and the loss due to coal which drops through the grates into the ashpit.

Coal and Coke Production in the United States

The following table has been compiled largely from data communicated by the several State mine inspectors, estimates having been made only where no such statistics were available, but in all cases upon the basis of good information:

PRODUCTION OF COAL IN THE UNITED STATES.

States.	1907. Short Tons.	1908. Short Tons.
Bituminous:		
Alabama	14,417,863	11,950,000
Arkansas	1,930,400	1,750,000
California and Alaska	45,300	55,000
Colorado	10,920,527	9,773,000
Georgia and North Carolina	365,300	275,000
Illinois	(c)51,317,146	48,000,000
Indiana	11,692,072	12,000,000
Iowa	(a) 7,568,424	7,050,000
Kansas	6,137,040	5,600,000
Kentucky	10,207,060	9,526,000
Maryland	5,529,663	5,000,000
Michigan	(b) 1,898,446	2,000,000
Missouri	4,350,000	3,900,000
Montana	1,810,000	1,800,000
New Mexico	(a) 2,302,062	2,725,000
North Dakota	268,300	250,000
Ohio	32,465,949	30,000,000
Oklahoma	3,450,000	3,250,000
Oregon	51,600	25,000
Pennsylvania	149,759,089	118,309,000
Tennessee	6.760,017	5,009,000
Texas	1,300,000	1,250,000
Utah	1,967,621	2,000,000
Virginia	4,570,341	4,000,000
Washington	3,713,824	3,000,000
West Virginia	47,205,965	44,091,000
Wyoming	6,218,859	6,100,000
Total bituminous	388,222,868	338,688,000
Anthracite:		
Colorado	45,113	30,000
New Mexico	17,000	10,000
Pennsylvania	86,279,719	80,240,000
Total anthracite	86,341,832	80,280,000
Grand total	474,564,700	418,968,000

(*a*) For the fiscal year ending June 30.
(*b*) For the 12 months ending November 30, 1907.
(*c*) As reported by the U. S. Geological Survey

PRODUCTION OF COKE IN THE UNITED STATES.

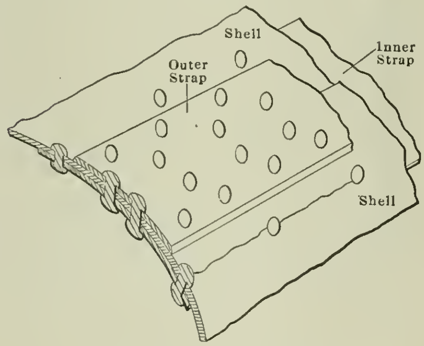
States.	1907. Short Tons.	1908. Short Tons.
Alabama	3,096,722	2,800,000
Colorado	1,097,051	854,000
Georgia and North Carolina	71,460	70,000
Illinois	372,697	270,000
Kentucky	77,055	60,000
Montana	31,400	30,000
New Mexico	203,437	260,000
Ohio	310,640	250,000
Oklahoma	57,600	50,000
Pennsylvania	23,516,309	11,287,000
Tennessee	495,200	250,000
Utah	324,692	290,000
Virginia	1,622,734	1,200,000
Washington	61,400	48,000
West Virginia	4,078,222	2,978,000
Other states (*c*)	1,650,000	2,000,000
Total	37,066,619	22,697,000

(*c*) Includes output of by-product coke for Massachusetts, Maryland, Minnesota, New York, Michigan, Wisconsin, New Jersey.

If the production of coal in 1908 had shown as large an increase as in 1907, the long predicted half-billion total would have been reached. To satisfy our fuel demands during the last 12 months, we have exhausted about 61 square miles of our available coal lands. If our production should remain stationary, at this total, in future years, it would require over 6000 years to exhaust our coal beds; if, however, the future production should increase at a rate equal to that shown in 1907, the available coal seams would last only about 200 years.—*Engineering and Mining Journal.*

Hidden Crack in a Strapped Butt Joint

The triple-riveted butt-strapped joint has been assumed to be a complete remedy for the hidden crack to which the lap joint is liable. The following account of the failure of a butt joint in this manner will, therefore, be of exceptional interest. It is written by T. T. Parker, chief boiler inspector of the Fidelity and Casualty Insurance Company, and will appear in the bulletin issued by that company. Mr. Parker says that this is the third instance



WHERE THE FAILURE OCCURRED

of the kind which has come to his attention:

A recent failure of a horizontal tubular boiler by rupture through the double pitch of rivet line of the longitudinal seam is of more than usual interest. The boiler was 72 inches in diameter and of $\frac{7}{16}$-inch shell plate. It was about sixteen years old. The inner and outer straps were each ⅜ inch thick. The joint was triple-riveted, the single pitch being 3⅜-inch, the double 6¾-inch and the rivet holes $\frac{15}{16}$-inch. This represents standard practice for this thickness of plate and the calculated efficiency of the joint is 86 per cent. of the solid plate, the weakest section of the joint being the net plate in the double pitch or outer row of rivets, at which point the failure occurred.

The boiler had been cut out and thoroughly cleaned and steam had been raised to 80 pounds preparatory to cutting the boiler in with others, when the engineer noted steam escaping through the brickwork at the rear sheet on top. Removing some of the brickwork disclosed a crack extending for five rivets, a distance of 33¾ inches, the rupture being from $\frac{1}{16}$-inch to ⅛-inch. The main valve had not been opened. The engineer quietly pulled the fire and, pumping up, reduced the pressure to zero.

The removal of the straps resulted in finding the plate cracked on the inside from rivet to rivet from the rear-head seam to the circular seam. This condition, of course, had been hidden by the inside strap and was not revealed until the crack had broken through and leaked. The rivet holes had been punched and the burs were not removed. There were slight marks in the plate along the double-pitch line, indicating the usual bending action when the sheet entered the cold rolls. The plate at the fracture was full size and showed no reduction in area, which is significant of segregation of carbon at the end of the sheet.

Multiplying the 80 pounds pressure by the radius gives a pressure of 2880 pounds per square inch on the shell. This multiplied by 33 inches gives 95,040 pounds on a strip the length of the fracture. According to all calculations this condition should have resulted in a terrible explosion, as there was nothing to hold the ruptured sides of the sheet together save the frictional resistance of the rivet heads to the severed plate. It is impossible to determine how long the crack existed under the strap prior to showing through the sheet, but there is no doubt it first started from the inner side and worked outwardly. Had the boiler been made with lap seams unquestionably an explosion would have occurred, as the strength of the inner strap in connection with the frictional value o the rivets on this strap would have bee lacking. The accident leads one to believ that a test piece should be cut from *eacl end of each sheet* and subjected to th usual chemical and physical requirement and that the rivet holes in such seams, i punched, should be reamed out at least ⅛ of an inch, with a view to removing th evil effects of the punch.

The conduct of the engineer in charg was truly admirable. First, there was hi carefulness in noting and examining th defect; second, his courage in staying wit the boiler (a dynamite bomb with the fus burning) until the pressure had been car fully removed. Such devotion to duty i the moment of danger stamps the eng neer as a hero in the highest degree an reflects great credit on the profession.

The entire sheet was condemned, course, and a new boiler was ordered.

The twenty-fourth anniversary of Ne ark Association No. 3, N. A. S. E., will held at the new Auditorium, 81 and Orange street, Newark, N. J., Februa 12 next.

The next meeting of the National G and Gasolene Engine Trades Associati will be held at the Auditorium hot Chicago, Tuesday, February 9.

Power Plant Machinery and Appliances

Original Descriptions of Power Devices
No Manufacturers' Cuts or Write-ups Used

MUST BE NEW OR INTERESTING

Center Crank and Crosshead Pin Oiler

The accompanying illustration, Fig. 1, represents a device for oiling the crank pin of a high-speed center-crank engine. It is manufactured by William W. Nugent & Co., 18 to 30 West Randolph street, Chicago. The object of this oiler is to provide a continuous tube from a stationary oil supply to the crank pin when the engine is in motion. The tubes telescope and are self-lubricating.

Fig. 2 shows a method of oiling a center crank and crosshead pin on a vertical trunk engine, such as vertical gas engines, etc. The oil is fed under pressure and must go to the parts to be oiled. This device will stand high speeds.

The illustrations show how the oil is distributed to the parts to be oiled by means of the Nugent steel oil-tight knuckle joints. This method prevents short circuiting of generators, in direct-connected units, due to splashing oil, and the danger from trouble in the brasses, due to grit, is eliminated almost entirely.

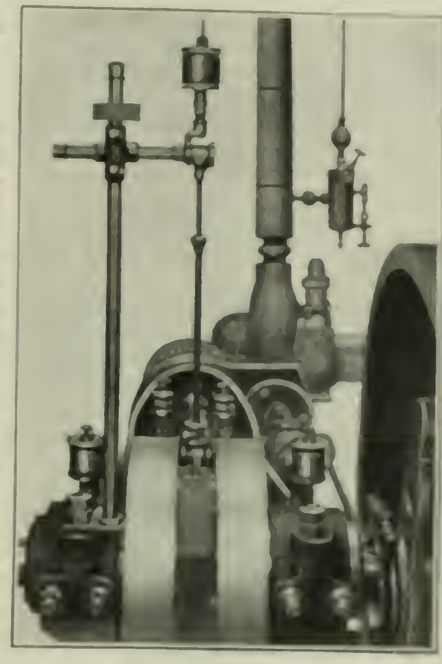


FIG. 1 THE NUGENT CRANK-PIN OILER

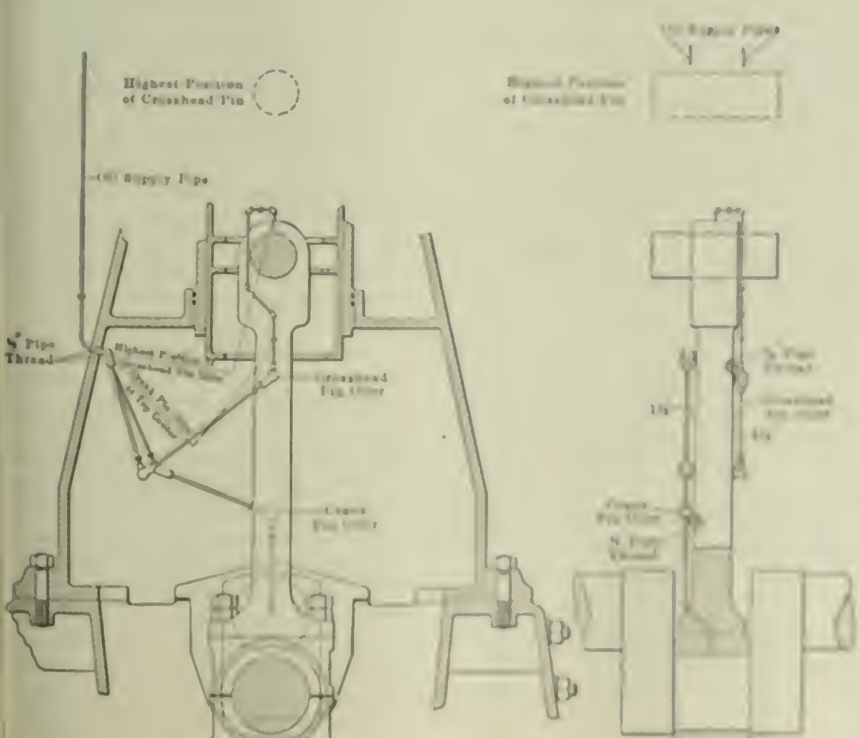

FIG. 2. DETAILS OF CRANK-PIN OILER

Simplex Blowoff Valve

In Fig. 1 is shown the exterior of a valve without a seat or a tapered plug, known as the Simplex blowoff valve.

The sectional drawings, Figs. 2 and 3, show the interior construction of the valve in open and closed positions. The two sets of packing rings C, Fig. 2, surround the plug valve D, and are compressed when the valve comes to a closed

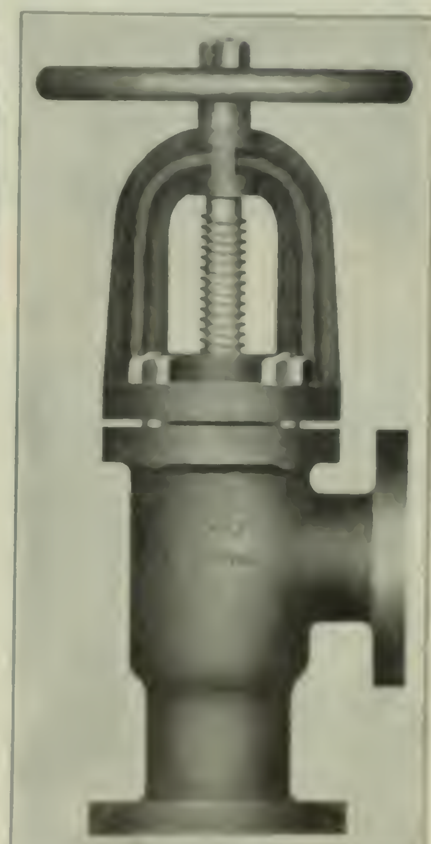

FIG. 1

position, thereby insuring a tight valve. The packing box [illegible] to take up the [illegible] ground plug valve D is moved, operating the handwheel, which revolves [illegible] of the valve.

The valve plug is prevented from turning by guides in the yoke and the packing is compressed by the [illegible] the plug valve. When opening the valve [illegible] compression is released from the packing, allowing a free and

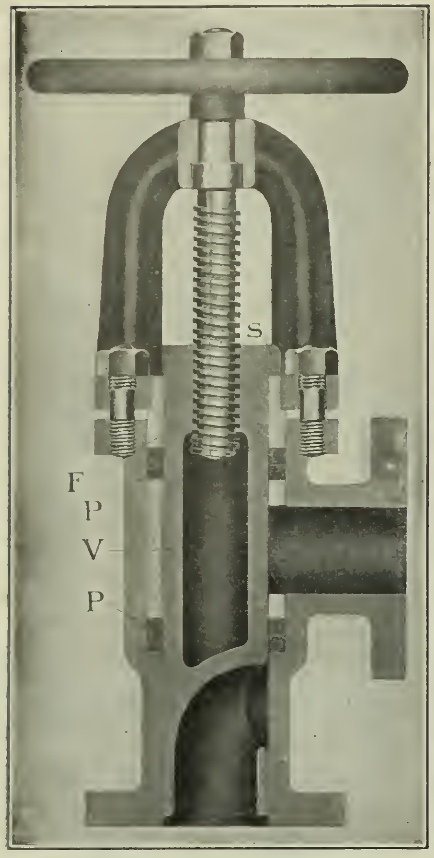

FIG. 2

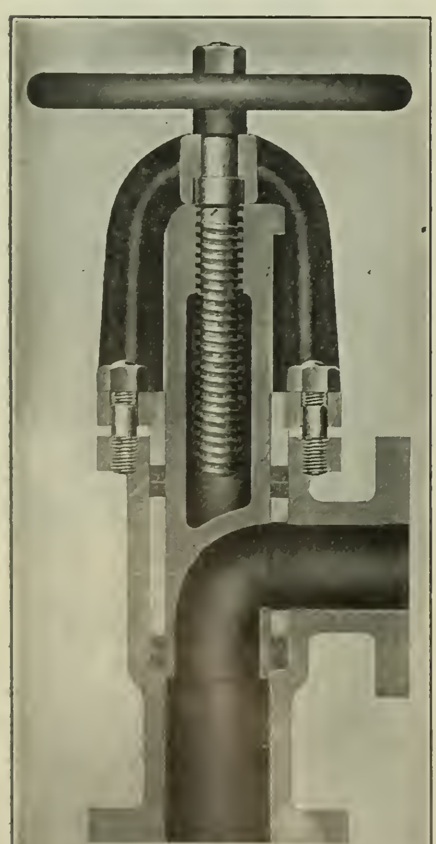

FIG. 3

easy movement to the valve, at the same time reducing the wear and tear on the packing, giving a free, unrestricted blow-out through the port (which is curved). See Fig. 3. This removes severe strains from the valve body.

The valve has no seat nor projection on which scale, sediment, etc., can accumulate, in either the closed or open position. The operation of the plug valve *V* is exposed to view, as well as the means of preventing the rotation of the plug valve, and the means of adjusting the packing. The valve is also made in the globe or Y-valve shape and with special connections and flanges as ordered. It is manufactured by the Simplex Engineering Company, Philadelphia, Penn.

Emergency Non-return Stop Valve

Referring to the drawing, the flange *A* is attached to the nozzle of the boiler, and the flange *B* is attached to the main steam line. The seat *C* has an extending flange which fits in a groove cut in the flange *A*, and the lower face, fitting against the flange of the boiler, is held in position by the bolts *D*, to prevent the seat from working loose. No screw threads are employed to hold the seat in position, therefore it is easy to remove. The method of guiding the valve disk *E* on the long stem held in position to the valve seat *C* dispenses with the stem projecting from the valve, and is also intended to assist in preventing hammering and chattering of the disk. Also, attached to the valve disk *E* is a piston *F* provided with piston rings *G* which take up the wear inside the dashpot *H*. A drain is provided to remove the water of condensation which might collect on top of the valve seat.

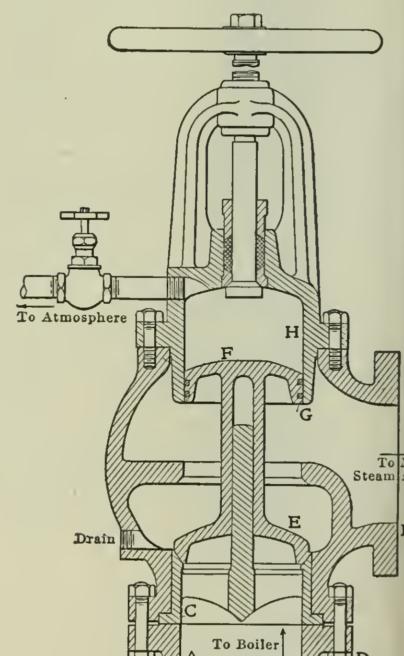
When attached to the boiler and steam header, with the stem and handwheel opened full, the valve is in operation, subject to the conditions existing in the pipes to which the valve is attached. With the main header pressure 150 pounds, the valve disk *E* is expected to remain on the seat *C* until the individual boiler has attained a pressure of 150 pounds, or the same pressure as the header, before steam can pass into the header. This feature points out a lazy boiler, so that one boiler cannot have the pressure of all the other boilers when the individual boiler pressure drops.

The opening and closing of the valve being subject to the pressures above and below the valve disk *E*, the valve cannot be opened into a boiler out of use, in which men may be working. Should a tube blow out in an individual boiler, that boiler alone is crippled, as the valve disk *E* closes on its lower seat automatically by the drop in pressure.

When desiring to discontinue using a boiler it is only necessary to stop firing and the valve will close without hand manipulation. To insure the certainty o the valve being closed, the handwheel t which the stem is attached is screwe down its full stroke.

In the event of a header explosion, th valve disk *E* is thrown wide open o account of the drop in the steam pres sure on the header or outlet of the valv and, coming in contact with the uppe seat in the valve body, shuts off th steam flow from each boiler to which thi valve is attached.

If an accident to the engines occur this valve may be closed from a distanc by opening the small pilot valve which re leases the steam on the upper piston an allows the boiler pressure beneath th valve disk *E* to close the valve against th upper seat without manipulating the hand



EMERGENCY NON-RETURN STOP VALVE

wheel. It will be noted this valve ha but one moving part, a valve disk t which is attached a piston. It is manu factured by John V. Schmid, 1823 Wes Allegheny avenue, Philadelphia, Penn.

Personal

J. E. Woodwell, of L. B. Marks & J. E Woodwell, New York City, has been re tained by McKim, Mead & White, arch tects, as consulting engineer for the en tire mechanical and electrical equipmen including the heating and ventilation, ele tric lighting and power, mail-handling de vices, etc., of the new United States po office to be erected at the Pennsylvan terminal station in New York City. Th cost of this installation will be upward $500,000. The firm has retained Prof. H. Woodbridge, of the Massachuset Institute of Technology, as associate co sulting engineer for the heating and vent lation of this building.

Inquiries

Questions are not answered unless they are of general interest and are accompanied by the name and address of the inquirer.

Comparative Evaporative Power

In J. G. McIntosh's book, "Technology of Sugar," I find the following paragraph: "The comparative evaporative power is not increased by adding more units (in speaking of double and triple effects)." Will a quadruple effect cut in two double effects give nearly double evaporation? If a plantation has a standard double effect and adds to it another cell, making it a triple effect, will this increase its capacity for evaporation, or will it be better to run the third cell as a single effect to be able to evaporate more liquid?

E. H.

Compared with the compound or triple-expansion engine, if the evaporating conditions are analogous to comparing the power capable of being developed by the whole three cylinders of a triple engine to the power capable of being developed by the low-pressure cylinder, the paragraph quoted is right, as the low-pressure cylinder with the same initial pressure will easily develop the same power as the whole three, but with less economy of steam. In the triple-effect evaporator the economy of steam will be greater when compared with single effect than it will be in a triple engine compared with a good single engine, and the economy will be due to a different principle than that of the triple engine.

Any one of the units of a triple-effect system of evaporators will evaporate the same quantity per hour as the whole three units, provided the initial steam pressure and the vacuum in the condenser are the same when used single or triple, but, of course, there will be three times as much steam used in the single effect.

Quadruple effects cut into two double effects will give double the quantity of evaporation, provided the pressure of steam in the two first effects of the two doubles is the same as that in the first effect of the quadruple (vacuum in the condenser must, of course, be the same in either case). As triple effects are ordinarily designed, the comparatively large amount of heating surface in each unit prevents them being used to their full capacity as single effects, for if the full steam pressure were used on a single unit, that is, used on the first of the whole three, the single cell would prime or foam to such extent that much valuable concentrate would be lost by entrainment.

Of course, triple effects could be designed with a smaller quantity of heating surface in proportion to the volume of the evaporator, so that the entrainment would be small when used as single effects.

With the same amount of heating surface in the new as in one unit of the double effects, it will not increase the evaporating capacity unless the steam pressure is also increased; although adding a larger third unit to the two units would somewhat increase the capacity provided the larger unit is used to evaporate the heavier or more concentrated liquor, which circulates with more difficulty and therefore needs more heating surface for a given rate of evaporation.

Run as a single effect to get the most liquor evaporated where economy of steam does not count.

By separating the two units of the double and making two singles, there is no need of installing another new one, provided economy is no object and foaming does not result.

Book Reviews

SHAFTING, PULLEYS, BELTING AND ROPE TRANSMISSION. By Hubert E. Collins. Hill Publishing Company, New York. Cloth; 157 pages, 4½x7 inches; illustrated. Price, $1.50.

This is another of the Power handbooks, made up largely of material which has appeared in the columns of Power, and has thus had the advantage of previous presentation, discussion and revision. It contains practical directions for the putting up, lining and leveling, and the care and maintenance of shafting, belting and rope transmissions, splicing of ropes and belts, etc. It treats the subject from the practical rather than the academic standpoint and should furnish the man who uses it hints which will be worth many times its cost.

MODERN POWER GAS PRODUCER PRACTICE. By Horace Allen. The Technical Publishing Company, Ltd., London, Eng. Cloth; 233 pages, 5x7 inches; 130 illustrations. Price, $[illegible].

This little work is one of the most satisfying that the reviewer has ever read. With the exception of some typographical slips, left in doubtless by careless proofreading, there are no inaccuracies that are discernible from reading the text without a slide-rule—and the reviewer has not skipped a paragraph. The names of [illegible] and [illegible] are spelled "[illegible]" and "[illegible]," the second table on page 213 is not arranged so as to be intelligible at first glance, the material forming the body of the book is rather [illegible] [illegible] [illegible] the [illegible] of [illegible] is disproportionately [illegible]. [illegible] [illegible] the book is [illegible] [illegible]. The author knows his subject thoroughly and [illegible] [illegible] till the reader [illegible] [illegible] [illegible] and clear, the English [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] "[illegible]." The book should be [illegible] [illegible] by everyone interested in the subject.

BOILERS. By Hubert E. Collins. Hill Publishing Company, New York. Cloth; 160 pages, 4½x7 inches; illustrated. Price, $1.

This book, which is one of the Power handbook series and was compiled largely from POWER AND THE ENGINEER, starts with a description of what goes on in a boiler as seen by watching a glass model of a water-tube type. Then follow simple talks on the Efficiency of Riveted Joints; the Bursting Strength of Boilers; the Bracing of Horizontal Tubular Boilers; Directions for Calculating the Strength of Riveted Joints and for Finding the Area to be Braced in Boiler Heads; a Graphical Determination of Boiler Dimensions; the Safety Valve; Horsepower of Boilers; Boiler Appliances; Care and Management of Boilers; Setting Return-Tubular Boilers; Removing Boiler Tubes; Use of Wood; Boiler Rules, and Mechanical Tube Cleaners. The presentation is in the simple style which has made the matter popular with practical men as it has appeared in our paper from time to time.

Books Received

"The Girl and the Motor." By Hilda Ward. The Gas Engine Publishing Company, Cincinnati, O. Cloth; 111 pages, 4½x7 inches; illustrated. Price, $1.

"Oil Motors." By G. Lieckfeld. J. B. Lippincott Company, Philadelphia, Penn. Morocco; 272 pages, [illegible] inches; [illegible] illustrations; indexed. Price, $[illegible].

"The Design and Construction of Ships." By John Harvard Biles. J. B. Lippincott Company, Philadelphia, Penn. Morocco; [illegible] pages, [illegible] inches; [illegible] illustrations; [illegible] folding plates; tables; indexed. Price, $[illegible].

Personal

F. C. [illegible], widely known [illegible] [illegible] [illegible] [illegible] [illegible] [illegible], manufacturers of "[illegible]" packing, was recently appointed [illegible] [illegible] of the company, with headquarters at [illegible] Lake street, Chicago, Ill.

Business Items

[illegible]

power boiler for the Pilgrim Laundry Company, of Philadelphia, two 122-horsepower boilers for the Southern Pacific hospital at San Francisco, and two 234-horsepower boilers for George W. Clayton College, Denver, Colo.

The Power Specialty Company, 111 Broadway, New York, builder of the Foster superheater and Heenan refuse destructors, recently received orders for 16,500 horsepower of superheaters, including those placed in boilers and separately fired units. They have also just been advised that the proposal to the city of Portsmouth, England, covering two Heenan destructors, each of 100 tons daily capacity, has been accepted.

The fact that equipment for power plants and industrial works is taking the lead in the resumption of business is well brought out by a list of recent sales comprising 80 fans, blowers and exhausters issued by the Green Fuel Economizer Company, of Matteawan, N. Y. These fans are to be used for such purposes as mechanical draft, heating and ventilating, hot-blast drying, etc., and their number indicates that many mills and other plants are being put into shape in anticipation of manufacturing operations on a large scale.

Henry W. Hess, chemist of the Toledo Gas, Light and Coke Company, Toledo, Ohio, made an examination of the liquid removed from a boiler by a Buckeye boiler skimmer and reports that he found the suspended solid to have been composed of calcium and magnesium carbonates mixed with a small amount of clay. In this particular case, the skimmer removed one hundred gallons of such liquid containing solids to the amount of 0.9259 pound per gallon, or 92.59 pounds per hundred gallons, each day. This skimmer is made by the Buckeye Boiler Skimmer Company, South End, Toledo, Ohio.

The Dearborn Drug and Chemical works reports that the general business of the company for the last six months of 1908 was larger than for any other six months in its history, indicating the quick return of prosperous business conditions. The percentage of increase the past few months, and especially for January, in the Eastern department of the company is particularly gratifying. Grant W. Spear, vice-president and Eastern manager, at the general Eastern offices, 299 Broadway, New York, who has been for years vice-president of the Dearborn company, at Chicago, ably assisted by Herbert E. Stone, as general sales manager, P. H. Hogan, manager of the Boston office, and Paul T. Payne, manager of the Philadelphia office, with P. G. Jones as special representative in the Philadelphia district, together with such popular and able representatives out of the New York office as Messrs. McConnaughty, Mitchell and others, constitute a most effective organization, which is an assurance of the high-grade manner in which the affairs of the Dearborn company will be handled in the Atlantic coast States.

An announcement of interest in the fan and blower business has just been given out—the consolidation of the American Blower Company, of Detroit, and the Sirocco Engineering Company, of New York. S. C. Davidson, of the parent Sirocco works, Belfast, Ireland, is financially interested in the deal. The factory of the Sirocco Engineering Company, at Troy, N. Y., and the plants of the American Blower Company, at Detroit, will continue in full operation under one management, and the home office will be at Detroit. In anticipation of a general improvement in business, also the necessity for increased foundry facilities, and the consummation of the "ABC"—Sirocco consolidation, the American Blower Company purchased outright during 1908 the complete foundry and plant formerly operated by the Northwestern Foundry and Supply Company, Detroit. The large triangular-shaped property, owned and occupied by the American Blower Company since about 1881, being entirely covered by buildings by the completion in 1907 and 1908 of a large steel-plate fan shop and office addition, the company recently purchased a large tract of land across the street, upon which it is expected new buildings, covering approximately 175x300 feet, will be erected. All business of the Consolidated companies will hereafter be transacted under the style and name of American Blower Company. The personnel of the management of the new company is as follows: James Inglis, president, who has been at the head of the American Blower Company; William C. Redfield, vice-president, who was president of the Sirocco Engineering Company; Charles H. Gifford, treasurer, who was, until a year ago, manager of the B. F. Sturtevant Company; Mr. Still, the secretary, is well known, especially among engineers, as chief engineer of the American Blower Company.

New Equipment

The Ozone Ice Company, Bogalusa, La., has awarded contract for the erection of ice plant.

The Athens (Wis.) Electric Light and Power Company contemplates installing larger generators.

The Idaho Power and Transportation Co., Idaho Falls, Idaho, is planning to double its output.

The Lebanon (Ky.) Light, Ice and Power Company is contemplating increasing output of plant.

Water-works at a cost of $20,000 will be constructed at Swink, Colo. E. G. Ritchie, city clerk.

It is reported that the Osceola (Ia.) Light, Heat and Power Company is planning to install an ice plant.

It is reported that water-works will be erected at Kearney, Neb., at a cost of $100,000. G. E. Ford, city clerk.

The citizens of Albion, Neb., voted to issue bonds for the construction of a municipal lighting and heating system.

The Chicago & Northwestern Railroad Company has commenced construction of power house at Clinton, Iowa.

The Jefferson (Texas) Ice, Light and Power Company is contemplating the installation of a producer gas plant.

It is reported that the Blackwell (Okla.) Electric Light and Power Company contemplates installing gas engines in plant.

The Keokuk (Iowa) Gas and Electric Company has been incorporated by Frederick Sargent and associates. Capital, $300,000.

The citizens of Sapulpa, Okla., voted to issue $65,000 bonds for extending and improving water-works. S. N. Hurd, city clerk.

The City Council, Hugo, Okla., will receive bids until February 2 for construction of water-works plant. W. T. Echols, city clerk.

The Sorento (Ill.) Electric Light Company will enlarge its plant. Will need a 150-horsepower engine and 100-kilowatt generator.

The Fowler (Ind.) Utilities Company contemplates installing new equipment, including engine and generator, meters, transformers, etc.

The Citizens Electric Company, Williamsport, Penn., contemplates installing additional equipment, including engines, generators and boilers.

The Union Central Light and Ice Company, Hubbard City, Texas, contemplates the erection of a new electric light plant and an addition to ice plant.

It is said about $40,000 will be expended for reconstruction of municipal electric-light plant at Topeka, Kan. H. K. Goodrich, superintendent.

The Savannah (Ga.) Ice and Storage Company has been organized to establish ice and cold-storage plant. J. G. Nelson, and others, organizers.

The village of Bergen, N. Y., has been authorized by the Public Service Commission to construct a municipal electric-light plant and water-works system.

The Scholl Engineering Company, Youngstown, Ohio, has been awarded contract for constructing water works at Girard, Ohio, and will receive all sub-bids.

Plans are being made to increase the output of the municipal electric light plant, Bethany, Mo. A new generator will be installed. J. F. Slinger, superintendent.

Plans are being considered for the installation of a 500-kilowatt steam turbine in the municipal electric light plant at Jamestown, N. Y. Chas. G. Sundquist, manager.

The West Penn Electric Company is said to be planning the erection of another power house at a cost of over $1,000,000. L. H. Conklin Connellsville, Penn., is general superintendent.

Plans are being considered for improvements at the municipal electric light plant at Elberton, Ga. These will include a new alternator, turbine pump and 50-horsepower motor. G. W. Hubbard, superintendent.

The Pasadena Rapid Transit Company has been incorporated to build an electric line between Pasadena and Los Angeles. Capital, $3,000,000. Incorporators, E. J. Sheehan, W. H. Smith, E. H. May, of Pasadena, and others.

New Catalogs

Hancock Inspirator Company, 85 Liberty street, New York. Catalog. Valves. Illustrated, 40 pages, 6x9 inches.

Thos. H. Dallett Company, Philadelphia, Penn. Catalog No. 100. Air compressors. Illustrated, 24 pages, 6x9 inches.

The M. W. Kellogg Company, 50 Church street, New York. Catalog. Piping and chimneys. Illustrated, 48 pages, 8½x11 inches.

American Steam Gauge and Valve Manufacturing Company, Boston, Mass. Catalog. Valves, Illustrated, 90 pages, 6x9 inches.

Wm. A. Harris Steam Engine Company, Providence, R. I. Catalog. Harris-Corliss engine. Illustrated, 80 pages, 7x10 inches.

Western Electric Company, 463 West street, New York. Bulletin No. 5370. Steam turbines. Illustrated, 12 pages, 8x10½ inches.

Wagner Electric Manufacturing Company, St. Louis, Mo. Bulletin No. 82. Polyphase motors. Illustrated, 16 pages, 8x10½ inches.

Walch & Wyeth, 87 Lake street, Chicago, Ill. Booklet. Erwood straightway swing gate valve. Illustrated, 16 pages, 6½x7 inches.

Ridgway Dynamo and Engine Company, Ridgway, Penn. Bulletin No. 20. Single-valve side-crank engine. Illustrated, 14 pages, 8x10½ inches.

Lathrop Engineering Company, 126 Liberty street, New York. Pamphlet. Lathrop system, of "Equalized Draft" for steam boilers. Illustrated, 16 pages, 4x7½ inches.

Help Wanted

Energy in a Pound of Steam

Net Energy of Expansion from 150 Pounds down to Atmospheric Approximates Energy from Atmospheric down to 27 1-2 Inches of Vacuum

BY FRED R. LOW

A correspondent writes: "In your issue of October 26, page 675, the following statement appears:

> When it is remembered that there is as much power in the steam from atmospheric pressure down to 27½ inches as there is from 150 pounds down to atmospheric pressure, it is easily seen that the power of a noncondensing plant can be doubled by the addition of an exhaust-steam turbine and condenser.—Gerald Stoney, before the British Association.

I would like very much to see this example worked out in full, so that I might follow it step by step."

The energy is proportional to the area of a diagram in which, as in that made by the steam-engine indicator, vertical distances represent pressures and horizontal distances volumes. Fig. 1 is such a diagram, plotted upon the assumption that the product of the pressure and volume remains constant. A volume *o 1* of steam at 120 pounds absolute pressure is expanded to twice that volume *o 2*, and in so expanding generates energy represented by the space *B C 2 1*. It is started with one volume at 120, and since the product of the volume and pressure remains constant the pressure at two volumes *C* must be 60. Notice that this area is made up of a triangle *A B C* and a rectangle *A C 2 1*, each 60 pounds high and one volume wide.

Suppose this steam at 60 pounds to be again doubled in volume. Its pressure would be reduced to 30 pounds and an amount of energy proportional to the area *C D 4 2* would be developed. This area consists of a triangle *C D E* and a rectangle *E D 4 2*, each 30 pounds high and two volumes wide, and since the area *1 B C 2* is twice as high, but only half as wide as *2 C D 4*, their areas must be equal, and since the work performed is represented by the area the work is the same. If the diagram is followed along it will be seen that the successive areas into which it is divided are equal, and that the last expansion from 15 to 7½ pounds results in the development of as much energy as that from 120 to 60. The energy developed depends upon the number of times the steam is expanded, i.e., the "ratio of expansion," the final volume divided by the initial volume. The energy is the product of the mean pressure during expansion and the increase in volume. In the early part of the diagram the pressure is high and the volume correspondingly small. In the later part of the diagram the pressure is small, but the volume is correspondingly great, and their product (the energy) is equal for the same ratio of expansion.

This much by way of simple illustration, but unfortunately steam does not expand in this way. A perfect gas would expand according to this mode if its temperature were kept constant. Steam cools as it expands and its volume would increase less rapidly than the expansion curve in Fig. 1 shows, dropping the pressure. The expansion line of the ordinary indicator diagram follows the line of Fig. 1 quite closely, because there is enough evaporation in the cylinder as the pressure is reduced to make up the shrinkage due to cooling, but this means that the diagram deals with a varying quantity of steam.

Let us get at the problem in another way. Every pound of the working fluid carries into the engine a number of heat units, and in passing out carries away a lesser number. The difference has been converted into work, and if it can be found how many heat units each pound of the fluid carries in and how many it takes out, the difference will be the number of heat units that have been converted into work, for the ideal case at least, for each pound of steam used. As each heat unit is equivalent to 778 foot-pounds the work can be expressed in those units by simple multiplication.

There are reproduced herewith a couple of fragments from Peabody's "Tables of the Properties of Steam." The second line gives the properties for steam of 2 pounds absolute pressure, the pressure *p* being given in the first column. In the second column is given the Fahrenheit temperature at which water will boil under that pressure, in this case 126.1 degrees. In the third column is given the "heat of the liquid" *q*, that is, the number of British thermal units which are required to raise a pound of water from 32 degrees to the above temperature.

Let the line *O X*, in Fig. 2, represent the absolute zero of temperature, 459.2 degrees below the zero of the Fahrenheit scale. On the line *A* [illegible] erected to any convenient scale of vertical distances, representing temperature, the freezing point, 32 degrees, which is the base from which

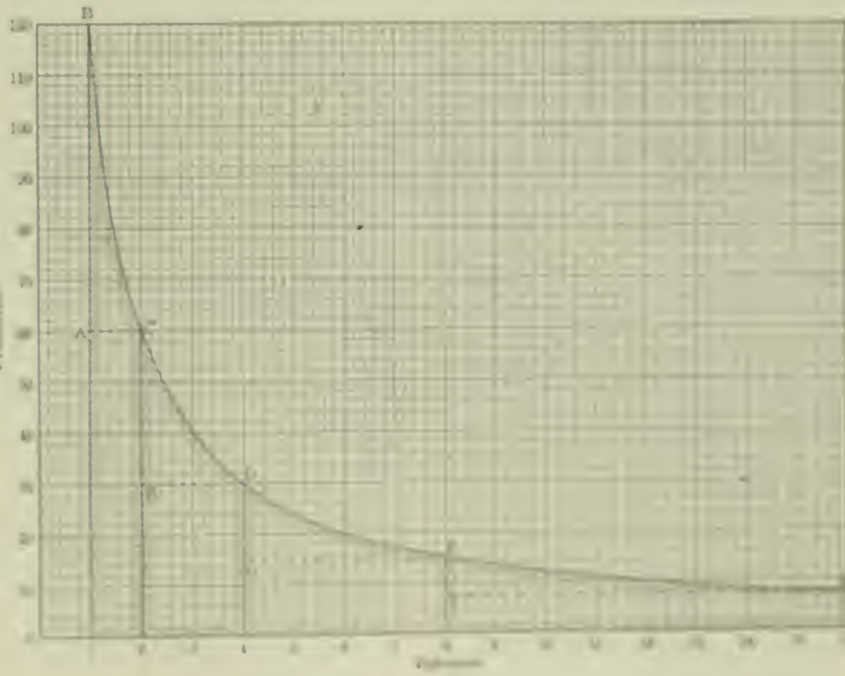


Fig. 1

most of the values of the steam table are reckoned. Locate the point *B* at the hight corresponding to the temperature, 126.3, to the chosen scale, and at such a distance from the line *I J* that the area *A B H I* will be proportional to the 94.3 B.t.u., which the table says it has required to bring the water from 32 degrees to this point. In other words, to bring the pound of water from 32 to 126.3 degrees has required 94.3 B.t.u. of energy in the form of heat, and the area *A B H I* represents that energy just as the area of the diagram from a steam-engine indicator represents energy.

Now look at the line of the table for 120 pounds pressure. The temperature here is 341 degrees, and the heat of the liquid is 312 B.t.u. Imagine the point *C* to be located at a vertical distance corresponding to 341 degrees Fahrenheit, and at such a distance horizontally from the line *J I* that the area *A C G I* will represent 312 B.t.u. If a number of points were located for different temperatures in this way the change would be found to occur along some such curve as *A B C*.

At 341 degrees the water under 120 pounds pressure would be ready to boil, and any further addition of heat would go to making it into steam, which process will take place at constant temperature. In the fourth column of the table it will be seen that the "heat of vaporization" *r* of 120-pound steam is 874 B.t.u., i.e., that

$$874 \times 778 = 679{,}972$$

foot-pounds of energy in the form of heat are required to tear the molecules of that pound of water at 341 degrees apart and convert it into dry-saturated steam of the same temperature. Of this energy 822 B.t.u., as shown in the sixth column, are required to push back the surroundings as the water expands into steam, to perform external work *A p u*, while the rest,

$$874 - 82.2 = 791.8$$

B.t.u., are required to overcome the attraction of the molecules for each other, to do internal work ρ, as shown in the fifth column.

FRAGMENTS OF PEABODY'S "TABLES OF STEAM PROPERTIES."

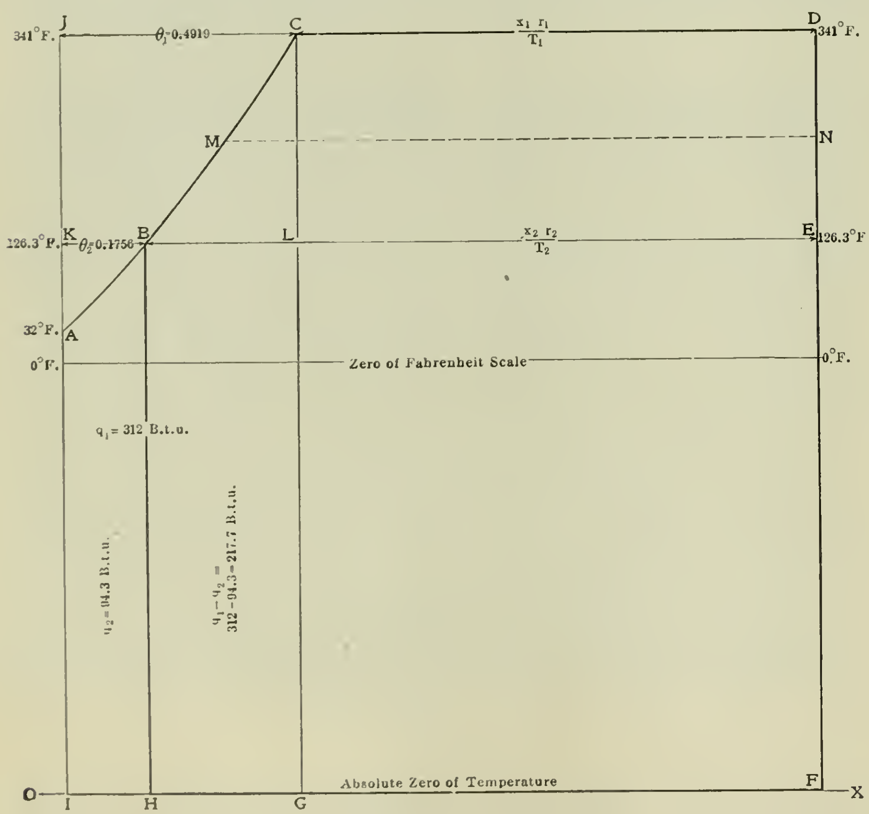

FIG. 2

At *C* the pound of water is about to change into steam. As the process takes place at constant temperature the change of state will be represented by a horizontal line *C D*. If the pound of water is all changed to steam the line *C D* must be of such length that the area *C D F G* will be proportional to 874, the heat of evaporation, on the same scale as the rest of the diagram. If only 0.98 of the water is changed to steam, i.e., if there is 2 per cent. of moisture it will take only

$$0.98 \times 874 = 856.52$$

B.t.u. to make the change, and the area *C D F G* would be drawn to represent that number of units. Similarly, to produce a mixture of steam and water of any quality *x* (the quality being the fraction of the mixture which is steam, 0.98 in the above case), will require *x r* heat units, *r* being the heat that would be required to evaporate the whole pound.

To convert the pound of water from 126.3 degrees, at *B*, into the pound of steam at 120 pounds, or 341 degrees, has taken an amount of energy in the form of heat proportional to the area of the diagram *B C D F H*, made up of *B C G H*, which is the difference between the heats of the liquids *q* at 341 and 126.3 degrees, and *C D F G*, the heat of vaporization of the mixture and equal to *x r*, or to *r* if *x* is unity and the steam is dry saturated. Therefore, the heat put into the pound of steam is

$$q_1 - q_2 + x_1 r_1,$$

the subscripts, or little figures below the letters, meaning at the higher temperature for 1 and at the lower for 2.

Now, suppose expansion to take place without any heat being either added to or taken from the mixture. In Fig. 2 addition of heat has resulted in movement to the right; abstraction of heat would be represented by movement to the left. As the steam expands its temperature falls, and as no heat is added or abstracted the change of state would be represented by a vertical line, as for instance *D E*, if the expansion occurred between 341 and 126.3 degrees. This would result in a pound of mixed steam and water at 126.3 degrees, for even if the steam were initially dry-saturated, there has been condensation due to the conversion of heat into work. The area *B E F H*, therefore, represents the heat of vaporization of that part of the pound of working fluid which is still steam, or $x_2 r_2$. The heat of vaporization r_2 at 2 pounds or 126.3 degrees may be taken from the table. How shall x_2, the quality after expansion, be found?

The area *CD F G* is proportional to $x_1 r_1$. Its hight $C G = T_1$, the absolute temperature at 120 pounds. Then its length CD must be its area divided by its hight or

$$\frac{x_1 r_1}{T_1}.$$

The horizontal distance of any point from the line JC, which passes through the point of 32 degrees, is proportional to the "entropy of the liquid" θ, at the temperature corresponding to the vertical position of the given point. For example, the distance JC of the point C is 0.4919, the entropy of the liquid θ, at 341 degrees (see seventh column of the table opposite 120 pounds).

The line $JD = CD + JC$ is proportional, therefore, to

$$\frac{x_1 r_1}{T_1} + \theta_1.$$

Similarly the line KE is proportional to

$$\frac{x_2 r_2}{T_2} + \theta_2.$$

And since these lines are equal,

$$\frac{x_1 r_1}{T_1} + \theta_1 = \frac{x_2 r_2}{T_2} + \theta_2. \quad (1)$$

All of these quantities with the exception of x are obtainable from the steam tables, and if one of the x's is known the other can be easily determined.

The heat remaining after expansion is $x_2 r_2$.

Then the number of heat units converted into work is

$$x_1 r_1 + q_1 - q_2 - x_2 r_2 \quad (3)$$

And if each heat unit is equivalent to 778 foot pounds, the net energy E_n developed by making a pound of water into steam and expanding it (the energy represented by a pressure-volume diagram like Fig. 3) would be

$$E_n = 778\,(x_1 r_1 + q_1 - q_2 - x_2 r_2). \quad (4)$$

For dry-saturated steam expanded from 120 to 2 pounds absolute these quantities become:

$x_1 = 1.$	$x_2 = 0.8038$
$r_1 = 874$	$r_2 = 1015.5$
$q_1 = 312$	$q_2 = 94.3$
$\rho_1 = 791.8$	$\rho_2 = 961.9$

and

$E_n = 778\,(1 \times 874 + 312 - 94.3 - 0.8038 \times 1015.5) =$ 214,294 foot pounds.

The area $b\,e\,f\,a$ of Fig. 3 is the product of the pressure and volume of the steam (or mixture) at the lower temperature. It is proportional to the external work found by subtracting $x_2 \rho_2$ instead of $x_2 r_2$ in formula (4), ρ being the heat equivalent of the internal work and the difference between r and the external work, so that subtracting ρ_2 instead of r_2 leaves in the result the external work at the lower pressure, the area $b\,e\,f\,a$ of Fig. 3. The formula for this case becomes:

$$E_t = 778\,(x_1 r_1 + q_1 - q_2 - x_2 \rho_2). \quad (5)$$

778 (874 + 312 − 94.3 − 0.8038 × [illegible]) = [illegible] foot pounds.

If the total energy of expansion, Fig. 5, is desired, the area $a\,b\,c\,d$ of that figure must be subtracted from Fig. 4. That is the external work of the steam at the higher pressure. To push a pound of steam into the cylinder of an engine and make the line $a\,b$, Fig. 5, on an indicator diagram, a pound of water would have to be evaporated in the boiler and the work done by that water in changing into steam is proportional to the area $a\,b\,c\,d$. This can be subtracted by changing the r_1 of formula to ρ_1, because ρ_1 is just this much less than r_1, and this makes the formula for the total energy developed during expansion:

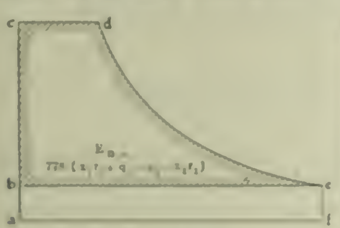

FIG. 3

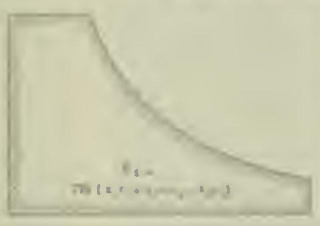

FIG. 4

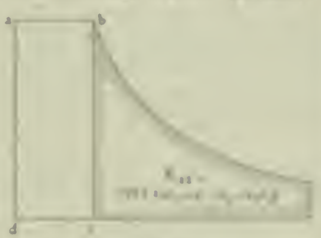

FIG. 5

FIG. 6

Transposing formula (1):

$$x_2 = \frac{x_1 \dfrac{r_1}{T_1} + \theta_1 - \theta_2}{\dfrac{r_2}{T_2}}. \quad (2)$$

The values of $\frac{r}{T}$ are given in the eighth column of the table. If you try to calculate them, remember that T is the absolute temperature, i.e., the Fahrenheit temperature plus 459.5.

Assuming dry-saturated steam to start with, $x_1 = 1$, and the following quantities may be found in the table:

$$\frac{r_1}{T_1} = 1.0918. \qquad \frac{r_2}{T_2} = 1.7519.$$

$$\theta_1 = 0.4919. \qquad \theta_2 = 0.1756.$$

Substituting these values in formula (2):

$$x_2 = \frac{1 \times 1.0918 + 0.4919 - 0.1756}{1.7519}$$

This is only common arithmetic:

```
        1.0918
             1 Multiply
        ------
        1.0918
        0.4919 Add
        ------
        1.5837
        0.1756 Subtract
        ------
1.7519) 1.4081 Divide
        ------
        0.8038 = x2
```

The heat put into the pound of steam was

$$B\,C\,D\,F\,H = x_1 r_1 + q_1 - q_2$$

done by a pound of water in changing to this mixture. If the working fluid were all steam, this value reduced to B.t.u. would be the $A\,p\,u$ of the sixth column of the table. For x per cent. of a pound still in the condition of steam it would be $x_2\,A\,p\,u$. And this is the amount of work which would have to be done upon the steam to expel it against the 2 pounds back pressure. It would have to be subtracted from the total energy represented by Fig. 4 to get the net energy represented by Fig. 3, but this has been done in formula (4), and in this way. The heat of evaporation r is the sum of the internal energy ρ and this external energy, and when $x_2 r_2$ was subtracted in formula (4) it included this external energy at the lower pressure. Of the [illegible] B.t.u. making up the heat of evaporation at the lower pressure, [illegible] would be used in pushing back the surroundings, in making room for the steam, in helping to push the piston away, if the expansion takes place in a cylinder, or in accelerating the mass if in a nozzle, so that they are a part of the energy available by the expansion, and should not be subtracted unless it is desired to take out the equivalent work of overcoming the back pressure in expelling the steam.

If the total energy represented by diagram Fig. 5 were desired it could be

$$E_{te} = 778\,(x_1 \rho_1 + q_1 - q_2 - x_2 \rho_2). \quad (6)$$

778 (791.8 × 1 + 312 − 94.3 − 0.8038 × 961.9) = [illegible] foot pounds.

And, finally, to get the net energy due to expansion, that represented by Fig. 6, the energy to expel the expanded steam must be deducted, which can be done by adding it to the amount to be subtracted in formula (6) by changing the ρ_2 to r_2:

$$E_{ne} = 778\,(x_1 \rho_1 + q_1 - q_2 - x_2 r_2). \quad (7)$$

778 (791.8 × 1 + 312 − 94.3 − 0.8038 × 1015.5) = [illegible] foot pounds.

Applying these formulas to the cases quoted by our correspondent the results would be as follows, showing that it was the net energy of expansion which Mr. [illegible] had in mind in making the statement quoted.

*[illegible]

from Peabody's Temperature - Entropy Table. On the first follow the line for 358 degrees (the temperature in even degrees most nearly corresponding with 150 pounds) to the quality nearest unity, which will be in the triple column on one side or the other of the broken line extending zigzag across the table. To the right of that line the figures in the column marked quality mean degrees of superheat, while to the left they mean the fraction of the pound converted into steam, the x of the foregoing calculations. The quality nearest unity lies in the triple column under No. 1.56, and gives the heat contents as 1185.

On the other page in the column bearing the same number, 1.56, and opposite 212, find the heat contents (after expansion to that temperature) of a pound of steam (having the initial quality given at the higher temperature) to be 1018. table says that steam at 212 degrees and 99.89 per cent. dry has a heat content of 1145.6 B.t.u. This same steam expanded to 108 degrees would have 987.5 B.t.u. (found by locating the value for the lower temperature in the same column of entropy) and

$$778\ (1145.6 - 987.5) = 123{,}000$$
foot-pounds.

Numerous diagrams have been devised from which these values can be measured. Of such are those by H. F. Schmidt and W. C. Way, on page 524 of POWER for August, 1907, and one by R. M. Neilson, which will appear soon.

It is the heat which develops (or reappears as) work in falling from one temperature level to another, and it is the temperature range rather than the pressure range which should be compared when the relative amount of work is in

SECTIONS OF PAGES FROM PEABODY'S TEMPERATURE-ENTROPY TABLES

If the difference between the heat contents at the two conditions be multiplied by 778 to reduce it to foot-pounds, it will be found that

$$778\ (1185 - 1018) = 129{,}926$$
foot-pounds,

which is the total net energy, Fig. 3, for one pound of steam in that initial condition expanded adiabatically through that range.

Under the same column (1.56) and opposite 108 the heat contents are given as 879.7, so that if this same pound of partially condensed steam is further expanded down to 108 degrees the energy developed will be

$$778\ (1018 - 879.7) = 107{,}597$$
foot-pounds.

But starting over again with practically dry steam at atmospheric pressure the question. The temperature of steam of 150 pounds absolute is 358.3 degrees, and of steam at 27½ inches vacuum about 108 degrees, so that the ranges compare as follows:

358.3	212
212.0	108
146.3	104

A glance at Fig. 2 will show that the energy represented by a diagram like Fig. 3 will not be the same for the same range of temperature; *B C D E* of Fig. 2 is equivalent to *b c d e* of Fig. 3. The dotted line *M N* divides the temperature range equally, but the energy, equivalent to the area *M C D N* developed by the fall through the first half of the range, is less than that, equivalent to *B M N E*, developed by the fall through the second half. If the cycle were changed to *C D E L* it is plain that equal falls in temperature would produce equal amounts of work. Just as the vertical line *D E* represents expansion without reception or loss of heat (adiabatic or isentropic expansion), so the line *L C* represents compression by the same mode. The diagram then consists of a line *C D*, representing expansion at constant temperature (the expansion of the water into steam represented by the steam line of the pressure-volume diagram *c d*, Fig. 7), a line *D E*, Fig. 2, representing adiabatic expansion (*d e* in Fig. 7), a line *E L*, representing compression at constant temperature (the line *e l* of Fig. 7, during which the steam is being reduced to its original volume at the constant temperature of the condenser), and the line *L C*, representing adiabatic compression to the original temperature (*l c* in Fig. 7). This is called the Carnot cycle, and from steam worked in this way the energy produced and represented by a diagram like Fig. 7 will be directly proportional to the temperature range.

A Dangerous Omission

By W. H. Wakeman

POWER for October 20, 1908, contained a short article under the above title, and the illustration is herewith reproduced for reference with the following explanation (see Fig. 1): A direct-acting steam pump *A* is used to operate hydraulic elevators. It discharges water through *B* into the pressure tank *C*. A relief valve is shown at *D*, which opens and allows water to flow into the surge tank *E* when the safe limit of pressure is reached. A power pump *F* was installed and is driven by an electric motor. It was connected to the system by inserting the cross *G*. The relief valve *D* was removed and connected at *H*, while *I* represents a stop valve.

The original article called attention to the fact that *I* might be closed and *F* started, thus causing trouble and expense by creating a very high water pressure from which there would be no automatic relief.

This is exactly what did happen about midnight a short time ago, since the original article appeared. There was no engineer in charge, but the fireman on duty heard an unusual noise in the pump room. On going in to investigate the matter he found that the heavy cast-iron air chamber that formerly was located at *J* had leaped upward, making a large dent in the ceiling above it, and had then fallen to the floor, while water was coming out of an irregular hole that was left when the air chamber failed. The switch was pulled out and the pump stopped.

The air chamber is illustrated in Fig. 2. The break occurred in the lower part of

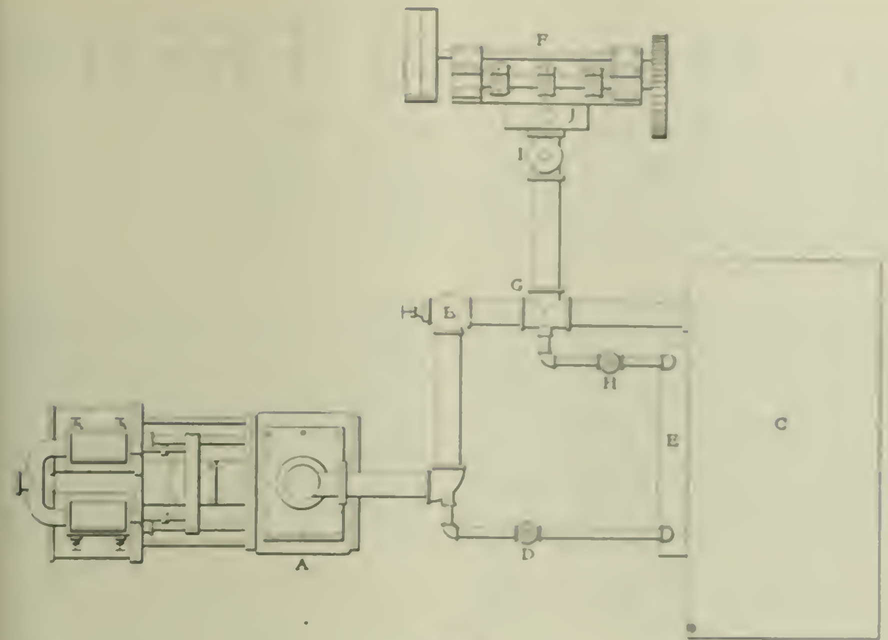

FIG. 1

the neck, which is 5 inches in diameter, while the head above it is 12 inches. It is about 31 inches high above the break, and the flange below is 14 inches. Fig. 3 is a plan of the broken flange, showing a rupture of very irregular form. The iron is from $\frac{13}{16}$ to $\frac{15}{16}$ inch thick; its appearance indicates that the break was new, and the metal was free from air holes, etc.

It is morally certain that the immediate cause of this so-called accident was the fact that the valve *I*, Fig. 1, was closed, and as this prevented the relief valve *H* from opening, a very high pressure accumulated in a short time, especially as it could not find even partial relief by starting seams in the tank *C*, as it did on a former occasion. The automatic electrical apparatus evidently failed to work properly.

Fig. 4 illustrates the pressure gage that is connected to this pump. The pointer evidently made a complete circle on the dial and was forced against the pin with sufficient force to loosen it from its pivot; consequently, it gave up in despair the effort to indicate the great pressure resulting from this mismanagement and hung idly on the pivot, point downward.

The following facts should be taken into consideration in this connection: The power pump *F* was installed a few months ago by two well informed engineers. They advised the superintendent, who has had no previous experience with steam and electrical machinery, to install a relief valve between *I* and *J*, and offered to supply the valve and install it complete for $30, but he replied that it was unnecessary; therefore, it was omitted, with the stated result, which is what would be expected by any practical engineer.

Less than 10 days previous to this failure the night engineer, who held a license the night previous to the date of disaster, under the city government, was kept on duty for 36 hours, because nobody was provided to release him, and then discharged for some trivial fault a few days later. He finished his labors at this plant therefore, it occurred the first night that a new man was operating the machinery. The new man had not secured a license for this plant, as the law allows one week in which to secure the necessary papers. The trouble could not have been caused by the discharged employee, as the day fireman operated the plant for 12 hours after he left, and the night man had been on duty for several hours when the failure occurred. While the night fireman could have kept the valve *I* open while the pump was either in active operation, or else liable to be started automatically at any time, and thus maintain communication with the relief valve *H*, the superintendent, who allowed such a dangerous state of affairs to exist after he had been informed of it and warned of what might happen at any time, is directly responsible. A relief valve, which is only another name for a safety valve, should never be located where an ignorant or careless fireman can prevent it from operating by closing a valve, and any man who does not understand this principle, or is not sufficiently impressed with its importance to apply it rigidly, is not qualified to have charge of a steam plant located in one of the largest buildings in the central part of the city of which it forms a conspicuous part.

FIG. 2

FIG. 3

FIG. 4

The Plunger Hydraulic Elevator

Construction and Operation Details of the Highest Type of Passenger Elevator Made by the Standard Plunger Elevator Company

BY WILLIAM BAXTER, JR.

For the highest type of passenger elevator the Standard Plunger Elevator Company uses the system shown diagrammatically in Fig. 302. In this arrangement it will be noticed that the discharge tank *G* is located several floors above the top of the lifting cylinder. The hight of the discharge tank varies according to the car speed, and ranges from about 40 feet for

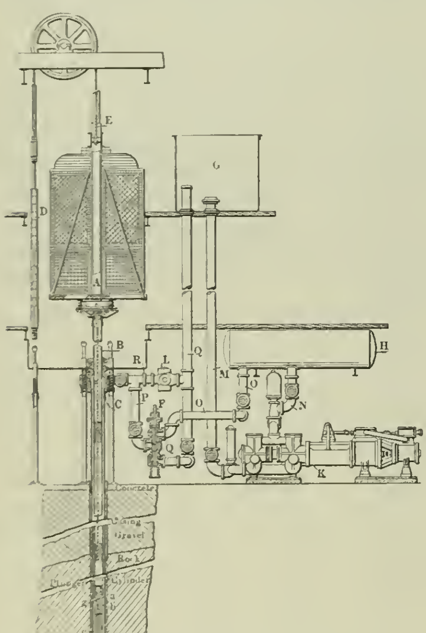

FIG. 302

moderate car speed to double this hight for speeds of 500 or 600 feet per minute. In addition to setting the discharge tank at an elevation, the discharge pipe *Q* is connected with the inlet pipe *P* through a branch *R* in which is inserted a check valve *L*. The object of this pipe connection is twofold; first, it prevents drawing the plunger away from the water in making stops on the upward trips and, second, it saves a considerable quantity of pressure water, and thereby increases the efficiency of the apparatus. The valve *L* permits water to flow freely from the pipe *Q* into the cylinder, but prevents water from passing through it from the cylinder to the pipe *Q*. The operation of the system is as follows: Suppose the elevator is running up at full speed and that the operating valve *F* is closed quickly; then the momentum of the counterbalance *D* will carry the car upward and draw the plunger away from the water, as explained in previous articles. This would be the effect if the pipe connection *R* were not provided, but with this connection, as soon as the plunger begins to draw away from the water, the vacuum developed, assisted by the pressure due to the elevation of the tank *G*, will cause water to run down through the pipe *Q*, the valve *L* and the pipe *R* into the cylinder and keep the latter full. When the plunger comes to a state of rest there is no empty space under it, and as a result the car will not drop down as would be the case if water could not enter the cylinder.

To avoid drawing the plunger away from the water by too rapid a valve closure on the upward trips when the simple pipe arrangement of Fig. 301 is used, the pilot valve is adjusted so that the main valve cannot close too rapidly. With the arrangement of Fig. 302 it is immaterial how quickly the main valve is closed, providing the discharge tank is placed high enough to develop as much pressure as may be necessary to cause water to flow in through the pipe *R* and follow up the plunger as fast as it moves until its motion is arrested by the greater weight of the car. All the water that is drawn into the cylinder through the pipe *R* in making stops represents energy saved, because it reduces the amount of water drawn from the pressure tank *H*.

It is not practicable in all buildings to set a discharge tank at the desired elevation, and in such cases the elevated tank *G* must be replaced by a pressure tank located in the basement. A system of this kind is shown by Fig. 303, which is far more elaborate than Fig. 302 and shows every detail of a high-class passenger-elevator system. Of the two tanks shown, the top one is the pressure and the lower one the discharge tank. The pipe *Q* leads to an inverted U consisting of two legs, as shown, the function of

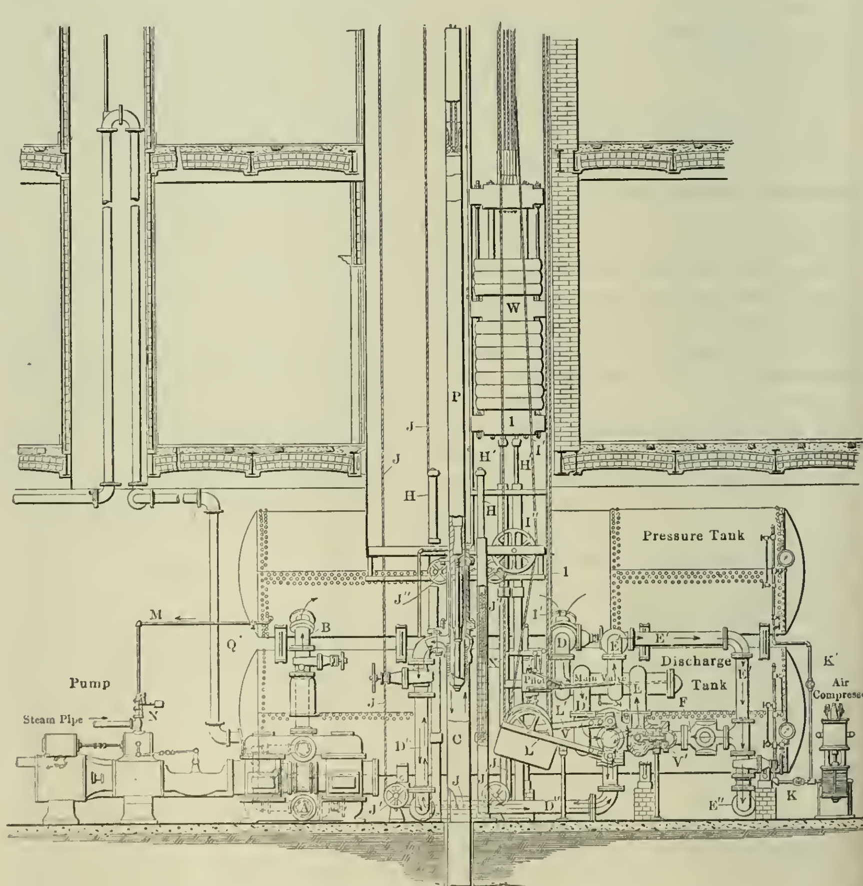

FIG 303

which is to maintain a uniform pressure in the discharge tank. This U-pipe is extended up to whatever hight may be necessary to develop the required pressure. At the bend at the top a short vent pipe is provided, which is open at the upper end, so as to prevent the inverted U from acting as a siphon and drawing the water out of the tank. The pilot valve lever X is actuated by the rope J which runs under stationary sheaves J' at the bottom and over and under the two sheaves J'' at the top of the pit at the bottom of the shaft. At the top of the building the rope J runs over other sheaves, as shown in Fig. 304 which represents all the apparatus at the upper end of the elevator well, and also the elevator car. The lever L of the top automatic stop valve V' is actuated by the rope I, and the lever L' of the down automatic

through the suction pipe A and delivers into the pressure tank through the pipe B. The air compressor forces water into the discharge tank through the pipe E and into the pressure tank through pipe K'. Each tank is provided with gages to show the pressure and the water level. The compressor is run only occasionally, when the air supply runs low. The operation of the main pump is controlled by a pressure regulator N which is connected with the pressure tank by the pipe M. This regulator controls the valve in the steam pipe and thus stops and starts the pump whenever required by the variations of pressure in the tank.

The operation of the elevator is as follows: To start on the up trip the pilot-valve lever X is depressed, causing the main valve to be moved to the left; this allows water to pass out of the pres-

is running upward the valve V' is open so that water coming from the discharge tank through the check valve U can pass through it freely. When the car is descending [illegible] the down stop valve V'' is open until the lower floor is reached; consequently, the discharge water returning from the cylinder C can pass from the pipe D'' to the connection E, thence through the main valve to the pipe E' and to the discharge tank through the pipe E''.

The automatic stop valves shown in Fig. 3[illegible] are arranged slightly different from those presented in Fig. 3[illegible], the arrangement being in the position of the shafts upon which the operating levers are mounted. The main valve also is provided with a safety feature not shown [illegible] other drawings. These points of difference can be understood by inspection of Fig. 3[illegible], which is an enlarged sec-

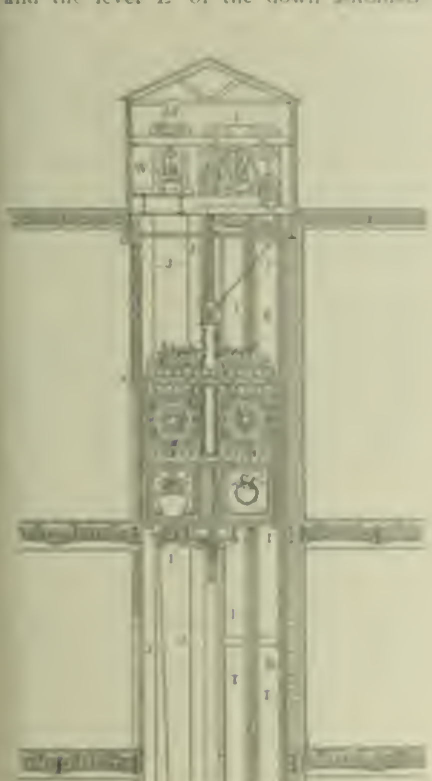

FIG. 304

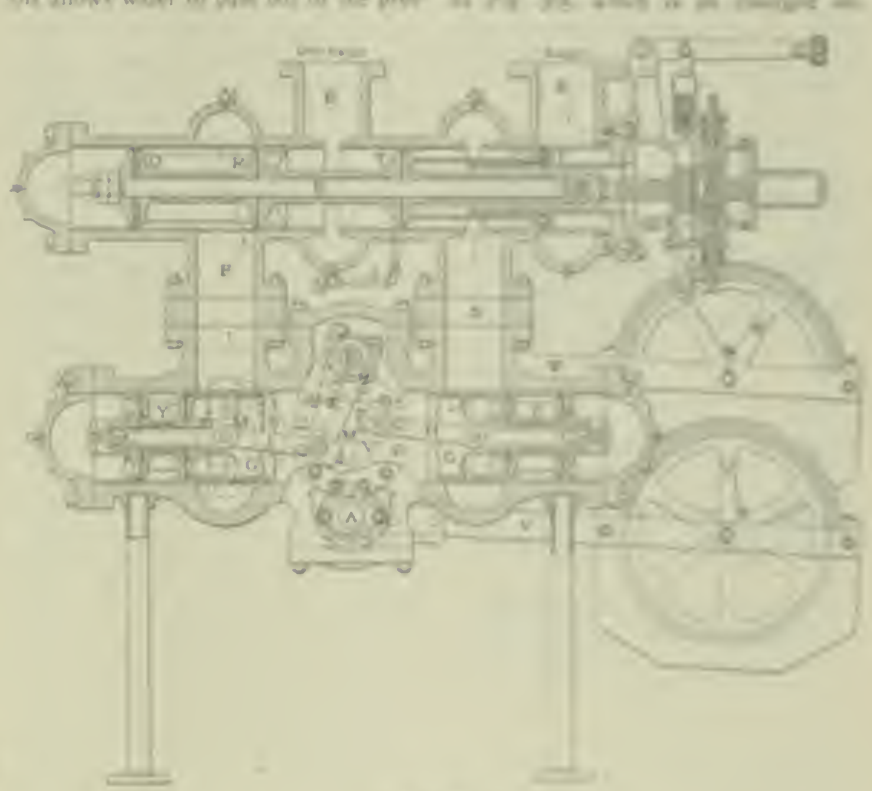

FIG. 30[illegible]

stop valve V'' is actuated by the rope I'. The points of attachment of these ropes to the car and the way in which they are supported at the top of the elevator well are shown in Fig. 304.

The construction of the car buffers is shown in Fig. 303 at H H. The counterbalance buffers are of similar design but are not generally provided with the rubber cushions shown below the spiral springs in the car buffers. If either the car or the counterbalance strikes the buffers running at a high speed, the latter are pushed down until the compression of the springs arrests the motion. The stroke of the buffers depends on the speed of the elevator, being made greater as the speed increases. The pump on the right draws water from the discharge tank

sure tank through the pipe D and the main valve to the connection D', thence through the top stop valve V' to the pipe D'', and to the cylinder C, forcing the plunger P and the car upward. If the car is stopped on the up trip, the flow of water through this path is arrested by the closing of the main valve, and if the latter closes so rapidly that the plunger tends to run ahead the water in the cylinder, then the water in the lower discharge tank flows upward through the pipe E'', to and through the check valve U and into the chamber of the down stop valve V'', as indicated by the dotted lines back of the valve, from here it [illegible] into the cylinder until the car stops. In [illegible] [illegible] the check valve U is the same as the valve L of Fig. 3[illegible]. When the car

[illegible] view of the main and stop valves of Fig. 3[illegible]. The advantage of placing the shafts S and S' [illegible] the wheel is that the levers W and T can be attached directly to them, while in the construction shown by Fig. 3[illegible] one of the levers swings on the shaft of the opposite lever, and requires connection to its own shaft through [illegible] segments. In Fig. 3[illegible] the operation of the stop valves does not appear to be practicable because it looks as if a very small movement of the crank T'' to the left would move it past the center S''. This difficulty will be fully cleared up by the aid of Fig. 3[illegible], which is a vertical section at right angles to the view in Fig. 3[illegible] and passing through the centers of the shafts S and S'. Looking at this drawing it will be seen that the crank

V'' and W'' are made so that they can swing past each other. This view also shows the way in which the bearings of the shafts A and B are made water-tight by the use of the cup packings a' and b'. The shafts are incased in brass tubing $a\,b$ to prevent corrosion.

The safety device attached to the main valve in Fig. 303 is clearly shown in Fig. 305; it consists of the small pipe connection a, and its operation is as follows: Suppose the car is running upward; when it reaches the upper floor the top stop valve Z will close, and at the same time the main valve piston T' will move to the left, thereby locking pressure water in the space S' between the main valve and the stop valve. This pressure will force the cup packings of the stop valve Z out so as to develop possibly sufficient friction to prevent the lever V and the weight of the sheave V' from shifting the valve to the open position when the car starts on the down trip. When the pipe a is

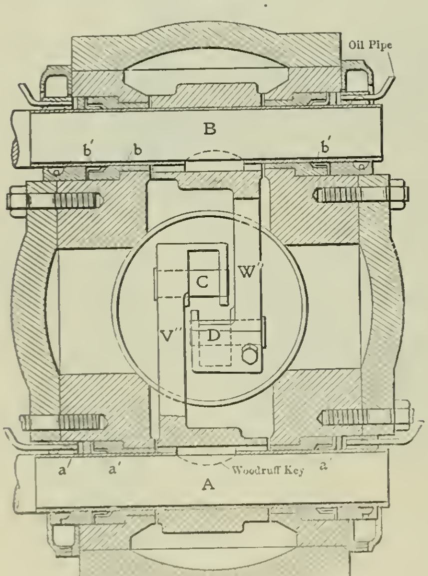

FIG. 306

provided this cannot happen because in order to run the car down the main valve has to be moved to the left so that the piston R may be carried beyond the port and thus open communication between E and E'. As soon as the main valve moves far enough for the piston T to pass to the left of the inlet of the pipe a, the pressure in S' drops to equality with that in E' and then the friction of the cup packings of the valve Z is so reduced that the valve cannot stick. It might be said that this samê result could be accomplished by putting additional weight on the lever V, but this would increase the tension on the operating rope, which is objectionable.

Professor Rateau has granted a license to the British Westinghouse Company for the manufacture of his steam turbine and the company has sold two units of 5000 kilowatts capacity each to London city.

Coal Specifications and Tests

By A. V. Doane

The practice of buying coal by specification, rather than by trade name or other time-honored methods, is rapidly increasing among large purchasers of fuel, and while this tendency is undoubtedly in the right direction, it is by no means a simple matter to write satisfactory specifications or properly to enforce them when written.

It is practically impossible to draw any general specification which shall be universally applicable, for the reason that coal is a natural product varying widely in composition from lignite to graphite. The great variety of purposes for which coal is used and the conditions under which it is burned make it necessary to select the kind best suited to the particular work to be done, if the best results are to be obtained. The most that could be done in the way of general specifications would be to formulate requirements suited to the different classes of service.

As by far the greater part of the bituminous coal mined is used for generating steam, specifications for coal to be used for this purpose have naturally been given the most attention. Even in this special use of fuel there are wide variations, as the quality and composition of the coal which can be economically obtained in different sections of the country vary considerably.

The types of boiler and furnace in use should be considered in specifying the quality of coal desired. For instance, vertical boilers do not give as good results with coal containing a high percentage of volatile matter as the horizontal type, while even a gas coal can be burned smokelessly and efficiently in a properly designed and proportioned furnace.

If more care were given to selecting the coal best suited to the particular case under consideration, and to the training and supervision of firemen, the smoke nuisance would be largely abated, with considerable saving in the fuel charges.

There is generally, at first, considerable opposition on the part of coal dealers to bidding according to specifications. There are several reasons for this: The opportunity for selling inferior coal at a good price is much diminished; there are more bother and detail about delivering and billing; also, a quite general fear that, owing to rejections or onerous requirements, they will sustain losses, which fear often leads to an increase in the price bid as a precautionary measure.

Ill-advised and too severe specifications or lack of judgment and tact in enforcement have sometimes caused a prejudice against this method of purchasing coal, also, but as a rule, if the dealer is treated fairly and the matter is properly explained, he soon becomes accustomed to the change. The honest dealer is protected by the specification method, as unscrupulous competitors who under the old system might have bid on furnishing some well known high-grade coal, intending to substitute an inferior and cheaper grade when making deliveries, will hesitate about playing this trick if they know that the coal will be tested and that they will be held strictly to the terms of the contract.

Writing Specifications

In writing specifications the properties which the coal should possess must be carefully considered, having in view the types of boiler, furnace, stoker, etc., methods of handling, storage and disposal of ashes, character of the load on the engines and the characteristics of the coals which can be readily obtained in the locality.

The amount required, place and time of delivery, mechanical condition of the coal and allowable proportion of slack should be specified. The maximum percentage, based on dry coal, of ash, volatile matter and sulphur and the minimum of B.t.u. per pound should be defined. Also, the coal should not heat dangerously when stored in large piles, nor cause an undue amount of smoke when fired with reasonable care.

In some cases the bidder is allowed to submit his own specifications covering the properties which he guarantees the coal shall possess, and the payment is based on the success of the contractor in delivering coal up to the standard he has set. If the price paid is based on the B.t.u. contained and the coal is weighed when received, the determination of the heating effect may be based on the coal as received, thus correcting for moisture.

The methods of sampling and testing should be described and in case of disagreement between the contractor and purchaser some way should be provided, generally by calling in a disinterested expert, of settling the controversy.

The basis of payment is, of course, one of the most important features of the contract. It is usual to pay the price per ton quoted by the successful bidder, deducting a specified amount as penalty for failure to deliver coal up to the standard, and adding a stated sum as premium for exceeding the requirements. The amount of B.t.u. per pound and the percentage of ash are generally the items on which premiums are paid or penalties deducted, but in some cases the amounts of volatile matter and moisture are included. In some instances, too, any variation from the specified standard makes a change in the price.

Another method, and one which, considering the unavoidable errors in sampling and testing, seems more equitable, is to allow a small variation, perhaps 1 or 2 per cent., above and below the standard before the premium or penalty becomes operative. The amount to be deducted or paid as premium should be given careful consideration in order to protect the interests of both parties to the contract. The purpose should be to deduct enough from the price bid to make good any loss sustained by the purchaser through failure to receive coal of the specified quality and to add enough to reward and encourage the contractor if the standard is exceeded.

It may be said that if the required B.t.u. per pound are received it is hardly fair to make a deduction for excess percentage of ash, but aside from payment for inert matter there are other important considerations: In using a coal having a high ash content more coal must be handled by the fireman to produce a given result, the ash must be heated to the temperature of the furnace and much of this heat is lost. The ash clogs the fire, requiring more draft; the fire must be sliced or shaken more frequently, resulting in a loss of unburnt coal through the grates, a greater tendency to form clinkers and increased expense in handling and disposal of ashes. If the ashes have to be carted to a considerable distance, this item alone may make it economical to buy a higher priced coal with a small percentage of ash, rather than a cheaper coal with high ash content.

In the case of Government, State or municipal contracts, the bidder is usually required to make a deposit with his bid, which may be retained if he fails to execute the contract, if it is awarded to him, and the successful bidder is also required to give bonds to insure the satisfactory carrying out of his obligations.

Tests

It was formerly the custom to calculate the heat units in the coal from the results of an ultimate analysis. This method has been largely superseded by the calorimeter test which is more accurate and can be made rapidly and conveniently, especially if a simple and easily manipulated calorimeter is employed.

In addition to the heat units, determinations of moisture, volatile matter, sulphur and ash are commonly made.

The moisture test is a difficult one to make with accuracy as, if an attempt is made to drive off all the water by heating the coal, some of the combustible volatile is very likely to go with it.

In the same manner the test for volatile matter shows that there is no well-defined line between combined water and combustible volatile matter on the one hand and between the latter and so-called fixed carbon on the other. In order to minimize the error it is customary to heat the coal in a platinum crucible for a definite time over a standard flame.

The test is an important one, as the percentage of volatile matter plays an important part in the heating effect, and while a high volatile coal may give a satisfactory result in the calorimeter, it does not follow that it will make an equally good showing under the boilers, unless the plant is particularly adapted to burn coal of this kind. If anthracite screenings, buckwheat or some of the other small sizes of hard coal are mixed with the bituminous coal the percentage of volatile in the soft coal may be considerably higher than would be desirable if it were to be used alone. It is much more difficult to secure smokeless combustion with a high volatile coal than with one containing only a moderate amount.

It is customary in reports on boiler tests to state the evaporation per pound of combustion or coal free from moisture and ash regarding the residue, after subtracting these constituents, as entirely combustible. This assumption has been shown to be erroneous, as in some coals, particularly those from the western part of the country, a large proportion of the supposed combustible volatile is in reality water of composition. This error ranges from 3 or 4 per cent. for Eastern coals to 14 or more for Western, so that if a true basis of comparison is desired an ultimate analysis is required.

The test for sulphur is of considerable importance with some coals, particularly those from the West, which contain from 1 to 5 per cent. While sulphur is combustible, it has only about one-quarter of the calorific value of carbon. It makes a fusible ash, especially when combined with iron or iron pyrites. The melted ash runs into the air spaces, stopping the air supply and often ruining the grate.

The hot gases containing sulphur are commonly supposed to attack iron, but it is doubtful if the comparatively cool boiler shell is injured; but highly heated ironwork in smoke stacks, etc., may be attacked, and if the sulphurous products of combustion combine with moisture, an acid is formed which rapidly corrodes ironwork exposed to its action.

It is popularly supposed that so-called spontaneous combustion of coal is caused by the sulphur present, but investigation has shown that while the oxidation of pyrites in a coal which has a tendency to heat may play some part in starting the action, the true cause is the capacity of the coal to absorb oxygen, which seems to depend on the molecular condition.

Some coals low in sulphur heat dangerously, while others with a high content of this element give no trouble. Great care should be taken to avoid getting a dangerous coal, as a large mass of coal on fire in the storage bins or pile is an expensive and dangerous proposition.

There appears to be no reliable test which will give absolute information about the heating tendency, although coal which retains considerable moisture when air-dried is said to be more likely to heat. Freshly mined coal containing a large proportion of dust is more liable to heat, especially if wet when stored.

In making coal tests one of the most important operations is the collection of the sample, as it is evident that if this is not truly representative of the coal, the care and refinement with which the tests are carried out are of little use.

If the coal is delivered by carts or hoisted to bunkers a small quantity may be taken from each load or from the tubs or conveyors at convenient intervals and put in a pile, from which the sample is taken. If necessary to obtain the sample from a pile or car, small portions should be taken from different parts, not only on the surface but at some distance below, as there is a tendency for the heavier lumps, which contain the most slate or bone, to settle to the bottom, particularly in railroad cars.

Enough coal should be taken to make a pile containing about one bushel. This should be spread out flat on a clean, dry surface and all large lumps broken. The pile should then be divided into quarters and a section rejected. The lumps should then be broken finer and the coal shoveled over thoroughly to mix it, and again quartered and a section rejected, repeating the operation until there remains but a small quantity, containing no lumps larger than a pea, from which the sample for analysis is taken and placed in an air-tight can or jar holding about one quart. A tin can with a friction top, such as is used for paints or varnish, is convenient.

In order to identify the sample a brass label holder, such as is put on drawers or cases, may be bent to fit the outside of the can and soldered at the corners to hold it in place. A card is then slipped into the holder with the necessary information written on it. The card is changed when the can is used again.

The sample should be taken by a representative of the purchaser and little dependence should be put on tests of sample lumps or of samples sent in by bidders. It is common practice for dealers to send a carefully selected sample to some well known chemist for analysis and then make use of his report to show the high quality of the coal. It is more than probable that a test of a sample of the coal as received by the purchaser will fail to equal the figures given in the report.

In making contracts it is usual to specify that the tests are to be made in accordance with the methods adopted by the American Chemical Society. Experience has shown that if the specifications are so drawn that the purchaser gets the coal which is best suited to his plant and requirements, if the tests are made by a competent person and the interests of both parties to the contract are properly protected, bidding in accordance with these specifications is the best and fairest way to obtain a satisfactory supply of coal.

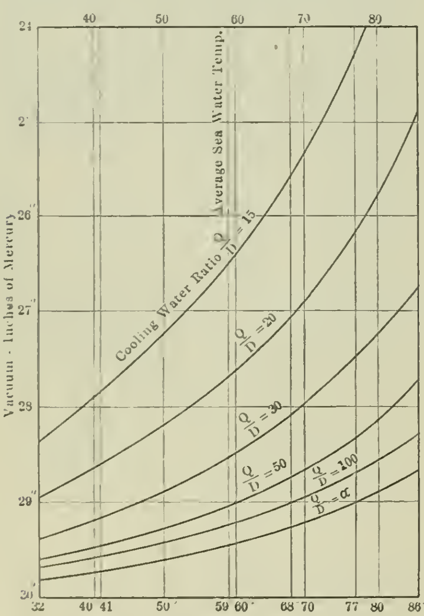
Surface Condensation for Steam Turbines*

Coefficient of Heat Transference, Influence of Air Leakage, Condenser Pumps, Temperature of Air and Water and Contra vs. Ordinary Flow

BY PROFESSOR E. JOSSE

On shipboard surface condensers are always preferred because the condensed water should be fit for use as boiler feed. Even in stationary-turbine plants preference is often given to the surface condenser over the more economical jet condensers for three reasons: (1) the surface condenser produces a good vacuum more easily than the jet condenser; (2) the condensed water is free from oil and can be reused; (3) there is danger that the cooling water of the jet condenser might flow back into the turbine. Messrs. Tosi, of Leghorn, are installing an air-operated nonreturn valve to obviate this difficulty. As a rule surface condensers



Ratio of Cooling Water to Feed - Degrees F.

FIG. 1

are insisted upon for turbines and they may cost from 30 to 60 per cent. of the whole turbine-plant cost. On board ship the large dimensions and weight are factors of importance.

An investigation was made of the effect of increasing vacuum on the thermal efficiency of the prime mover, bringing out the facts that the available heat increases considerably as the vacuum increases above 21 inches. The reason is that the specific volume of the steam augments rapidly as the condenser pressure is reduced, and the cylinders of reciprocating engines cannot for practical reasons be enlarged to accommodate this volume. It is well known that reducing the vacuum below 26 inches does not increase the efficiency of steam engines. In turbines there is ample steam space for large volumes and the lower condenser pressures can be fully utilized. These investigations proved that the engineer is on the right track when he endeavors further to improve the condenser vacuum. What can be achieved by enlarging the condenser dimensions has already been done and it is no good to go farther in this direction. Other ways must be found.

The attainable vacuum depends on the temperature and mass of the available cooling water. Given an unlimited amount of cooling water at 60 degrees Fahrenheit, the steam pressure can be reduced to half an inch absolute, or a 98 per cent. vacuum. With warmer circulating water, the vacuum will, of course, be poorer. In Fig. 1 are plotted the possible vacua with various ratios of circulating water to condensed steam and various initial temperatures. On board ship a ratio of 50 to 60 can generally be managed and an excellent vacuum should hence be realizable, if other considerations did not complicate the problem.

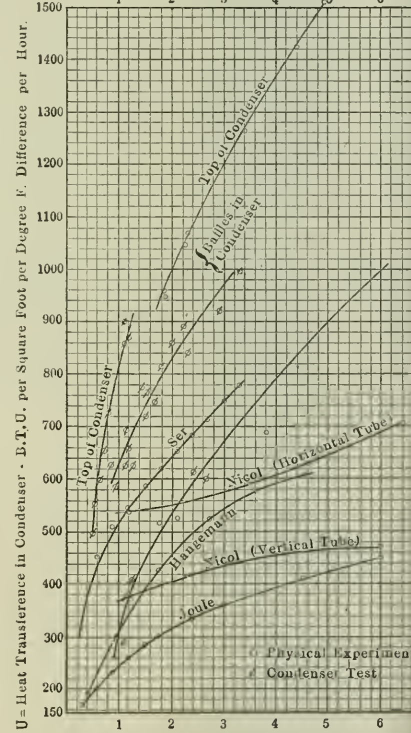
Coefficient of Heat Transference

In order that the steam may give off its heat to the cooling water, the heat has to pass through the metallic wall of the condenser tube and may be considered in three stages: in the transference from the steam to the metal; in the metallic wall of thickness d and thermal conductivity L; and in the transference from the metal to the water. The coefficient of transference U, the number of heat units transferred per hour through 1 square foot of metallic condenser wall when the temperature of the steam is 1 degree Fahrenheit higher than that of the water, can be deduced from the formula

$$\frac{1}{U} = \frac{1}{A_1} + \frac{d}{L} + \frac{1}{A_2},$$

d being the usual thickness of condenser tubes (1 millimeter or 0.0393 inch). For this thickness the value of L is fairly well known and may be given as 18,430 for brass, 61,500 for copper, 11,270 for iron, 5740 for zinc, 11,050 for tin and 2660 for aluminum. The middle term $\frac{d}{L}$ would have the value of $\frac{1}{18{,}430}$ and be of comparatively little importance.

The term $\frac{1}{A_2}$ is the most importan[t] and has been investigated with the aid o[f] two concentric tubes, water being sen[t] both through the inner tube and the annular jacket. The values of various experimenters differ greatly. Professo[r]



Rate of Flow of Cooling Water - Feet per Second

FIG. 2

Josse agrees best with Ser, who gave th[e] approximate formula

$$A - 2 = 510\sqrt{V},$$

where V is the velocity of water throug[h] the tubes in feet per second. This velo[city] is the decisive factor; far more im[portant] than the material of the con[denser] tubes and their thickness, and als[o] of greater consequence than the velocit[y] of the steam, about which, or, rather, th[e] term $\frac{1}{A_1}$, there is even less agreemen[t]. The coefficient A_1 is generally suppose[d] to be about 2085, although Ser give[s] a much higher figure. From an analysi[s] of Ser's figures and his own experiment[s]

*Abstract of paper read before the summer meeting of the Schiffsbautechnische Gesellschaft at Berlin, June 16 to 18, 1908, by Prof. E. Josse, director of the department of engineering at the Technical High School at Charlottenburg.

Professor Josse concludes that 3900 is a more correct value. The velocity of the steam has its influence, but the whole term does not count for much. For water flowing at the rate of 1.64 feet per second Josse's formula would be:

$$\frac{1}{U} = \frac{1}{3900} + \frac{1}{18{,}430} + \frac{1}{653} = \frac{1}{445}$$

and

$$U = 445.$$

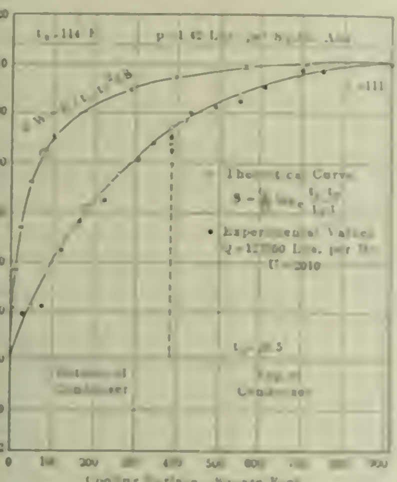


FIG. 3

If A_1 be increased to twice its value U would rise only to 475, and if the tube thickness be increased to 2 millimeters U would hardly be affected. An increase, however, in the rate of flow from 1.64 to 5 feet per second would raise U to 625. As an increase of the steam flow is undesirable the best plan is to accelerate the flow of the circulating water and by introducing the baffle strips or retarders of Pape, Henneberg & Co., of Hamburg, into his condenser tubes, in order to break the water currents up into vortices, he raised the U at a velocity of 3.28 feet per second from 614 to 922. The results of Professor Josse's experiments conducted with condensers and of experiments made by others with physical apparatus are plotted in Fig. 2, the curves showing that in condenser tests better results are obtained than in experiments conducted in the physical laboratory.

Opinions differ concerning the increase of U with greater differences of temperature. According to some the heat transferred should increase proportionately to the difference; according to Weiss and others, proportionally to the square of the temperature differences. His investigations were conducted by placing thermocouples in different portions of the condenser tubes. If the heat transferred increases as a linear function of the difference then the rise of the temperature in the cooling water should follow an exponential law and it was found to be so.

The curves in Fig. 3 are in equally close agreement with the formula

$$Surface = S = \frac{Q}{U} \log_e \frac{t_s - t_1}{t_s - t},$$

where t_s is the saturation temperature and t_1 the temperature of the cooling water at entrance, t being the discharge temperature. It will be seen that the quadratic formula of Weiss does not conform at all with the theoretic curve.

Influence of Air Leakage

Before proceeding to a calculation of suitable condenser dimensions the influence of air leakage must be studied. Air enters into the condenser with the exhaust steam, the temperature of the air being that of the steam; the pressure of the mixture will be the sum of the partial steam pressure and of the partial air pressure. The air must be withdrawn by the air pump. If the withdrawal takes place at the temperature corresponding to the condenser pressure the partial steam pressure would be equal to the condenser pressure; that is, the partial air pressure would be zero and the pump would have to deal with an enormous air volume. The air pressure should, therefore, not be re-

FIG. 4

duced to zero and the temperature be lowered, at the spot where the air is withdrawn, below the saturation temperature of the condenser pressure. The condenser is to cool the air as well as the steam, for while the heat transference from steam to metal takes place readily, the respective coefficient U being in round numbers 4100, air is known to be a good thermal insulator and its U is of the order of 1.

Experiments on the heating of air when passing along pipes have been made by Ser. He noticed that the U improves with the diameter of the pipes, and also with the velocity of the air (the pipe diameters range from 16 to 40 millimeters), but he did not introduce a diameter term in his empirical formula, and all his experiments were conducted at ordinary air pressure.

In the condenser vacuum the heat transference should obviously be smaller than at atmospheric pressure and Professor Josse investigated this problem by carrying air at different speeds and pressures through a pipe of 25 millimeters internal diameter and 1500 millimeters in length placed in a steam bath at 212 degrees Fahrenheit. The air was drawn by a pump through a meter, its volume determined and its pressure adjusted by means of a valve inserted between the meter and the pipe. The heat transmission from the steam through the pipe wall to the air was deduced from the heat of the air and checked by determining the amount of condensation taking place in the steam space.

Figs. 4 and 5 and the accompanying table show the results in a striking manner, the experiments indicating that the rate of flow of the water which is decisive for the cooling of the steam will be of little consequence for the cooling of the air, which will essentially depend upon the rate of flow of the air, in consequence of which large air-cooling surfaces should be provided.

The curves of Fig. 6 illustrate the rise in the temperature and the cooling water resulting when different amounts of air enter the condenser. In both cases, the first portion of the curve is horizontal, i.e., there is no temperature rise at first. In the lower curve about 40 per cent. of the total condenser surface seems to have essentially served for cooling the air, since if the exhaust were free of air the curve would at once rise.

In steam turbines it is more easy to keep air out than in reciprocating engines. In turbines air can only gain access, as a rule, through the shaft glands, which are packed with water, oil or steam. Steam turbines are, however, as liable as reciprocating engines to air contamination through the feed water, if the pipes are leaky or the pumps do not work well.

FIG. 5

For well constructed turbines the amount of air leakage should be very small. Experiments with a 3000-kilowatt Parsons turbine show that not more than 11 pounds of air was delivered per hour when 3000 pounds of steam was used per hour.

Condenser Pumps

Turning to the condenser pumps, Professor Josse points out that the wet and condensed water may either be removed separately, by a so-called dry-air pump, or both together, by a wet-air pump. As dry-air pumps have to deal with high compression ratios, with high vacua and single-stage pumps, the clearances must be small. When the clearance amounts to 5 per cent. the vacuum cannot be maintained at more

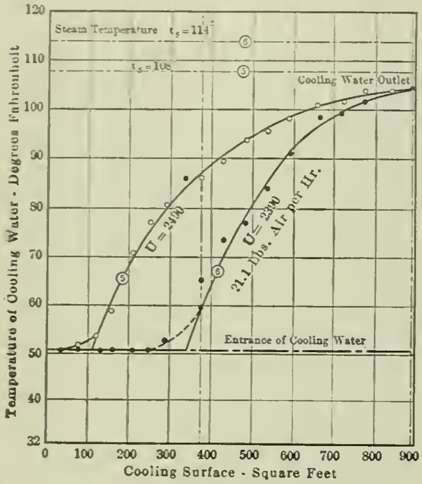

FIG. 6

than 95 per cent. and the clearance must be reduced, or other expedients adopted. Three are mentioned: (1) the air pump may be built in two stages; (2) the pump may be fitted with an equalizing pipe so that the two sides of the piston are connected near the end of each stroke, the volumetric efficiency is raised by this expedient, but considerable more power is absorbed to accomplish the result; (3) with the wet-air pump the clearance space is made to receive the condensed water which will fill at least part of it.

Fig. 7 illustrates the construction of these double-acting wet-air pumps. It will be noted that means are provided in the upper valve deck to allow the noncondensable vapors to enter above the piston on each down stroke, together with the water which flows in through the center ports passed over by the piston.

A pump of this design, 20 inches in diameter, 6.3 inches stroke and running at 250 revolutions per minute, for a plant condensing 22,000 pounds of steam per hour with a vacuum of 28 inches, was also illustrated. It is important in this pump that the valves should be very light in weight.

Temperature of Discharged Air

Returning to the temperature at which the mixture of condensed water and air should be withdrawn, the case represented

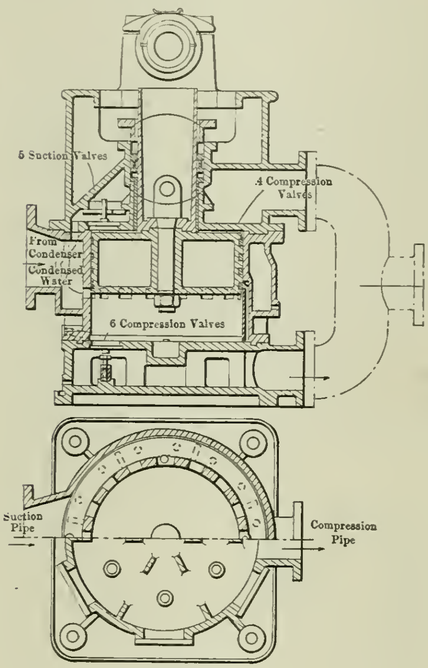

FIG. 7

in Fig. 8 is that of a 28½-inch vacuum, one kilogram of air entering per hour, and the air-pump capacity is 50 cubic meters, 1765 cubic feet per hour. The abscissas are the temperatures at the condenser outlet. If the pump is merely to remove the dry air the flow of air would be little influenced by the temperature, as the straight line in the upper part of the diagram indicates, but the partial pressure of the air at saturation temperature dwindles to zero and the air volume becomes very great.

In the case represented the volume to be removed would equal the pump capacity of 50 cubic meters at 25.6 degrees Centigrade, when the partial air pressure will be 0.017 atmosphere. If the pump had a capacity of 2800 cubic feet, or 80 cubic meters per hour, then the temperature might rise to 29 degrees Centigrade. If, on the other hand, two kilograms of air should leak into the condenser instead of one, the cooling would be carried down to 15 degrees Centigrade.

The temperature of the discharged air is a criterion as to the fitness of the con-

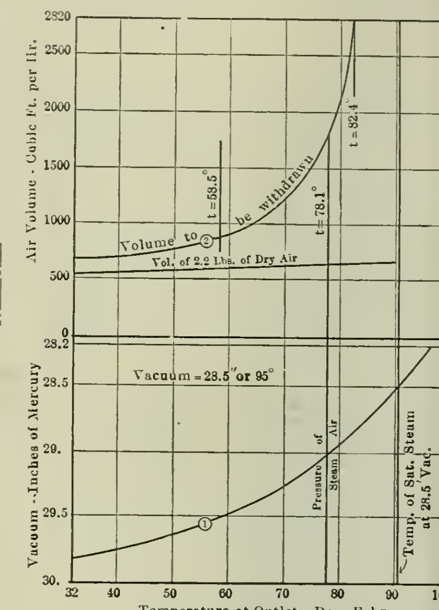

FIG. 8

denser plant, but caution should be exercised in forming an opinion. A claim that the condenser must work the better the lower the temperature of the discharged air is unjustified. The air temperature may be low because there is much air leakage, or because the pump delivery is poor. Air leakage becomes a serious factor when a high vacuum is to be utilized and the air must be cooled whether a dry- or wet-air pump be used.

Temperature of Condensed Water

As regards temperature of condensed water the two systems differ. When the air is separately withdrawn the condensed water need not be cooled. When a wet-air pump is used extra cooling of the condensed mixture is necessary, lest an after escape of air ensue; Professor Josse first cools the liquid, then the air, by bringing it into contact with the liquid, as the cool-

ing of the water requires much smaller surfaces than the cooling of the air. This arrangement is said to save surface space. The extra cooling of the liquid is [illegible] far undesirable, as the cold feed water has afterward to be reheated with modern high vacua which generally do not require a cooling of more than a few degrees below saturation temperature. This loss of heat will not amount to more than 1 or 1½ per cent. of the heat of the feed water. The wet pumps are, on the whole, simpler, occupy less space, absorb less power than dry-air pumps. Another point is that the steam withdrawn, together with the air, has to be compressed; for this purpose injection is sometimes resorted to. In the wet pump the steam will condense again as soon as compression is begun.

A Series of Condenser Tests

Professor Josse's experiments have extended over three years, during which his improved condensers have been working satisfactorily.

The first series of tests concerns the 300-kilowatt Parsons turbines of the engineering laboratory at Charlottenburg, which a vertical pipe of ample dimensions connects with the surface condenser below. The wet-air pump of Professor Josse is driven by belting from an electric motor at 300 revolutions. The chief dimensions are as follows:

Cooling surface	968	sq. ft.
Tubes, diameter	0.79	in.
Tubes, thickness	0.04	in.
Tubes, length	[illegible]	in.
Number of tubes (upper set)	316	
Number of tubes (lower set)	242	
Total	[illegible]	
Surface (upper set)	[illegible]	sq. ft.
Surface (lower set)	[illegible]	sq. ft.
Total surface	[illegible]	sq. ft.
Total cross-section (upper tubes)	[illegible]	sq. in.
Total cross-section (lower tubes)	[illegible]	sq. in.

The average duty of the condenser was 35 kilograms of steam condensed per hour per square meter (7.15 pounds per square foot) of cooling surface. The excess of cooling over the theoretical at the highest vacuum was 16 per cent., with a 27-inch vacuum, which went down to 5 per cent. The difference in temperature between the temperature of the condenser and the discharged cooling water was generally less than 2 degrees Centigrade.

The average coefficient of heat transference was high to 600, even 800, although the rate of flow of the cooling water was, as a rule, only 0.4 of a meter per second (16 inches). This high efficiency is ascribed to the good services of the baffles. The cooling water was very pure and baffles had not required any cleaning in three years.

The second condenser experimented with was that of the 200-kilowatt turbine of the laboratory built at the Allgemeine Elektricitats Gesellschaft. This condenser was built for experimental purposes and is of peculiar construction. It consists of [illegible] tubes, disposed in an upper and lower condenser, [illegible] of the tubes of the upper condenser run crosswise, their length being 558 millimeters (22 inches). The three sets of longitudinal tubes have each a length of 1200 millimeters (47 inches), a common internal diameter of 15 millimeters (0.59 inch), and a total cooling surface of 28.52 square meters ([illegible] square feet). This small area is to condense 2000 kilograms (4400 pounds) of steam per hour, 65 kilograms per hour per square meter (13.3 pounds per square foot), nearly twice as much as the first condenser. The best vacuum reached was 96.4 per cent., and nearly 50 per cent. more than the theoretical amount of cooling water was needed for this performance. The wet pump was also too small. The heat transference was very good, the coefficient rose to 1470 in the case of the top tubes. For the condenser as a whole the heat transference was 786, when the cooling-water ratio was 50. The cross tubes were added to see whether vortices set up in the steam would raise the efficiency; no such effect was observed.

Contraflow and Ordinary Flow

Professor Josse then discusses the piping system connecting the pumps to the condensers, the main case being where a cooling-water ratio of only 21 could be obtained, in consequence of which the vacua were much lower than what they should be. He questioned also the justification of the general distinction between contraflow and ordinary flow. For the greater portion of the condenser there is a rise of temperature only on the water side, the temperature of the steam side remains that of the saturated steam and the term "contraflow" should, strictly speaking, only be applied if there is a temperature fall in the one direction and a corresponding temperature rise in the opposite direction. As far as the condensation is concerned, it is immaterial in which direction the water flows. The con[illegible]

[illegible]

Increasing the Efficiency and Capacity of Large Gas Engines by Cooling the Charge

By F. E. Junge

Professor Junkers, of the Technische Hochschule of Aachen, Germany, has been conducting a long series of investigations to ascertain the influence of charge temperature on both the capacity and the

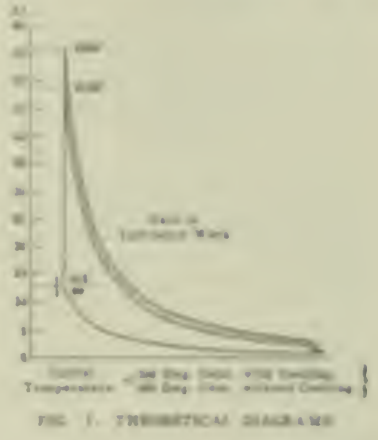

Fig. 1. Theoretical Diagrams

reliability and economy of gas engines. Fig. 1 shows the theoretical difference in the internal working process of the same gas engine operated with and without cooling the charge. According to the figure, there is a gain in work output attainable as represented by the small area along the expansion line, and as a further result of all-round reduction of temperatures in the cyclic process is realized.

The Junkers experiments were made on one of the Oechelhaeuser two-cycle engines of the Hörder Verein, at Hörde, Westfalia. Fig. 2 gives a schematic view of the engine, which was described in detail in Power in 1906. The operation here [illegible]

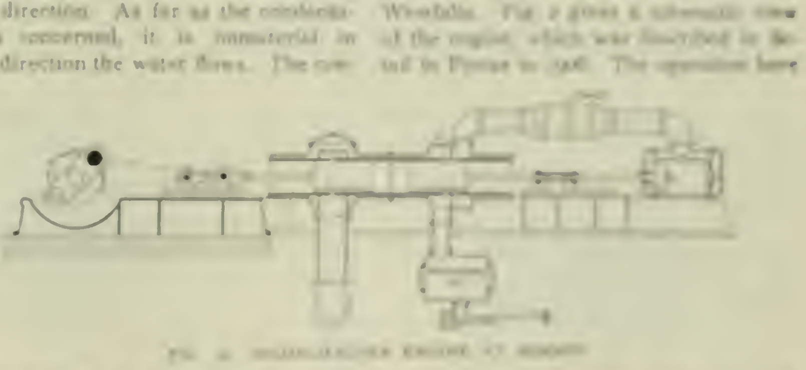

Fig. 2. [illegible]

[illegible]

pipe above, which is provided with a cooler, as shown in the sketch.

In the first trial the engine ran, without cooling the charge, at its maximum capacity, yielding a mean pressure in the working cylinder of 4.55 atmospheres and developing 395 indicated horsepower. The charge temperature was 90.5 degrees Centigrade. In the second trial the engine ran with cooling of the charge and yielded a mean pressure of 5.29 atmospheres, or 460 indicated horsepower in the working cylinder. The cooler reduced the charge temperature from 90.5 to 30.5 degrees Centigrade, the difference or refrigeration amounting, therefore, to 60 degrees Centigrade. From this follows a theoretical increase of capacity, with cooling, of 0.198 of the amount attained without cooling. The practical increase was 0.165 of the ordinary result. In other words, when cooling the charge the engine showed an increased output of 17 per cent. beyond what was attainable without cooling.

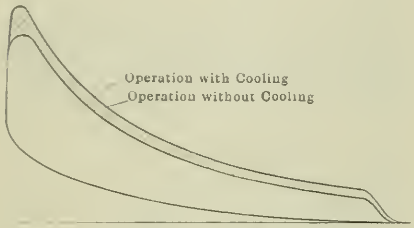

FIG. 3. ACTUAL DIAGRAMS TAKEN AT HOERDE

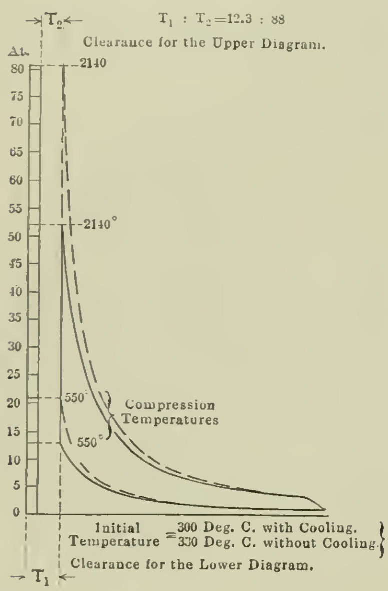

FIG. 4. DIAGRAM SHOWING EFFECT OF MIXTURE COOLING ON COMPRESSION RATIO

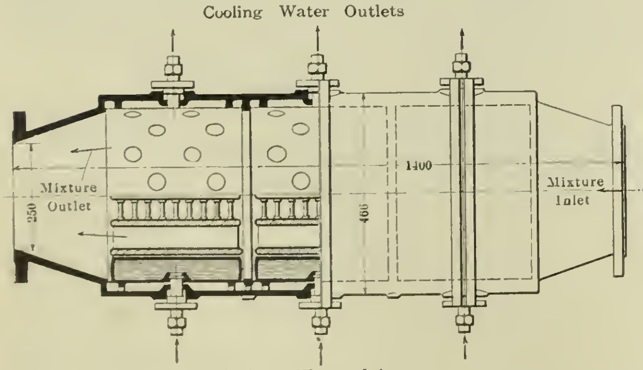
Fig. 3 gives two diagrams plotted one above the other, the one taken without and the other with cooling. The pump work amounted to 55 indicated horsepower in the first and to 51 indicated horsepower in the second instance. But this difference is probably due to the fact that the charging pump was too large for ordinary operation and its intake had to be throttled, while, owing to the larger free volume taken when cooling, the throttle was opened and its resistance diminished. The cooler carried away approximately 38,500 heat units per hour from the charge. A comparison of heat absorption by cooling water with and without mixture cooling, respectively, gives the following results, it being assumed that 700 heat units per horsepower-hour were being carried away by the cooling water: Output without intercooling = 395 indicated horsepower; loss to cooling water of cylinder = 700 × 395 = 276,500 heat units per hour. Output with intercooling = 460 indicated horsepower, and it was ascertained that the heat loss to the cooling water for the cylinder was not larger than before, 276,500 heat units per hour. In addition, there were wasted 38,500 heat units for cooling, making a total of 315,000 heat units per hour. An engine not equipped with the cooling device would lose, for the same output of 460 horsepower, 460 × 700 = 322,000 heat units per hour. It follows that the cooling also has a favorable effect on the total heat carried away per unit of power developed.



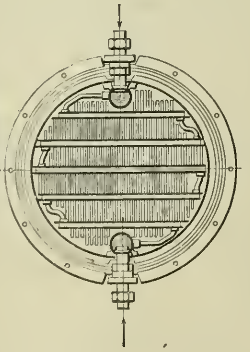


FIG. 5 COOLER OF OECHELHAUSER ENGINE AT HOERDE FIG. 6

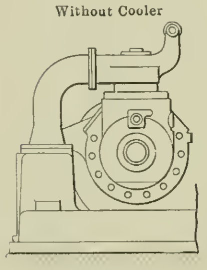
Among other advantages of the Junkers system may be mentioned that the number of misfires is reduced, whereby the average mechanical efficiency of the engine is increased. Also, part of the water vapor of the charge is separated out by the cooler, by condensation, which must have a favorable effect on the combustion process. But these advantages are not all that can be realized by the innovation of mixture cooling. If, instead of reducing the temperatures of the whole cyclic process, cooling is used for increasing the compression pressures, then a far greater capacity may yet be obtained. For instance, cooling the charge by only 30 degrees Centigrade allows an increase of compression pressure from 13 to about 21 atmospheres to be used, without thereby increasing the cylinder temperature above



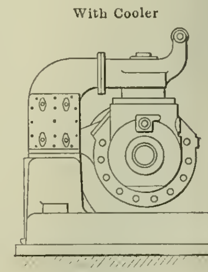


FIG. 7 FIG. 8

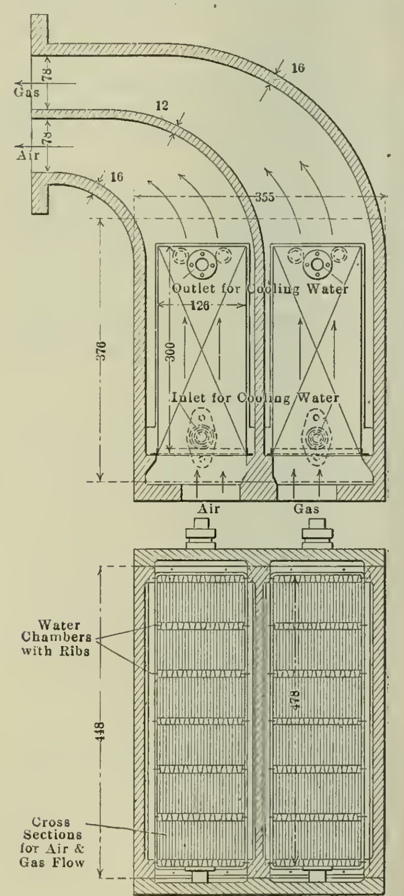
200-HORSEPOWER KOERTING ENGINE WITHOUT AND WITH COOLER



FIGS. 9 AND 10. EXPERIMENTAL COOLER FOR 200-HORSEPOWER KOERTING ENGINE

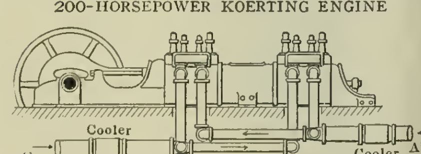


FIG. 11. FOUR-STROKE TANDEM ENGINE WITH COOLER

that of ordinary engines. A Korting engine running on producer gas and driving an electric generator showed thus an increased capacity of 12 per cent. at the switchboard. The fact was also confirmed that preignition, which had been a weak feature of the particular installation, disappeared entirely when cooling the mixture.

As to the construction of the cooler, those surfaces which absorb the heat of the gases must bear the correct proportion to the others which conduct their heat to the cooling water. The coolers are made of copper and are tinplated. They are mounted in solid cast-iron casings in such manner that the reciprocating movements, which accompany the operation of large engines, do not impose unfavorable stresses on the cooling system. The coolers allow the gases to pass through without change of direction, and the path of their travel is short, so that the friction resistance is small.

Figs. 5 and 6 show the cooler used at the Horde Verein. Figs. 7 and 8 show an arrangement of coolers used in connection with Korting engines. It will be evident that the appearance or floor space of the engine is not changed at all. The coolers are put in place from one side, like drawers, and can be removed for inspection and cleaning in a few moments after loosening the cover. Fig. 11 gives a schematic view of a tandem four-stroke engine with coolers built in both the air- and the gas-intake pipes. They show very favorable results, especially in summer; of course, it is impossible to realize such a considerable increase of capacity as with two-stroke engines, because the air is not compressed before it passes to the engine cylinder and the temperature differences are therefore smaller.

According to a contemporary, the turbinal tubeless boiler is made of concentric annular conical vessels with narrow water spaces and narrow flame spaces, heated by a liquid-fuel burner from below. The steam produced in the boiler proper descends through a helically coiled superheater tube placed in the middle space of the innermost cone. The issuing steam is dried and comes out at a high temperature, something that may be over 600 degrees Fahrenheit.

An interesting departure in steel works practice is about to be begun by the United States Steel Corporation in the establishment of a bureau for scientific research near Duquesne, Penn. A laboratory is to be created, the work starting in the spring, and experiments will be systematically carried on with the purpose of improving the processes and methods of steel manufacture for the benefit of the various constituent companies of the United States Steel Corporation.

Tests of Run-of-Mine Coal and Coal Briquets

A bulletin on the comparative tests of run-of-mine coal and coal briquets on locomotives and on a torpedo boat has just been issued by the technologic branch of the United States Geological Survey. The author of the bulletin, W. F. M. Goss, consulting engineer on briquet tests, gives the results of the tests in the following:

1. The briquets made on the Government's machines have well withstood exposure to the weather and have suffered but little deterioration from handling.

2. In all classes of service involved by the experiments, the use of briquets in the place of natural coal appears to have increased the evaporative efficiency of the boilers tested.

3. The smoke produced has in no case been more dense with the briquets than with coal; on the contrary, in most tests the smoke density is said to have been less when briquets were used.

4. The use of briquets increases the facility with which an even fire over the whole area of the grate may be maintained.

5. In locomotive service the substitution of briquets for coal has resulted in a marked increase in efficiency, in an increase of boiler capacity, and in a decrease in the production of smoke. It has been especially noted that careful firing of briquets at terminals is effective in diminishing the amount of smoke produced.

6. In torpedo-boat service the substitution of briquets for coal improves the evaporative efficiency of the boiler. It does not appear to have affected favorably or otherwise the amount of smoke produced. The briquets used in this series of tests were of a form requiring considerable bunker capacity for their storage, but as the form of the briquet is a detail entirely within control, this objection need not apply to the use of the briquets in actual service.

The tests of the coal and briquets on the locomotives were made under the direction of A. W. Gibbs, general superintendent of motive power of the Pennsylvania lines, by E. D. Nelson, engineer of tests, at Altoona, Penn., in coöperation with the technologic branch of the Geological Survey, which supplied the coal and manufactured the briquets.

Many low-volatile coals, such as those mined in the vicinity of [illegible], Penn., are semi-smokeless and therefore very desirable for use in locomotives at or near terminals; nevertheless, on account of their low evaporative efficiency, they have not been found altogether satisfactory when used as locomotive fuel. Their tendency to disintegrate rapidly on the grate during combustion causes large quantities of cinders and sparks of high calorific value to be discharged. These [illegible] accumulate in the smokebox or the front end, cinders obstruct the draft on the fires and reduce the capacity of the boiler. The investigation here reported, therefore, was undertaken to determine in what measure, if any, the briquet process will serve as a remedy for these defects and to discover the effect of the process on efficiency and economy.

The coal selected for the tests was taken from a mine working the "Lower" Kittanning seam, located near Lloydell, Penn., on the South Fork branch of the Pennsylvania Railroad; its characteristics as a locomotive fuel were therefore well known. The Lloydell coal is a very friable low-volatile bituminous coal, and the carloads selected for the tests consisted of run-of-mine. They were loaded and shipped under the direction of J. S. Burrows, of the Geological Survey. The coal was exposed to the weather for thirty days on the way to the St. Louis testing plant, before being made into briquets. It showed but little change due to this exposure except a decided increase in moisture, which, however, was eliminated in the briquetting process.

The binding material in all the briquets was water-gas pitch. This material was furnished to the briquet plant of the United States Geological Survey, at St. Louis, at $8 per ton, or .44 cent per pound. The least amount of binding material that would make perfect briquets was found to be 5 per cent. of the weight of the coal. The cost of the binder in one ton of the 5 per cent. briquets was, therefore, 45 cents.

The cost of the briquet process, including all charges, is estimated to be about $1 per ton of briquets; that is, the briquet process added approximately $1 per ton to the cost of the coal. The briquets were made, however, by an experimental plant, and the price is for this reason probably not so low as if they had been made on a much larger scale.

The briquets were made by the coal-testing plant of the United States Geological Survey at St. Louis. The coal was shipped from the mine at Lloydell under the supervision of an inspector of the Survey, who at the same time obtained mine samples. The samples were hermetically sealed and sent to the St. Louis laboratories for analysis. After the coal was made up into briquets it was returned to the locomotive-testing plant at Altoona for the tests.

To observe the effect on briquets of exposure to the weather, a number of the round and square briquets were placed on the roof of the testing plant. After four months of exposure for the round and three months for the square briquets, no serious change from their original condition was noticed. They seemed to be equally impervious to moisture and were still firm and hard.

The briquets were little affected by handling. They were loaded at St. Louis in open gondola cars, and shipped to

Altoona, where they were unloaded by hand and stacked. They were handled a third time in taking them to the firing platform of the test locomotive. After these three handlings they were still in good condition, very few were broken, and the amount of dust and small particles was practically negligible.

Conclusions Reached

The results of the tests justify the following conclusions:

(a) The evaporation per pound of fuel is greater for the Lloydell coal briquets than for the same coal in its natural state. This advantage is maintained at all rates of evaporation.

(b) The capacity of the boiler is considerably increased by the use of coal briquets.

(c) The briquet process appears to have little effect in reducing the quantity of cinders and sparks; the calorific value of these, however, is not so high in the briquets as in the natural fuel.

(d) The density of the smoke with the coal briquets is much less than with the natural coal.

(e) The percentage of binder in the briquet has little influence on smoke density.

(f) The percentage of binder for the range tested appears to have little or no influence on the evaporative efficiency.

(g) The expense of the briquet process under the conditions of the experiments adds about $1 per ton to the price of the fuel, an amount which does not seem to be warranted by the resulting increase in evaporative efficiency.

(h) With careful firing, the briquets can be used at terminals with a considerable decrease in smoke.

(i) The briquets appear to withstand well exposure to the weather, and suffer little deterioration from handling.

Western-coal Briquets

In coöperation with the Missouri Pacific, the Lake Shore & Michigan Southern, the Michigan Central, the Chicago, Rock Island & Pacific, the Chicago, Burlington & Quincy, and the Chicago & Eastern Illinois railroads, 100 locomotive tests have been made by the United States Geological Survey to determine the value, as a locomotive fuel, of briquets made from a large number of Western coals. All tests were made on locomotives in actual service on the road. In some tests there was small opportunity for procuring elaborate data, but in others, where dynamometer cars were employed, it was possible to obtain more detailed results. The purpose which these tests were intended to serve was not so much to determine the evaporative efficiency of briquets as to investigate their behavior in practical use.

Briquets made from Arkansas semi-anthracite, two qualities of Indian Territory slack, Indian Territory screenings, Missouri slack, Indiana Brazil block slack, coke breeze, and a mixture of coke breeze and washed Illinois coal were tested, and comparisons were drawn either with the same coal that was used in the briquet or with coal similar to it. In nearly every test the results reported show that the coal when burned in the form of briquets gives a higher evaporative efficiency than when burned in the natural state.

For example, Indian Territory screenings give a boiler efficiency of 59 per cent., whereas briquets made from the same coal give an efficiency of 65 to 67 per cent. Decrease in smoke density, the elimination of objectionable clinkers, and an apparent decrease in the quantity of cinders and sparks are named as the chief reasons for this increased efficiency.

An Obscure Armature Trouble

By H. F. Rudolph

The following case of motor trouble caused much worry to the electrical force in an industrial plant and was finally brought to the attention of the writer, who found the cause of trouble more through accident than anything else. A 6-horsepower series-wound direct-current crane motor had a winding of a peculiar character; the coils, instead of being form-wound, were hand-wound directly in the slots and the winding was so arranged that the finishing end of the wire in each coil was connected to the bottom of the cummutator bar, after which the beginning end of the coil was brought through the slot and connected to the top of the commutator bar. The armature winding was wave-connected, with two brushes; the machine was a four-pole motor, and the brush holders were so located that the top connection from each of the armature slots led to the commutator bar directly opposite (Fig. 1). This motor burned off two or three end connections per week at the point x in the sketch and no amount of investigation supplied any clue to the cause of the trouble. A new armature was finally procured from the makers, which developed the same trouble, burning off four end connections the first week. The motor was not overloaded, and the field-magnet coils were not partly burned out, so the motor was kept going for some time by repairing the spare armature and changing armatures every few days. Finally the coils were all disconnected from the commutator and individually tested for grounds, short-circuits or loose connections, and a bar-to-bar test of the commutator was made with a 10,000-ohm magneto. No trouble being found, the armature was reconnected and put back in service; it burned off four leads the first day.

We gave up in despair and appealed to the manufacturers, who suggested that expansion and contraction of the wire might be the cause and suggested the change indicated in Fig. 2. The wires were cut at S and new pieces of a larger size spliced on and loops for expansion left at the commutator end. A band of twine was wound on next to the commutator and the armature replaced in the motor, where it promptly burned out six coils completely. The design of the winding was such that replacing six coils involved the complete rewinding of the armature.

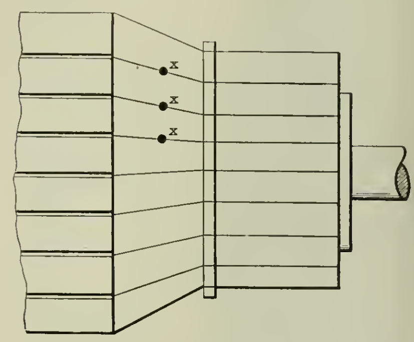

FIG. 1

This was done and before the commutator was replaced it was again tested for short-circuited bars, this time with 110 volts instead of the magneto. Upon the application of the current the mica at first smoked and finally became red hot, remaining so until the current was withdrawn. As all bars tested the same, new mica was placed in the commutator and the armature connected and put in service, where it remained for six months without a sign of trouble.

In the meantime the spare armature was tested and, the mica proving defective, new mica was inserted and the old armature coils reconnected. In order to satisfy ourselves that it was the new mica and not the new coils that cured the trouble, the armatures were again changed, but not a sign of trouble has been seen, although the old armature has been in service three months.

WE PAY FOR USEFUL IDEAS

Low Pressure Turbines and Steam Engines

The article in the January 5 issue, by J. R. Bibbins, states that "Professor Rateau's work in steel-mill and mine hoisting has also resulted in the practical application of low-pressure turbines in connection with the steam-regenerative principle, permitting the turbines to operate constantly, using the exhaust steam from engines intermittently operative. His work has been brought to our notice in this country by H. H. Wait in discussing regenerative application to steel mills. (American Institute of Electrical Engineers, December, 1907.)"

Mr. Bibbins' statement is undoubtedly correct as to his personal knowledge of the question, but I wish to say that I introduced Professor Rateau's steam-regenerative principle in America, and have been working to develop it since 1903.

In 1904, Professor Rateau himself presented to the American Society of Mechanical Engineers, at a meeting held in Chicago, a paper on "Different Applications of Steam Turbines." This paper fully described his regenerative system and gave illustrations of what had been done by him previous to his coming to America.

On September 21, 1904, I read a paper before the Western Society of Engineers, entitled, "Utilization of Exhaust Steam in Connection with Low-Pressure Steam Turbines," and in October, 1905, I also read a paper before the Lake Superior Mining Institute, entitled, "The Utilization of Exhaust Steam from Rolling Mill Engines, Hoisting Engines, etc., by Means of Steam Regenerators and Low Pressure Turbines on the Rateau System."

The International Harvester Company's plant described by Mr. Wait, in his paper before the American Institute of Electrical Engineers, was put up by the Rateau Steam Regenerator Company, which was the sole contractor for the entire equipment. This same company has also acted as sole contractor for the Vandergrift plant of the American Sheet and Tin Plate Company. These two plants are the only ones in America utilizing the steam-regenerative principle. They are also the only plants in this country where the exhaust of intermittent-running engines is compounded with low-pressure turbines.

Incidentally I should like to remark that two of the most complete and striking articles regarding the use of exhaust steam in low pressure turbines were published in POWER; one by F. G. Gasche, entitled, "First Rateau Regenerator Installed in America," and one by Professor Rateau in the issue of October, 1907, under the heading, "Compounding Piston Engines with Turbines."

I strongly agree with Mr. Bibbins when he mentions J. W. Kirkland in connection with low-pressure turbine work, as no one admires more than I do the splendid missionary work done by Mr. Kirkland on this subject.

L. BATTU.

President, Rateau Steam Regenerator Co.
New York City.

A Safety Stop

The stop shown in the accompanying illustration was made and put on by W. A. Bright, foreman of the Decatur Novelty Works, and is a neat little device. It is intended to take the place of the pin used on some Corliss-engine governors.

THE BRIGHT SAFETY STOP

The device is very simple and any engineer can make and attach one himself. The illustration shows three positions. The first is that in which the stop is placed just after closing the throttle and before the speed is much reduced. It will be noted that the lock is not directly under the end of the rod that comes down from the collar. As the rod drops the lock tumbles and allows the small lug to drop as shown in the second view. When the engine is again brought up to speed the rod rises, and the lock is pulled over to one side out of the way by the weighted end as shown in the third view. This leaves a clear path for the rod should anything happen to stop the governor.

[illegible]

Decatur, Ill.

Selection and Safety of Pipe Fittings

In the issue of December 15 there is an article on "Selection and Safety of Pipe Fittings," by A. J. Dixon, in which there appears to me to be a mistake. On page [illegible], in figuring the stress on the cap screws of the bonnet of the angle valve, he has added the stress due to tightening the cap screws to that of the steam pressure on the under side of the bonnet, which I do not think is correct.

Taking the figures given in his article, the total stress due to the steam pressure is [illegible] pounds, and that due to tightening cap screws [illegible] pounds, which he adds together to get the total stress.

The steam pressure can add no stress to the cap screws until it exceeds that due to the screwing down of the cap screws, as up to this point the two pressures are opposed and will be balanced when one is equal to the other. In this case the stress due to the steam pressure is greater than the initial stress on the cap screws, so that the stress added by the steam pressure would be only the difference between the two pressures, or a total of [illegible] due to the steam pressure only, or [illegible] pounds, a stress of [illegible] pounds for each screw instead of [illegible] pounds, as given in his article.

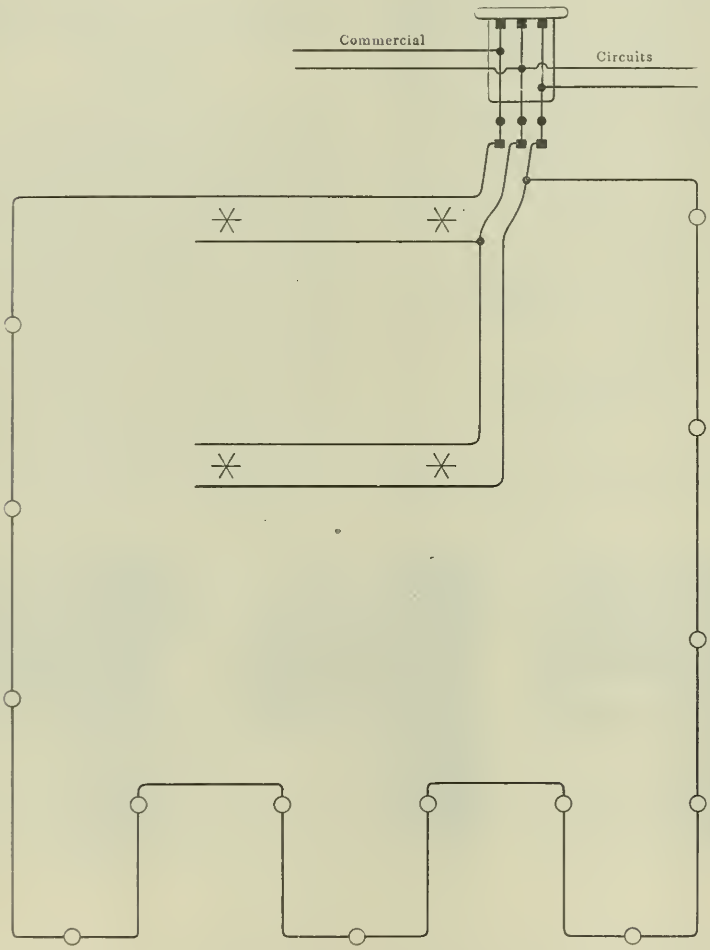
In a case where the initial stress due to screwing down the cap screws exceeded that due to the steam pressure there would be no additional stress on the screws upon admitting steam to the valve.

W. O. PERKINS.

Bristol, Conn.

A Lighting Problem

The accompanying sketch shows the proposed circuit-arrangement for a small country town which is going to be lighted from a larger town several miles away. The public square has a multiple-arc lamp at each corner, indicated by the crosses; the rest of the lamps, indicated by circles, are series tungsten incandescents, fourteen in number. The town being small, it is proposed to use a three-wire circuit and connect two of the arcs on each side of the neutral wire and the series lamps on a separate circuit. I suggested connecting them as shown in the diagram; as a time switch will be put in to handle the street lights, this will save a switch.



PROPOSED LIGHTING CIRCUIT

It is also proposed to run secondary circuits for commercial lighting, as in the diagram, instead of running three wires both ways.

I would be glad to have the opinion of some other readers as to how they would connect these circuits and run the commercial lines, and whether they think the diagram shows a feasible plan.

F. L. ROLPH.

Indianola, Ill.

Keeping Plant Records

Not very long ago the editors of POWER AND THE ENGINEER strongly urged the operating engineer to keep records from which to compute the cost of his plant output, but in the issue of December 8 they disparage the only means many of us have of keeping such records. While the criticisms in this latter editorial are doubtless well founded, it is nevertheless true that the periodical reading of switchboard instruments and the ordinary methods of measuring water and weighing coal can be made to give valuable results. Two years of experience with the methods under discussion have demonstrated to me that with careful readings and familiarity with the plant a reasonably close deduction can be made of the cost of output, even when elevator service, heating, etc., have to be taken into account. I have wished that some small-plant man would tell how he keeps his records, but perhaps they all think that without automatic recorders and special apparatus it would be useless to try to come anywhere near any useful figures.

We have no way of weighing the coal automatically; even the man who wanted to sell us a machine said it could not be installed owing to lack of head room. However, by many tests of the barrow capacity which are made at frequent intervals, I find that we get what we pay for in pounds, though not always in quality. As to the water, I have done nothing yet to verify the meter, but expect to do so before long. For obtaining an idea of the output, we have found reading the ammeter once an hour is often enough, as the load comes on gradually and remains at practically one point from 10:30 a.m. until 5 p.m., and then falls off gradually.

The voltage is kept constant and the load in amperes is put down each hour on a log sheet. The next morning I figure the total ampere-hours of the day's run. It is also noted on the sheet when engines are put on and taken off, so that the difference in their consumption of steam can be taken into account. The ampere-hours, the number of hours run, the kilowatt-hours and the percentage of the rated load made by the Corliss and the automatic engines are put down so as to be seen at a glance. The number of barrows of coal and ashes is also added and this completes the log sheet for one day. Saturday's sheet also shows all of the items for the week and the sheet for the last day of the month contains them for the whole month, as well as the coal delivered to the plant, the water (by ordinary meter) evaporated, and that used for blowing down and washing out the boilers and heater, the average tons of coal burned per day, the percentage of ashes to coal and the number of loads of ashes which we must pay to have removed.

From the records mentioned I figure how much of the coal, etc., must be charged to lights, and I do not think I am seriously out on the cost per kilowatt-hour.

Of course, by this system one cannot tell exactly the evaporation per pound of coal, but having the coal company's bill, the water bill, the supplies bill, the payroll and a good idea of the number of kilowatt-hours generated, I am able to tell very nearly what the costs are. Any engineer who has not tried it before will find keeping plant records more interesting than any other branch of his work.

A. N. BOGART.

New York City.

[We are glad to learn of Mr. Bogart's excellent work in the systematic keeping of plant records, and we admit, most cheerfully, that the methods under discussion *may* be made to yield fairly satisfactory results under the close supervision of a painstaking chief. Our experience, however, is that unless the supervision is exercised to a burdensome degree, records taken as described become slovenly and unreliable. However, our criticism was directed at the plant owners who fail to provide adequate facilities, not at the engineers, like Mr. Bogart, who do the best they can with what they have.—EDITORS.]

A Station Load Indicator

In an electric-light plant with which I am connected it is necessary for the engine-room force to know at all times the load on the station. For this purpose, there was formerly mounted on the switchboard-gallery railing a frame having card figures to indicate the load. As

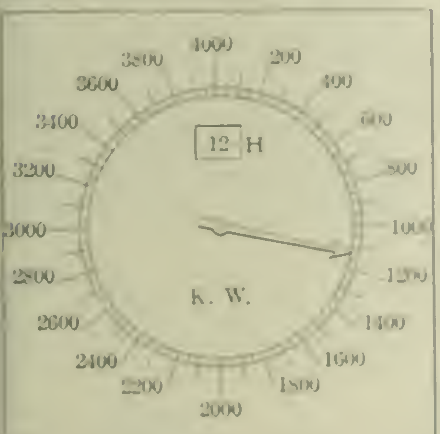


FIG. 1

FIG. 2

it was inconvenient for the switchboard operator to change the cards every half hour, I devised a dial indicator, as shown in the accompanying sketches. Fig. 1 is a face view and Fig. 2 a back view.

It consists of a piece of sheet iron 30 inches square, mounted on a light wooden frame. The dial scale and figures are painted white on a black background; the pointer is gilded. Across the back a strip *A* is fastened, leaving a space of about 2 inches between the strip and the sheet iron. Through the center of the strip *A* and the sheet iron is passed a short piece of 1/2-inch pipe just long enough to reach through with room for locknuts on each end to hold it in place. Through this pipe is passed a piece of 1/4-inch pipe, to one end of which is fastened the pointer. To the other end is fastened a short pointer *B* and handle *C*.

The short pointer works over a small dial similar to the large one on the front dial, and is used in setting the indicator; *D* is a tension washer to hold the pointer in place when set.

The hours from 1 to 12 are marked on a circular piece of sheet iron *E* which is fastened to a wooden hub and mounted on the pipe between the front sheet and the strip *A*. Through a hole *H*, in the front sheet, the hour figures can be seen, one at a time, the sheet being revolved to bring the various numbers into view.

The indicator is on the switchboard-gallery railing and is operated from the rear, as stated. It is quickly set and very easily seen from the engine-room floor below.

Indianapolis, Ind.

A New (?) Steam Gage

Under the heading announcing that subjects to be eligible for description in that department must be new or interesting, there appears in the department of POWER devoted to the description of power-plant machinery and appliances, in the issue of January 12, a description of an independent steam-gage movement. If there is anything new about this, the article fails entirely to bring it out. The movement mounted upon the base of the Bourdon spring and entirely disconnected with the casing has been a well known feature upon the market for a number of years and made by several makers. It is not at all evident why jar and vibration do not affect the accuracy or sensitiveness of such a gage as much as or more than that of the gage which is attached to the case. In fact, I think that experience with this class of gage has shown it to be more susceptible to jar, although it is, of course, free from distortion due to relative movements of the case and the spring.

T. B. AYRES.

Chicago, Ill.

Approximation of Terminal Pressure

The graphical method of working problems appeals to many engineers who have a very marked dislike for figures and formulas. The accompanying sketch shows a graphical method of getting a close approximation of the terminal pressure in an engine with any initial pressure and point of cutoff.

The rectangle *O P X L* is laid out to represent in length *O L* the stroke of the engine (plus the percentage of clearance, if more accurate results are desired). In hight *O P* represents the absolute initial pressure. The atmospheric line *E F* is drawn parallel to the vacuum line *O L* and at a distance above it equal to 14.7 or 15 pounds on the scale used, in this case a 40 scale.

Next, the diagonal *O X* is drawn, and from the line *P X* a vertical line is drawn from any point of the stroke at which it is desired to have cutoff take place. The distance between the diagonal and atmospheric lines measured with the given scale on the vertical lines will be found to be very close to the terminal pressure for that point of cutoff.

GRAPHICAL METHOD OF DETERMINING APPROXIMATION OF TERMINAL PRESSURE

In the sketch vertical lines are dropped at 1/4, 1/3, 1/2 and 3/4 stroke, and the distances between the arrow points indicate the respective terminal pressures for those points of cutoff.

In checking up the results mathematically consider the following example: Required terminal pressure in an engine with cutoff at 1/4 stroke, initial pressure 100 pounds gage and clearance 5 per cent of stroke size to keep the steam line well up. The absolute initial pressure will be 115 pounds, and as, theoretically, the pressure varies inversely as the volume, the terminal pressure will be in the neighborhood of $\frac{3}{8}$ of 115 or $43\frac{1}{8}$ pounds, or $28\frac{1}{8}$ pounds gage. The actual pressure in an engine at the end of the stroke will be less than the computed result, owing to the exhaust valve being open.

By plotting out the expansion curves for the different points of cutoff, it will be found that the power derived from an engine does not increase in proportion to the length of cutoff by any means, i.e., if cutoff takes place at $\frac{1}{4}$ stroke, and it is increased to $\frac{3}{4}$ stroke, the power derived will not be three times as much, although three times as much steam is being used than with the former cutoff.

This goes to show how important it is to steam users to secure engines that will carry the average load at an economical point of cutoff.

J. A. Carruthers.

Bankhead, Can.

Piston Repair

Not long ago one of the engines where I was employed gave signs of trouble inside the cylinder, and upon removing the head we found that a $\frac{1}{2}$-inch hexagon nut had got into the cylinder on the crank end, between the piston and the cylinder head, and the nut of the cast-steel piston

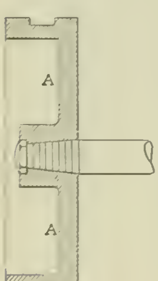

FIG. 1

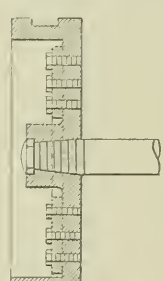

FIG. 2

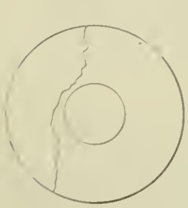

FIG. 3

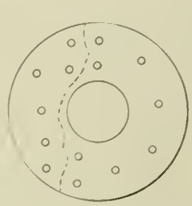

FIG. 4

of the type shown in Fig. 1 was cracked as shown in Fig. 2.

As we needed that particular engine the next morning, we at once got to work and procured a piece of $\frac{5}{8}$-inch steel plate which was cut and drilled in the shape shown in Fig. 3, fitted into the recess (*A*, Fig. 1) of the piston, and securely fastened in place with machine bolts, as shown in Fig. 4, the plate being drilled with a clearance drill and the threads cut in the piston.

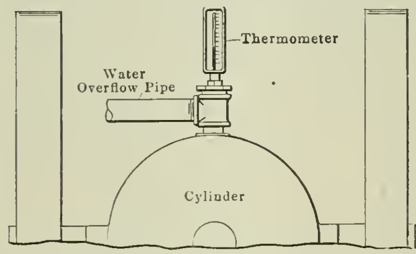
The engine was started the next morning and is running at the present time.

W. E. Chandler.

East Walpole, Mass.

Thermometer for Jacketing Water

One item gas engineers are prone to ignore is the amount of engine-jacketing water used. A scheme we adopted to decrease our water consumption was to



SHOWING LOCATION OF THERMOMETER

place thermometers on our outlet-water line just over the cylinders. Thus, we can watch the cylinder-water temperature and incidentally avoid turning too much water off.

We also placed a valve in the inlet pipe, having a pointer and index plate which, after experimenting, was marked at the proper point. We find that the engines work with the water temperature at about 140 degres Fahrenheit.

James Aylward.

Elyria, O.

Hydrostatics

On page 1051 of the December 22 issue, Mr. Livingston presents the results of some original investigations of the laws of hydrostatics. It is hardly necessary to state that there is a flaw somewhere in the experiment, for it would be contrary to all laws of hydraulics if the check valve were placed in equilibrium by equal unit pressures on unequal areas. Does Mr. Livingston know that the check valve was in equilibrium? Does he know that it moved off its seat? It would seem more probable that either there was a leak through the casting or that the water leaked through the valve seat.

If Mr. Livingston desires to be exact in figuring the pressures on the two sides of the valve, he should take the pressure on the top of the disk equal to the head shown, 5 feet 8 inches, less the hight of the disk, remembering that the pressure on the area taken by the stem is that of the head on the top of the stem, and not that on the valve seat, this also being true of the pressure on the stem on the under side of the disk.

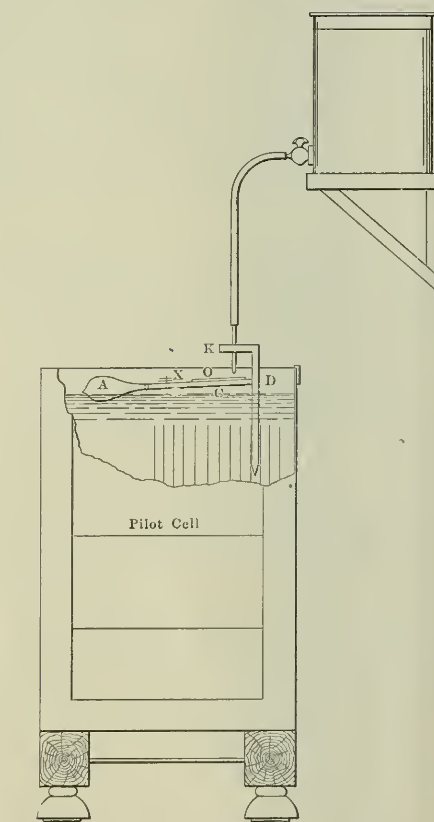
Brooklyn, N. Y.

Noncorrosive Float Valve

Difficulty has been experienced in attaining a standard hight of the electrolyte in pilot cells of storage-battery installations by corrosion of the movable joints of the float valve, causing sticking and failure to operate, the result being either a flooded cell, or no replacement for evaporation.

It is necessary with all pilot cells that the electrolyte be kept at a constant level so as not to deflect the specific gravity or the temperature readings. A sudden flooding of water would give a low reading by at least two points, for which no benefit of discharge or charge could be shown. By the condition of the pilot cell the standing of the entire battery is judged, both in charging and discharging. Therefore, the necessity of having a float valve which can be relied upon is readily seen.

The accompanying diagram gives an idea of how a noncorrosive float valve is constructed to meet all the requirements of a good cell filler. The materials used



CONSTRUCTION DETAILS OF FLOAT VALVE

are glass and hard and soft rubber. The glass float at *A* may be made out of an old 75-candlepower lamp, by first removing the metal base and sealing in the hard-rubber arm *C*. The counterbalance weights *X* are made of lead and placed as shown. The arm *C* moves on a hard-rubber pin inserted at *D*. The projection *K* is a hard-rubber holder for a glass tube, tapered at one end. A strip of soft rubber is fastened at *O* to close the opening in the glass tube when the water raises the float *A*. The storage tank for the water is placed about 2 feet above the cell. This style of float valve has been operating two years successfully.

New York City.

Pressure Required to Lift a Check Valve

Mr. Helm, in his academic discussion of Mr. Pearce's valve-lifting problem, on page 201 of last week's issue, correctly says that his method of figuring by the difference in area between the top of the valve and of the seven holes in the seat "assumes that the valve cover makes perfect contact with its seat." In other words, he assumes that there is no pressure acting between the valve and the seat, in which case the pressure holding it to its seat should be reckoned from absolute zero, and not from atmospheric pressure.

The pressure on top of the valve, then, would be 115 pounds per square inch, approximately, and the pressure required to lift the valve by acting on the 5.5 square inches of the seven 1-inch holes,

$$\frac{115 \times 19.63 + 5}{5.5} = 410$$

pounds per square inch or 395 pounds, gage.

As a matter of fact, however, the valve does not make anything like a perfect contact with its seat. A pair of accurately ground surface plates, carefully manipulated, might approach that condition. The probability is that the pressure existing in the film of liquid under the valve is pretty nearly that of the fluid surrounding it, varying with the condition of the surfaces and the length of time they remain in contact.

J. H. McCARTHY.

Bethlehem, Penn.

I read R. S. Livingston's letter in the December 22 issue, entitled, "Pressure on Both Sides of a Valve Disk," in which he describes a simple experiment performed by himself several years ago, which seems to show that results obtained in practice do not agree with theories and figures, or that theories and figures have no place in design, as they give results which are not at all borne out in practice.

If, however, the problem is looked into more carefully it will be found that they do agree, and that when taken together, each one serves its purpose in making clear the truth which is oftentimes hidden, and requires the combination of theory and experiment in order to know the hidden law and, knowing it, one is able to use it in practical everyday life for the benefit of mankind.

The apparatus as shown in the form of a diagrammatic sketch on page 1051 consists essentially of a check valve having a rubber-disk clapper $2\frac{9}{16}$ inches in diameter which closes a passage having a diameter of $2\frac{1}{16}$ inches. The upper or back side of the valve is acted on by a column of water 5 feet 8 inches high which gives a pressure *P* of

$$5.66 \times 0.434 = 2.456$$

pounds per square inch above the valve which, acting on the area ($A = 5.157$ square inches) of the valve, gives a total force of

$$F = 2.456 \times 5.157 = 12.67$$

pounds tending to hold the valve on its seat.

This assumes that the valve disk or cover makes perfect contact with its seat, thus preventing the pressure of the fluid from acting on the under side of the clapper.

The area A_1 of the passage is 3.34 square inches, being 2.0625 inches in diameter, hence, the pressure p_1 per square inch on the front or under side of the valve necessary to cause equilibrium or to balance it will be

$$p_1 = 12.67 \div 3.34 = 3.8$$

pounds, which corresponds to a head of water of

$$3.8 \div 0.434 = 8.75$$

feet, or 105 inches above the valve seat which means that the water will rise, in the ½-inch pipe, to a hight of

$$105 - 68 = 37$$

inches, plus a small amount required to overcome the weight of the valve seat, before the valve will open and the water will begin to overflow from the large pipe.

The results of Mr. Livingston's experiment, which he chooses to call "practice," showed that the water actually rose to only ½ inch above the top of the large pipe when rubber and metal were in contact, and to only ¾ inch above, when the valve seat was coated with white lead and oil. In other words, the experiment showed that theory and figures gave a pressure approximately 33.5 per cent. (average of the two cases) higher than was actually required in the particular case under consideration. Mr. Livingston's diagram shows a rubber clapper without any metal backing, which allowed the pressure from above to force the central portion of the disk downward, thus making it concave toward the back and convex toward the front, which resulted in greatly reducing the area of the seat, which is clearly shown by the results of the test.

If Mr. Livingston or any other person desires to repeat the experiment and use every precaution to make very sure the valve seats properly, thus obtaining in practice the actual test [illegible] which is assumed to obtain, and upon which the theoretical figures are based, he will find that theory and practice are not at variance, but are true friends, each one acting as an aid to the other.

F. C. HELM.

Schenectady, N. Y.

Throwing Lamps in Series and in Parallel

On page 71 of the January 5 issue, E. J. Williams asks for a diagram showing connections to throw three lamps from

MR. [illegible]'S SKETCH

parallel to series and vice versa. The accompanying sketch shows a method using two single-pole, single-throw switches which, on closing, will put the lamps in parallel and on opening, puts them in series.

[illegible]

Brooklyn, N. Y.

The first of the two diagrams herewith submitted shows one method of meeting the requirements of Mr. Williams. With

FIG. 1

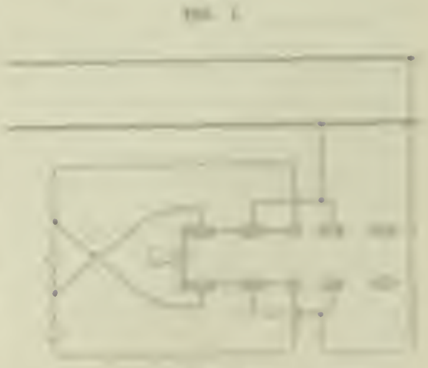

FIG. 2

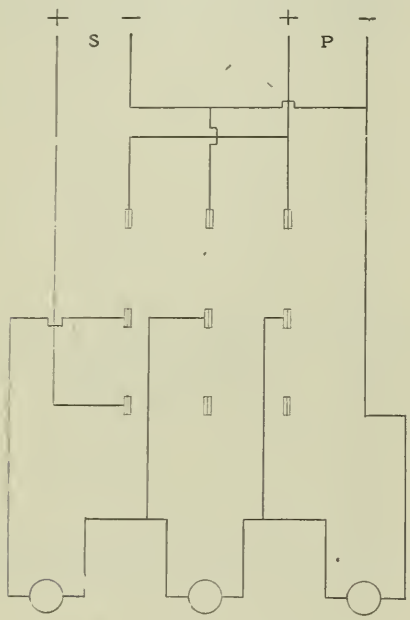
the double-pole switch closed, as [illegible], the three lamps will be connected in parallel to the supply circuit. When the switch open they will be in series. This method, however, would make it necessary to use another switch to extinguish the lamps. On this account the arrangement indicated in Fig. 2 is preferable. A double-throw double-pole switch is used; closed to the left, as here represented, it will connect the lamps in parallel; closed to the right it will put them in circuit in series, and when open, the lamps will be entirely disconnected from the circuit.

George W. Malcolm.

Brooklyn, N. Y.

Connect a triple-pole double-throw switch as shown in the accompanying diagram, in which *S* is the series circuit and *P* the parallel circuit. With the switch



MR. ATWOOD'S SOLUTION

in the lower position the lamps are in series; with it in the upper position the lamps are in parallel.

E. M. Atwood.

Lawrence, Mass.

Interesting Diagrams from a Dry Vacuum Pump

The accompanying diagrams were taken from a dry-vacuum pump driven by a cross-compound Corliss engine. Each engine piston rod extends through the head-end cylinder cover, and connects to an air-pump piston. The steam cylinders are 18 and 30 by 30 inches; the air cylinders, 40x30 inches. Four barometric condensers, of a total capacity of 10,000 horse-power, are connected by suitable air pipes to this pump, which was installed to take the place of a number of smaller dry-air pumps.

At the time these diagrams were taken, the outfit had been running quite a while, but had never been indicated. The governor was not in operation, the speed being controlled by throttling, as will be seen by an inspection of the "before adjusting" diagram, Fig. 1.

Through carelessness on the part of the erector, one of the low-pressure exhaust valves had been put in upside down. The governor was connected, and a few changes in the valve gear resulted in the steam distribution shown "after adjusting," Fig. 2.

The valves of the air cylinders are of the Corliss type, positively driven, and as

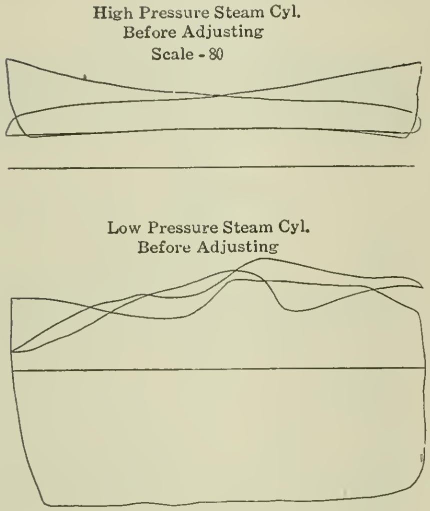


FIG. 1

set by the erecting engineer gave diagrams as shown by Fig. 3. By changing the eccentrics driving these valves and making some alterations in the lengths of the valve rods, the diagrams, "after adjusting," Fig. 4, were obtained.

This air pump is provided with a rotary valve which, at the end of each stroke, opens a passage between the two ends of the cylinder. The air in the clearance space, at a little more than atmospheric pressure, is then permitted to expand into

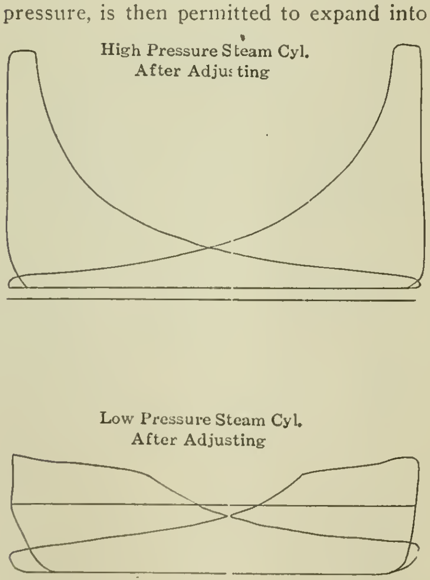

FIG. 2

the other end, where it may be forced out on the next stroke. The point in the stroke where this valve closes is clearly indicated at *A*, Fig. 4.

Although every precaution is taken to separate the air from the water before it leaves the condensers, a great deal of trouble is experienced with water entering the air-pump cylinders. The air coming from the condensers is passed through a baffle-plate separating arrangement and before entering the pump, it is passed through a large drum, which is intended to act as a separator for any water that

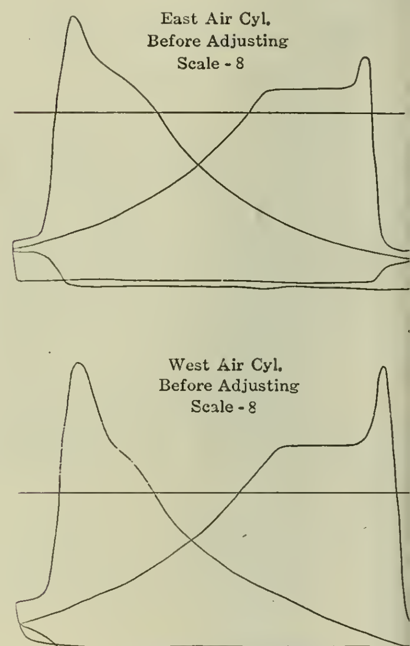

FIG. 3

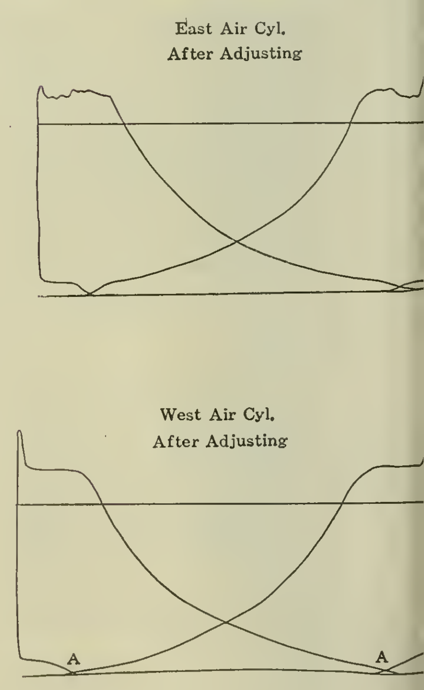

FIG. 4

may be carried over from the condensers. Yet water is being continually forced out of the relief valves, and it is necessary to run quite slowly to avoid danger of wrecking the pump.

A. L. Westcott.

Columbia, Mo.

Repairing a Valve Rod Stuffing Box

The accompanying illustrations show how a quick repair was made to the valve rod stuffing box on an indirect piston-valve engine. The exhaust pipe filled with condensation one night and the assistant started up the next morning without opening the drain on the pipe, which resulted in a broken gland at *A*, Fig. 1.

We removed the cap screws and replaced them with long studs, as shown in Fig. 2. The brass gland was held in place with a strip of wood, with nuts as washers instead of the screwed gland. There was only room enough for two turns of soft packing, yet it held so well that we replaced the wood strip with a cast-iron gland of the ordinary pattern, and drilled two extra holes in the head for gland studs.

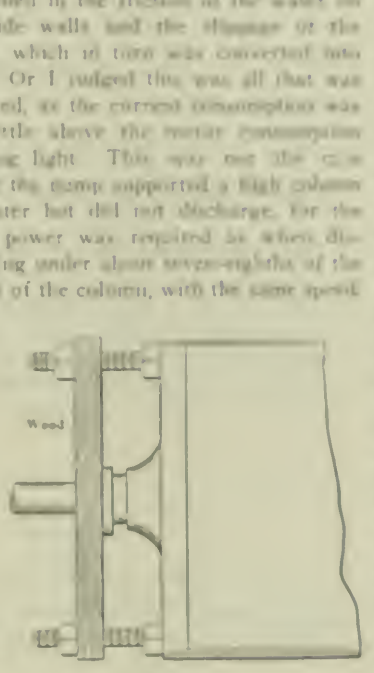

FIG. 2

Power Consumed in Centrifugal Pumps

I have noted frequent discussion in reference to the power consumed in centrifugal pumps when working under heads sufficient to prevent discharge, and under a closed discharge, and beg to offer some practical experience I have had.

Last year I had from one to twenty-five pumps, of all capacities, under my care, most of them working a 24-hour shift, and operated by an automatic device controlled by the rise and fall of the water in the building excavations, etc., which were being pumped.

Before the present automatic device was perfected various devices were used to control the discharge according to the supply, which varied greatly with tides, etc.

It may sound peculiar, but of the three methods where frequent stopping and starting were generally necessary, it was found most economical to allow the motor to run continually and close the discharge by a float, in preference to starting and stopping under the usual head or by use of a sliding resistance in series with the motor. The rank of the three methods in economy was as follows: Closing the discharge entirely; sliding resistance or variation of speed, and intermittent starting and stopping.

I noted that in pumps where either the suction or discharge was choked near the pump the only power required was that consumed in the friction of the water on the side walls and the slippage of the vanes, which in turn was converted into heat. Or I judged this was all that was required, as the current consumption was but little above the motor consumption running light. This was not the case where the pump supported a high column of water but did not discharge, for the same power was required as when discharging under about seven-eighths of the length of the column, with the same speed.

A specific case was that of a 2-inch pump working under an 85-foot head, with 7 feet for the suction. I had some difficulty in making it keep primed when running, for when at rest the weight of the column forced the packing out. In order to watch the action of the gland a vacuum gage was put on the suction, and a gate valve on the discharge pipe. When the gate valve was closed close to the pump, the current consumption of the motor was reduced and the vacuum dropped to from 8 to 10 inches or just sufficient to support the column of water in the suction pipe, and the pump soon became very hot. If the speed was insufficient to discharge in cases where the gate valve was open, the motor took about the same power as when discharging fully under seven-eighths of the head. I took many readings and obtained much data at the time, but unfortunately they were destroyed in a fire.

I came to the following conclusions: Pumps working under a closed discharge require only sufficient power to overcome the friction of water in the pump, support the column in the suction and overcome the loss in the bearings.

Pumps working against a column of water without discharge required the power necessary to overcome the friction of the water in the pump and bearings to support the column of water in the suction and discharge.

Pumps when working under full discharge followed very closely the law: Power required is proportional to the square of the speed and directly as the head. I also found that the [illegible] pumps [illegible] most economical when discharging at a velocity equal to eight times the square root of the head.

E. H. [illegible]

Berkeley, Cal.

Effect of Scale in Boilers

F. [illegible] McWilliams, in his letter in the December 8 issue, asks for information.

He says that many tell us that $\frac{1}{16}$ inch of scale will cause a loss of from 12 to 15 per cent. in fuel, depending on the character of the scale. While this is true to a certain extent, it is a difficult proposition to determine to just what extent the efficiency of a boiler is lowered by a deposit of scale on the plates and tubes.

There are a number of things to be taken into consideration in calculating the effect of scale in boilers, not only the character of the scale, but the thickness as well, and also the nonconductivity and the difference of temperature between the inside and outside surfaces of the boiler shell.

I have seen scale not over $\frac{1}{16}$ inch in thickness in boilers that, by actual test, showed a drop in efficiency of over 20 per cent. On the other hand, I have seen ½ inch of scale on the boiler shell and the ends of the tubes practically matted together, with the efficiency of the boiler impaired so little that it was hardly susceptible of calculation.

I have frequently seen carbonate of lime ½ inch in thickness, with very little injury done to the boiler and with very slight loss in efficiency. Alone it seldom produces a hard scale, but more often has a tendency to collect in large porous lumps or masses, in which case it is more liable to produce overheating and consequent burning of the sheets where so collected, than to lessen the efficiency of the boiler.

This scale can usually be washed out very thoroughly with a hose or by frequent blowing down of the boiler, unless there had been the presence of a lot of iron in the feed water, in which case the carbonate of lime will sometimes combine with it and produce a scale of varying degrees of hardness, depending on the amount of iron present. It is very seldom that carbonate of lime and oxides of iron are found in the same water in great quantities.

Entirely unlike carbonate of lime, the sulphate, or gypsum, has a hard, flint-like consistency, is moreover a nonconductor and one of the most detrimental of mineral substances. A very thin layer of this deposit is sure to bring about serious injury to the boiler unless treated very frequently with soda ash. Tannin is also very effective in precipitating sulphate of lime deposits, as is also caustic soda, but the simple soda ash is usually conceded to be about the best solvent for this form of scale.

Among the other common enemies of the boiler might be mentioned the carbonates and chlorides of magnesia, oxide of magnesia, silica and clay substances. Of these latter the chloride of magnesia is the most objectionable. At a temperature of 290 or 295 degrees Fahrenheit it will begin to give up free hydrochloric acid, due to decomposition, and as the temperature increases to near 298 degrees this liberated hydrochloric acid combines with the oxide of iron, continually forming on the surface of the boiler shell, with the result that the plates are corroded and pitted.

Deposits in boilers due to grease and oils in the feed water are also sources of great annoyance and danger, as a very thin film of this substance, while soft and apparently porous, forms a most perfect nonconductor, prevents the water from coming in contact with the plates, and is almost certain to bring about overheated sheets and tubes, with the attendant disastrous consequences.

Mr. Williams further asks: "If the loss with $\frac{1}{16}$ inch of scale is so great, it would be interesting to know where this heat goes to. Does the boiler setting absorb more heat than it would otherwise, or is the loss entirely accounted for by a rise in the temperature of the escaping gases?" To the first I would reply, not at all; to the latter, not entirely, but possibly to some extent.

We all know that the degree of heat transmitted from the furnace to the water in the boiler depends upon the conductivity of the intervening metal, and it is also known that the water cannot be heated to a higher temperature than is equal to a corresponding pressure of the steam.

Let us consider steam at 100 pounds, absolute pressure, the corresponding temperature of which is 327.9 degrees. It is impossible to increase the temperature of the water above this without increasing the steam pressure.

With a boiler plate free of scale, with the water in perfect contact with it, it is impossible to heat the plates much higher than the temperature of the water, or 327.9 degrees at 100 pounds pressure, a temperature which any plate will stand without any injury whatever.

Suppose the plates are coated with a thick deposit of nonconducting material, thoroughly insulating the water from them, then it is evident that the temperature on the different sides of the plates cannot equalize as formerly, one counteracting the other, thus permitting the plate to reach a higher temperature than the water in the boiler and the consequent overheating of the plate until it may reach a cherry red, depending upon the thickness, quality and nonconducting properties of the scale. This, then, explains where the heat goes, not in the brick setting of the boiler, nor all in the escaping gases, but the greater part is absorbed by the plates, which accounts for their rise in temperature. If the plates did not take up or absorb what the water loses, there would never be any danger of overheating due to the presence of scale in the boiler.

Memphis, Tenn.

Low Compression Saves Coal

I used to be ashamed to send my indicator diagrams for engineers to criticize, but when I saw a set of diagrams from a cross-compound engine which M. E. Copley praises as evidence of the only way to set valves to save coal, I thought they resembled a pair of Chinaman's shoes

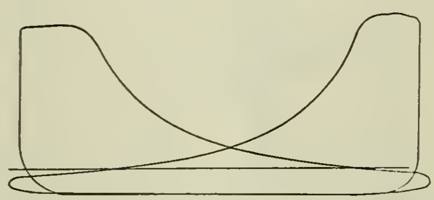

FIG. 1

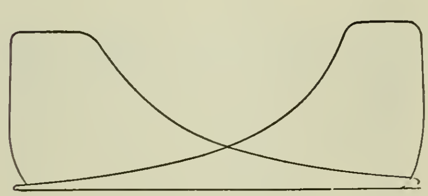

FIG. 2

after having been worn over the Texas border on the way to Uncle Sam.

Mr. Copley says that slight compression saves coal. Perhaps it does, but the valve setting on his compound engines does not seem to me to be the best for the coal pile. Readers who know about indicator diagrams can see that the exhaust valves do not get open until the piston has traveled over half stroke. Steam on the one side of the piston is pushing the piston ahead and the piston is pushing the steam out through the exhaust port.

What good is a condenser to an engine with such valve setting? If an engineer wants to get the benefit of the condenser he should set the valves so the exhaust will open before the piston reaches the end of the stroke and close as late as possible.

I inclose a set of diagrams from an old Corliss engine in service since 1872. In summer I run condensing, as the diagram, Fig. 1, shows. With this valve setting the engine runs on $2\frac{6}{10}$ pounds of coal per horsepower-hour. The diagram, Fig. 2, shows the valve setting for winter, as we use the exhaust steam for heating with the Paul system.

M. E. Cunningham.

Waterbury, Conn.

Grease Lubrication of Governor Pins

I use grease successfully in the lubrication of the governor pins of four Westinghouse compound noncondensing engines under my charge. This I consider a difficult lubricating proposition, as the weight on the bearing and journal is heavy and the motion, instead of being one of continuous rotation, is an oscillation through a short arc, only. The engines are direct-connected to 114-volt direct-current generators, delivering current for forming and charging storage batteries in the process of manufacture, and for laboratory purposes. For this work the requirements as to constancy of voltage are very exacting, and the matter of close speed regulation is therefore of unusual importance.

The plant consists of two 18 and 30 by 16-inch 350-horsepower engines, each direct-connected to a 2000-ampere eight-pole generator, and three 12 and 20 by 12-inch 150-horsepower engines, each direct-connected to an 800-ampere six-pole generator. These engines run at 150 pounds steam pressure and are operated for thirteen consecutive shifts through the week—two shifts each 24 hours for six days in the week, Tuesday to Sunday, inclusive, and one shift on Monday.

The governor pin of one of the larger units is lubricated by oil, from a regular Westinghouse center oiler, which consumes 2½ to 3 gallons of oil per week of thirteen shifts. The governor pins of the other 350 horsepower engine and the three 150-horsepower engines are lubricated with an A No. 1 grease, and consume 4 to 6 ounces of lubricant per week of thirteen shifts.

The lubrication by grease is accomplished as follows: The governor mechanism is of the Westinghouse high-speed engine type. The governor pin, which is 3½ inches in diameter and 12 inches long on the larger engines and 2x12 on the smaller, runs in a brass bushing which is carried on a radial extension of the flywheel hub. Fixed to one end of this pin is the lever carrying at its ends the two governor weights, aggregating 1000 pounds. In the operation of the governor, the pin oscillates through a maximum arc of about ¾ inch, between light load and full load on the engine. The movement of the pin in the bushing is therefore relatively small. At the same time the importance of safe and effective lubrication is very great. Any least liability of "sticking" would condemn the lubricant causing it, for it would result in impairment of the governor action, which would not be tolerated in these engines, operating under the stated exacting conditions, to say nothing of the risk of racing, with its attendant danger of bursting flywheels.

The grease is applied by means of two ordinary hand-feed spring-tension cups, set in ½-inch tapped holes in the bushing. These holes meet a half-round groove of ⅛-inch radius scored on the inside or bearing surface of the bushing, and running to within ⅛ inch of the ends. This (top) groove is thus fed direct by the two grease cups; and two similar horizontal grooves, spaced at 60 degrees from the top groove, are fed from the latter by several diagonal grooves, which serve also further to distribute the lubricant over the journal.

This arrangement answers well and for nine years has proved the effectiveness of grease for governor-pin lubrication. The cups are filled once a week, and the lubricant is not fed into the bearing by screwing down the plungers of the cup, but is allowed to flow naturally. The cups, once filled, require no further attention during the thirteen consecutive shifts and there is neither waste nor lack of lubricant.

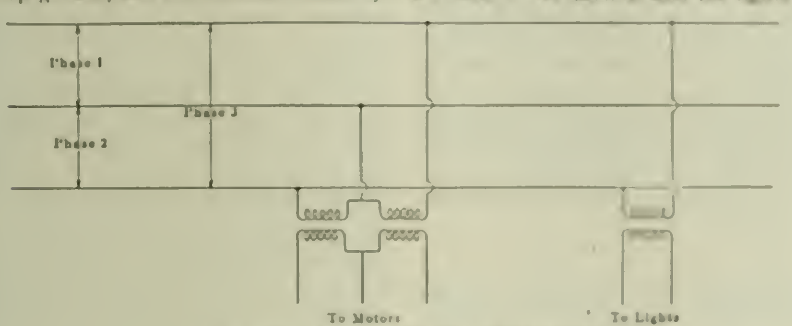
Although this and other experience going to show the success of grease lubrication and its economy, as compared with oil, make me an advocate of grease as a lubricant, I am ready to concede that there are places where oil must be used. Thus, in these same Westinghouse engines the lubrication of the main eccentric rod and its appurtenances is effected by oil fed at the top of the rod and shaken down by the oscillation to the bearing surfaces below. Here, of course, grease would not serve. But aside from such special cases, in the writer's opinion, since the lubrication of any moving part of a machine is really a greasing, it is better to use good grease to begin with. The value of oil as a lubricant resides in its permanent greasiness, while its other qualities tend to waste and to mess.

In conclusion, I wish to state that the engine room in which grease is used for this work, as described, is an unusually hot one, the temperature registering [illegible] degrees Fahrenheit for seven months in the year.

Frank Mellon,
Chief Engineer, Electric Storage Battery Company.
Philadelphia, Penn.

Transformer Connections

I submit the accompanying diagram and the following for criticism. Two transformers are connected in open delta on a three-phase line supplying current to three-phase induction motors, and a single-phase transformer is connected to one leg for lighting. If the power transformers are connected to phases 1 and 2 should not the lighting transformer be connected to phase 3? How will this affect the regulation of the system? The motors are used in the daytime and the lights are then turned off; at night the lights are on and the motors are out of service.



MR. CARROLL'S TRANSFORMER CONNECTIONS

R. S. Carroll.
Portland, Ore.

Reversed Polarity

The trouble caused by the reversing of the polarity of one of the generators operating a three-wire system, which Mr. Young gave an interesting account of in the number of December 22, could be caused in a number of different ways. In this case, however, it was probably due to weak residual magnetism, allowing the machine to build up in the reverse direction. This is often noticeable on generators having a magnetic circuit of very soft iron. I have also known of the polarity being reversed by a sharp heavy shock on or near the machine when repairs are going on. A momentary current from some outside source flowing through the field coils in the wrong direction while the machine is at rest often causes the same result.

The reason that the outside 220-volt wires gave no indication of voltage was because they were of the same polarity, the central or neutral wire then carrying the current formerly carried by the two outside wires, instead of the small balancing current which it is supposed to carry. If a load had been put on with this arrangement it would have been practically impossible to keep the voltage normal, owing to the excessive drop in the neutral wire.

When Mr. Young reversed the series field connections he made a bad matter worse, owing to the fact that as the machine began to generate it would cause the residual magnetism to become still weaker. After the brush connections had been reversed the current flowing in the series fields with a load would naturally tend to lower the magnetic flux through the armature, instead of increasing it, thereby causing the drop in potential as the load came on. If the brush connections had been changed in the first place no other alteration would have been needed.

It very often happens that connections cannot be easily changed, or if changed, would materially injure the appearance of the apparatus. In such cases, and in fact nearly every case where direct current can be obtained at the proper voltage, the writer favors magnetizing the fields from this outside source, so as to cause the polarity to stand as it should for proper operation. It is a good idea to have a pilot light connected across the two outside 220-volt wires and located either on the switchboard or, better still, near the generator set, where the operator can see it and when starting whether or not the polarity is reversed. He could then immediately remedy the trouble and not keep customers waiting for light or motive power.

Frank X. Bliss.
Bennington, N. H.

Card Indexing

Having preserved my copies of Power, as well as those of several other technical magazines, I began some time ago to look for some method of indexing the matter contained in them.

The separate issues were punched with five holes, about ½ inch from the back, and dividing the year's issues into two volumes, a dark paper cover was made for each, after which a shoe lace was run through the holes, binding all tightly together.

For the indexing, a form of card index is prepared. Matter is divided into main heads, such as Steam, Electricity, Hydraulics, Gas, etc. Under these heads come subdivisions, as Types (under which are listed the articles describing particular installations in different parts of the country), Operating, Repairing, etc.

These cards and combinations may be arranged in any way the user thinks best, but I have found the foregoing very convenient. One need not have a separate card for every article, for any number of articles bearing on one particular subject may be noted on one card, together with notes giving a short outline of the article in question. This last feature is where the card index surpasses the regular index furnished, as it is sometimes difficult to tell from the title of an article just what may be published in it, but a few notes on the card will show the gist at a glance.

William H. [illegible]
Berkeley, Cal.

Water Evaporated per Pound of Coal

Under the above caption appears a very interesting letter by E. E. Edwards, on page 1052 of the December 22 number. If Mr. Edwards will make a test of his coal he will very likely find that it is much higher in heating value than his boiler trial indicated, and that the trouble is more apt to be in the boiler and furnace, in the form of air leaks, poor circulation and faulty boiler setting.

If he would take a sample of his flue gases and have them analyzed he would doubtless be surprised at the results.

C. T. McKnight.

San Antonio, Tex.

Cement Roofing

In many cases cheap roof construction is used, which in the end proves very expensive. I caused to be placed on a roof about 30 squares of corrugated iron that did not last quite a year. Before it had become entirely unserviceable, I repaired it with a permanent, and what I consider the best, roofing that can be used. I stretched over the entire roof a 2-inch mesh poultry wire, and with a trowel spread cement about ¾ inch thick; by troweling the cement when in a plastic condition it entirely enveloped the wire.

No crack nor check appears in the roof, which has 4x12-foot spans, although the iron has nearly disappeared. In testing this roof, several men at a time have walked over it, and it showed no weakness. It is fireproof, and will practically last for all time. But the most interesting fact about this cement roof is the cost, about $2 per square, buying the wire and cement at retail. I used three parts sand and two parts cement.

Steam Gages and Indicator Springs

One night while indicating our engines we noticed an unusual drop in pressure between the boilers and engines. The gage at the boilers showed 100 pounds pressure, while the indicator on No. 1 engine showed an initial pressure of 74 pounds, a difference of 26 pounds. No. 2 indicator on No. 2 engine showed a drop of 20 pounds, although 20 feet farther from the boilers than engine No. 1. There is no apparent reason for such a drop, as the pipes are short and of ample size and have straightway valves.

To locate the trouble we put No. 1 indicator on one of the gage connections to the boilers. With the same spring, and the same gage pressure, 100 pounds, the indicator showed 82 pounds, a difference of 18 pounds. We then tried No. 2 indicator in the same way. This gave us 90 pounds. A 50 spring was used in both cases. We next tried No. 1 indicator with a No. 60 spring and got a reading of 90 pounds, the gage still showing 100 pounds pressure. The last two readings being alike, the No. 50 spring in No. 1 indicator must be 8 pounds heavy, and the steam gage 10 pounds light, if the two springs are correct.

The steam gage was tested six months ago. The indicator springs are also practically new, and of a well-known make. The difference in this case is in favor of the boilers, but in many others it may be otherwise.

The question is, how long may we expect springs to retain their accuracy and steam gages to remain correct?

Development of the High Speed Engine

I think Frank H. Ball, in his lecture before the Modern Science Club, as quoted in the January 19 number, is "off" in some of his historical statements. He credits Mr. Porter as having shown a high-speed engine at the Paris exposition in 1875. There was no 1875 Paris exposition. Mr. Porter exhibited a high-speed engine in the London exhibition in 1862, which, though not as high-speed as his later ones, was fast enough to astound the English builders, and at the Paris exhibition he exhibited three, one, I think, about 12x24-inch, which ran at 200 or 250 revolutions per minute, and a 6x12-inch engine which he thought to run at 1000 revolutions per minute, if I remember correctly, and which he did run, I believe, at 600 or 700 revolutions per minute. The third engine was a complete 6x12-inch engine with one-quarter of the cylinder cut out to show the construction and action of the valves and valve motion.

As to the Armington & Sims people building the first single-valve shaft governor, I do not think they started in business until the early eighties; while the first Straight-line engine was built in 1871, and the second built at Cornell in 1875, and exhibited at the Centennial in 1876.

J. C. Hoadley had built shaft-governor single-valve portable engines before, but they were not, as far as I know, introduced in regular horizontal engines before Mr. Hoadley went out of business.

Though Mr. Sims was a Hoadley man, when the Armstrong & Sims engine came out it could not be said to be a continuation of the Hoadley design, being different in all essential features.

Culm and Coal Dust for Fuel

In Mr. Jeter's article on "Culm and Coal Dust for Fuel," published recently, there are several statements that are not borne out by the experience of some us who have experimented with briquets. He states that a ton of briquets made from anthracite dust equals three tons of best anthracite, as proved by a number of tests.

The best anthracite to my knowledge comes from Colorado. According to Kent, the approximate analysis of the best quality of Gunnison county coal is as follows: Moisture, 2 per cent.; volatile matter, 2.5 per cent.; fixed carbon, 91.9 per cent., and ash, 3.6 per cent. This would give a heating value of 14,100 B.t.u. per pound of coal. According to Mr. Jeter's figures, a ton of briquets would develop 42,300 B.t.u., to attain which would require the consumption of one-half hydrogen by weight, or by volumes 12 parts hydrogen to one of carbon.

The first briquets of my acquaintance were made from Carterville (Ill.) washed slack. There was little difference in the burning qualities between them and the egg coal from the same district. The smoke was no greater and the ash slightly less. In my young days I believed the nearer the boiler was to the fire, the better it would steam. This is undoubtedly true with anthracite or wood, but it is a great mistake with soft coal, and the lower the ratio between the volatile matter and fixed carbon, the farther the grate should be from the shell of the boiler. My last venture was to set the grates 48 inches from the boiler (for Belleville, Ill., screenings), and my next one will be 54 or 60 inches. In the last case the ratio of volatile matter to fixed carbon was about 1 : 1 and the amount of soot generated was quite small.

I believe that anthracite culm washed and briqueted can be made the ideal fuel. The ash-forming ingredients and sulphur, if present, can be removed in great part by washing and a pitch binder will furnish enough hydrocarbons that the resulting briquets will approach the semi-bituminous coals of Maryland, West Virginia and Arkansas in composition and heating qualities. As anthracite does not usually exceed 10 per cent. in ash, and pitch has none, the briquets should be an improvement on the general run of commercial coal in that respect. They will need ample room for combustion of the volatile matter and must be fired as bituminous coal is fired, and when properly handled, produce no more soot or smoke than George's creek or Pocahontas coals.

A uniform boiler-construction law for the Dominion of Canada is being agitated, with a bright prospect of its adoption.

Some Useful Lessons of Limewater

Various Practical Experiments for the Boiler Room, Which Will Add to the Furnaceman's Knowledge and Increase His Efficiency

BY CHARLES S. PALMER

Mr. Furnaceman, this is for you. You are sitting on that barrel of lime that has been rolled into your boiler room, waiting for the masons to put on that addition to the mill. But you are not thinking of the mill; what is bothering you is the trouble with the water, and that scale that will get onto the boiler tubes. The water looks all right, and there is the heater in the corner which does take out some of the stuff that makes the scale; while up on your shelf are those samples of boiler compounds that the salesmen left for you to try; and sometimes they work, and just as often they don't, and you are at your wit's end. Now, you may not believe it, but you can do a bit of study and thinking right down here in this dusty place—thinking and doing, too—that will help you to get onto your job a little better. Try it; it will not do any harm, and it may put you on your feet as you have never stood before. It may help you to understand your work better, and no man is doing right by himself or his business unless he knows how to do the thinking that goes along with his special work. Some of the best and most skilled workmen wear plain clothes, and the hints that will be contained in these articles may put a dollar or two in your pocket.

Do you know that you are *sitting* on your opportunity? Do you realize that that barrel of lime has some secrets that it will pay you to know about? There is a whole college course of practical chemistry right under you, waiting only for you to take hold of it and use it in your daily work and thinking. It isn't merely a matter of muscle that makes the difference between a low-paid and a high-paid man. There isn't anyone who is holding you back, except one man, and he certainly has got it in for you. That man is the chap that walks under your hat. Did you ever think of that? Then take a brace—a good hard brace—and let us help you to do some commonsense study right down here in the boiler room. It can't hurt, and ten to one it will show you something that you can use to help the man who pays your wages, and to help you to command more pay. So, take right hold, here and now, and tell us if we talk over your head, for we want you to learn something to your advantage. Once you get started, you'll find it easy.

You may get the apparatus and chemicals which you will want in these help lessons from your druggist; and for every dollar you put out now on this furnace-room laboratory, to use right down by your boiler, you will get a return some time that will pay you back ten to one; not only in the mental satisfaction of knowing your work better, not only for your being able to hold your head higher from knowing what others know and are learning with you, but certainly, for the better position and pay that you

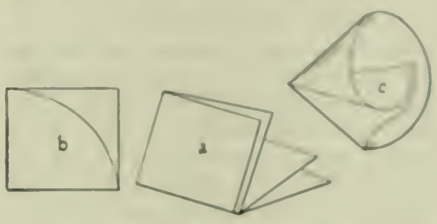

FIG. 1

can command in the long run, and perhaps in the short run. If it should happen that your druggist cannot supply you, the materials may be obtained from Eimer & Amend, 205 Third avenue, New York City, or E. H. Sargent & Co., 143 and 145 Lake street, Chicago, Ill. The former will charge $2 for them all packed ready to ship, and the latter will deliver them to the nearest railroad station for $3.00.

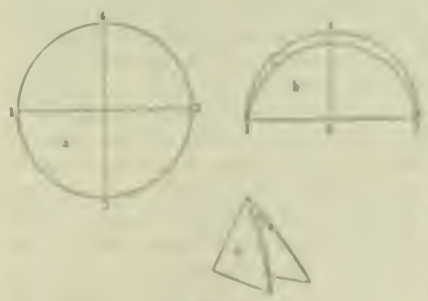

FIG. 2

Following is the list of materials required:

- 1 plain-glass pinch funnel, with long stem.
- 1 corrugated or grooved-glass 2-inch funnel.
- 50 sheets of filter paper, [illegible] inches, or several [illegible] sheets, as preferred.
- 4 straight glass tubes, 1 foot long each, [illegible] ¼ inch in diameter.
- 2 glass tubes bent at right angles, same size as the straight tubes, one with the arms of equal length, one with one arm 3 inches long and one with one arm 5 inches long.
- 2 glass stirring rods, 3/16 or ¼ inch in diameter.
- 1 foot of rubber tubing to fit the glass tubes.
- 2 four-ounce glass flasks, with glass corks.
- 1 four-ounce glass beaker.
- 1 six-ounce glass beaker.
- 1 round 3/16-inch file, to smooth the holes in the corks.
- 12 thin-glass test tubes.
- 2 sheets of litmus paper, one red and one blue.
- 1 four-ounce bottle of hydrochloric acid.
- 1 four-ounce bottle of nitric acid.
- 1 four-ounce bottle of sulphuric acid.
- 1 four-ounce bottle of ammonia.
- 1 four-ounce bottle of sodium hydroxide.
- 1 four-ounce bottle of sodium carbonate.
- ½ pound of potassium chlorate.
- ½ pound of black oxide of manganese.
- 1 two-ounce bottle of solution of barium nitrate.

A box of gummed labels is useful, but homemade labels will answer.

The First Lesson

Take a piece of lime about the size of an English walnut and break it into any clean bottle holding about one-half pint. Nearly fill the bottle with water as pure as can be got. Of course, distilled water is best, but rain water, boiled water, condensed water from waste steam, etc., will do very well. Close the bottle with a clean, common cork, shake well and let it stand a few minutes. Next prepare a clean funnel. One with channels and grooves down the inside of the conical part, and called a "corrugated funnel," will filter faster than a plain one. The funnel should be of glass, about 3 or 4 inches across the mouth, and if the stem is 3 or 4 inches long the suction of filtered liquid in the stem will actually help to pull the liquid through faster than it will in a funnel with a short stem.

As for the filter paper, common "qualitative" paper will do. It should be white and smooth, not like the close grained [illegible] that some druggists try to palm off on the beginner. You can buy it cut in round shapes, and of various sizes, so as to [illegible] to fit the funnel. A piece 4 or 4½ inches in diameter will fold down to [illegible] the funnel, being about [illegible] inches across the top. [illegible] in sheets, fold, crease and cut it as shown in Fig. 1. Take a piece about 7½ inches square, fold it twice, as shown at *a*, lay it down and trace a curve *from the closed corner* of the paper, as at *b*, and cut this folded paper along the curve; when you open it, it will look something like *c*. Or, if you get the filter paper in packages of "cut" paper, you will fold it as shown in

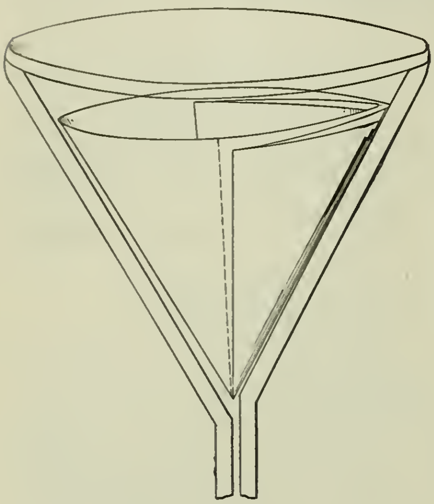

FIG. 3

Fig. 2. Referring to *a*, first fold it across the line *1-2*, to halve it, and then, to quarter it, fold along the line *3-4*, folding the point *1* over and down on point *2*; then when you open it, it will look much like *c*, Figs. 1 and 2.

Next, fit this piece of quarter-folded filter paper down into a funnel about 4 inches across, so the point or apex of the cone of the paper fits nicely down into the opening of the stem of the funnel. You will notice, when you have done this, that on one side there is only one thickness of paper, while on the other side there are three thicknesses. That is all right; it will do its work. You will also note that when the paper is in the funnel, closely fitting it, it will look like Fig. 3. You will further note that to have the conical cup of filter paper closed on the under side, where it fits the funnel, the paper has to turn back on itself twice. All this may seem simple to the man who knows all about it, but you will have to use your wits to get some of these simple things right. You can do it, however. A sketch of the corrugated funnel, with its stem in a bottle, is shown in Fig. 4.

When the filter paper has been fitted into the funnel, which has been set with its stem in the neck of a clean bottle, as stated, dampen the paper with a few drops of water, to "break its back;" otherwise, it will spring back and crawl out of the funnel, even if the funnel is standing upright.

The next step is to open the bottle of limewater, which may be quite milky. Don't lay the cork down anywhere, but hold it between the third and fourth fingers of the right hand, with the palm upward. In fact, that will be found to be the best way to take the cork out of the bottle. The cork will not get soiled, then, and is ready to go back in place instantly. Or, you may hold the cork in your left hand and use it to direct the stream of liquid as it is poured into the filter paper in the funnel. If the cork is held close to the mouth of the bottle, as it is tipped with care to pour, the stream will follow down the side of the cork.

We are to filter the milky limewater through the funnel into a second clean bottle, say half a pint, or even a pint or more; for you will use this limewater on a number of different occasions. If the stem of the funnel fits too tightly into the mouth of the second bottle, slip a bent match or wooden toothpick between the funnel stem and the mouth of the second bottle, to leave a crack for the air to escape through as the filtered limewater runs in (as shown in Fig. 4).

How to Clean a Bottle

To digress for a moment, you may as well learn a trick for cleaning bottles. Tear up a small piece of common paper (any kind, newspaper will do), say a piece 5 inches square, into little bits the size of a dime or smaller. Put these paper bits, with a little soapy water, in the bottle and shake well, and with a motion to make the wash water swing around the inside of the bottle. The edges of the paper cut off the dirt from the smooth surface of the glass, and when the bottle is rinsed several times it is clean, cleaner than washing with shot will make it, as a rule.

To go back: Don't fill the filter paper in the funnel higher than to within about ½ inch from the top, then there will be no danger of the milky water creeping up above the paper, running down the side between the paper and glass and thus get through without going *through* the paper. All this and a dozen other points you will learn by trying; it is really very simple, and anyone can do this in a kitchen or boiler room. Filter enough into the second bottle of water so that it will be full, for it will be found that the air will act on this filtered limewater, and if the bottle is full to start with less air can get in below the cork.

It takes a few minutes to get this bottle of filtered limewater ready for use. When it is ready you will label it with one of the adhesive labels which came with your outfit; or, if you haven't that, get your wife to make you some flour paste by cooking a teaspoonful of common wheat flour in hot water. You should write "Limewater" on the label. If you know how to do all this, why, just skip the reading up to this point; but you will have this first reagent on hand; and you had better fill the bottle of lime again with water, shake and cork it, laying it aside ready to filter more limewater as needed.

This bottle of filtered limewater is the *door* leading to a whole lot of useful facts and self-instruction; indeed, it is a laboratory by itself. Look at it. It is as clear as water, and you may doubt whether it is anything more than common water. But just *taste* it; that is test No. 1. It is perfectly safe to taste it, for you may have given some of it to your baby at home, with its milk. Before you get through with this, you will see why you gave it to the baby. The limewater tastes slightly bitter-sweet, and it has also what is called an "alkaline" taste, a taste that you will want to learn.

Pour some of the limewater into a clean tumbler or one of the little thin-glass cups, "beakers" they are called. Breathe down into this limewater strongly; or, better still, blow through the limewater your good, sound breath, through a clean pipe stem, a straw, or one of the pieces of glass tubing which came with your outfit.

How to Prepare Glass Tubing

When you use glass tubing, it is a good thing to soften the edges at the ends by holding the tube in a hot flame for a few moments so as almost to melt the glass, if the ends are not already rounded; the ends of the tube may also be rounded with a file; but be sure to smooth the edges, or you will cut your tongue, your

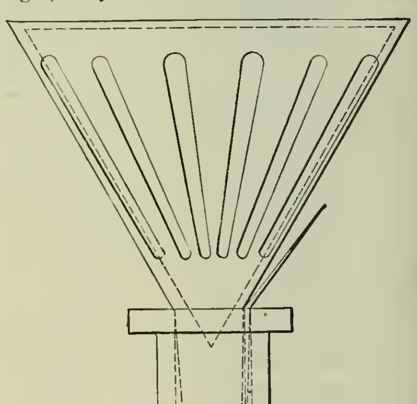

FIG. 4

corks, or your rubber tubing, and it is simply a matter of doing things shipshape *to round the edges* of glass tubing.

As you blow your breath into the limewater, and as you shake the liquid around, so that the gases of the breath can mix well with the liquid, you will notice that a whiteness comes in the limewater. It gets milky, and if left standing a white sediment soon appears. This white sediment is lime (or calcium) carbonate. It is a union of the carbonic-acid gas from the breath with the "base," lime, and the two together have made the "salt," carbonate of lime (or calcium, calcium being the hidden metal that is at the bottom of the lime, just as iron is the metal at the bottom of common iron rust). The carbonic acid gas in your breath came from the burning of the food in your body, by the millions of tiny furnaces in the muscles and red blood corpuscles; and the lungs make the chimney from which the invisible smoke of the breath gave off the carbonic-acid gas, just as truly as though the carbon of the food had been burned in your grate under your boilers. This shows again that the limewater is an active chemical. This is test No. 2.

You well know that all of your food contains carbon, the same element which makes up the bulk of coal. You know this from the fact that if the bread toast gets too much fire, it shows real coke or charcoal on the edges; and if your roast beef gets burned, there is the same coke or charcoal on the surface. You also know that bread and meat will burn in the fire as though they were of close kin to wood and coal; the same thing is true of sugar, starch and, especially, butter and fats. Now this turns your own attention to that fire right at hand. Why not test that with this limewater? You will do it in the following manner:

How to Apply the Test to the Furnace Fire

You will need a common wide-mouthed bottle, say, a horseradish bottle (see Fig. 5). Fit this with a good cork, which has two holes just wide enough to take in tightly the two pieces of bent-glass tubing *A* and *B*. Make the holes in the cork with the small blade of your knife, or with the cork cutter that comes with your outfit, then round the edges of the holes in the cork with a rat-tail file. The bent-glass tubes come with the outfit. You will note that one of these pieces of glass tubing goes just through the cork and the other piece reaches down below the surface of limewater which has been poured into the bottle. The tubing *A* is joined, by the bit of rubber tubing *C*, to the stump of a common clay pipe. You will want to try this piece of apparatus by sucking with your mouth at the end of tube *B*. Naturally, bubbles will come through the limewater, as indicated by the arrows. Don't blow in this, unless you want to force the limewater out of the pipe. Your common sense will show you why. Now that you know that your cork and tubes fit fairly tightly, place some small, live and glowing coals from your boiler fire in the pipe bowl. There you have the real Turkish pipe, with well-cooled smoke; but what you are after is the action of the gas from the glowing coals on the limewater. It will not hurt you to suck some of this any more than it does to smoke your old pipe with tobacco in it.

As you draw the burnt gas from the glowing coals through the limewater, you will notice the same milkiness forming, and the same white sediment will gather as when you blew into the limewater with your breath, and for the same good reasons. The coal is mostly made up of carbon, and if you don't pack the coal too tightly in the pipe, you will not get much through that you need to note now except this carbonic-acid gas. This acid

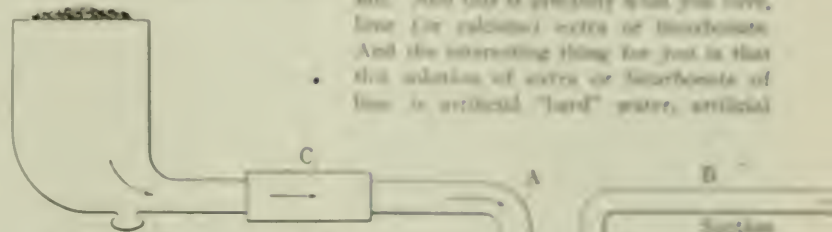

FIG. 5

gas will unite with the lime, which is a base, and together the two will make the same white insoluble salt, carbonate of lime (or of calcium). Note that the lime, as such, is soluble to a considerable extent in water, while the carbonate of lime is *not* soluble, or, as they say, when a thing is *not soluble*, it is insoluble. As a matter of measure, it takes about seven or eight hundred parts of water to dissolve one part of lime (not very much but enough to show well), and it takes some sixteen thousand parts of water (cold water) to dissolve one part of carbonate of lime; not very soluble, so it is called insoluble.

The Basis of Boiler Scale

Now this white sediment of insoluble carbonate of lime (or calcium) is a large part of the scale that forms in or on your boiler tubes when you use what is called temporary-hardness water (permanent-hardness water is another thing, which you will study later). But this form of carbonate of lime is the same thing as common white limestone or marble, and it is the same as much of your scale. But what you want to know is this: If this white sediment is so insoluble in water, how does it get into the boiler, when your water supply is quite clear and shows no such thing at least to the eye? You will see how to explain that if you go on to the next step with the limewater.

Go back to the beaker of limewater in which you blew your breath to bring down the white sediment of carbonate of lime. Take this and keep on blowing for some minutes, five or ten, shaking it about so that the bubbles of breath will mix thoroughly with the milky water. Pretty soon this will begin to clear up, and presently a change will come in it. The sediment will partly dissolve, and it will look as though you could almost see through it. Now filter this off, through a clean piece of filter paper and with a clean funnel, into another bottle. Now you have a new kind of limelike water; it is not the original limewater, for it has gone through the throwing down as carbonate; neither is it the plain carbonate, for that is insoluble in water, while this is soluble enough to dissolve somewhat in water.

You can begin to guess for yourself what has happened. If you got the "salt" carbonate of lime, by adding the carbonic "acid" of the breath to the "base," lime, why here you must have a "salt" which has still more of the carbonic acid; in fact, an extra or bicarbonic-acid salt. And this is precisely what you have, lime (or calcium) extra or bicarbonate. And the interesting thing for you is that this solution of extra or bicarbonate of lime is artificial "hard" water, artificial temporary-hardness water. You can do something with this artificial temporary-hardness water that is exactly like what you do with it if you put it wholesale into your boiler. Just warm it, and the extra carbonic acid will go off, and down will come the white, insoluble plain carbonate, not very much, but enough to see and quite enough to make trouble when on a large scale. It was the extra carbonic acid which changed the plain insoluble carbonate into the somewhat soluble extra, or double, or bicarbonate, "hard" water in fact. The plain carbonate is hardly soluble. From this you throw down plain carbonate of lime by the breath and by the gas from the glowing coal, by means of carbonic-acid gas in the breath and in the "breath" of the glowing coal. This plain carbonate of lime is *insoluble* in water. From this plain and *insoluble* carbonate you made some extra, or double, or bicarbonate (by adding extra carbonic acid): and this extra or double, or bicarbonate of lime is somewhat *soluble* in water. This is "hard" water, and it can be broken up and the limelike part thrown down again, as the *insoluble* plain carbonate; just as happens in making soft scale on your boiler tubes from your temporary-hardness water.

This temporary-hardness water can also be made, of course, not only by *blowing* the *breath* through limewater until the first plain *insoluble* carbonate has partly redissolved as extra or bicarbonate, which is fairly *soluble*, but also by *sucking* the gas from the glowing coals (as in Fig. 5) through the limewater in the horseradish bottle until it begins to clear again, say five minutes' suction with good glowing coals in the pipe bowl. After it begins to clear up, open the bottle, filter the water clear, pour it into a *clean* tumbler or beaker, and warm it. Enough plain insoluble carbonate will come down so that you will notice it if you look for it, and yet so little that one can easily overlook it if he doesn't look for it.

This is only the beginning of what that barrel of lime will teach you; but with all the bother of this fussy filtering, you may have done another piece of filtering which is worth your while, Mr. Furnaceman. That is, filtering out some clear ideas from the milky water of careless ignorance and prejudice. In the next article we will begin to discuss this filtering of new ideas, carefully and one at a time.

Electricity in Great Britain Mines

The appointment of an electrical inspector of mines in Great Britain is in itself an indication of the great strides being made in the application of electricity to mines. It is estimated that 50 per cent. of the new plant being put down in British mines is designed for production and distribution of electrical energy. The electrical industry is devoting a more intelligent study to the special conditions encountered below ground, on the one hand, to increase the safety and efficiency of the machine, and on the other to cheapen the cost. Mining engineers are now rapidly discovering advantages, from a purely mining point of view, in the use of electricity.—*The Mining World.*

At Charlottenburg 146 horsepower are transmitted by means of a belt, 10 millimeters = 0.39 inch in width and 5 millimeters = 0.185 inch thick, running at a speed of 61.5 meters a second, equal to 12,103 feet per minute, with a tension of 200 kilograms = 440 pounds. On the same shaft in another place is a 100-millimeter = 3.94-inch steel belt replacing a 600-millimeter = 23.6-inch leather one, both carrying 250 horsepower.

Calorimeter Tests of Steam

By W. H. Booth

Papers on power plants are often read, particularly in Europe, in which great weight is accorded to the calorimeter tests of the steam produced by a boiler. It is more or less amusing to note the assumption with which the reader of the paper sets forth his figures of 99.01 per cent. of dryness and the solemnity with which his listeners sit and receive such figures, and the natural sequel to such figures in the shape of some grotesque efficiency of the boiler which never could have given such an efficiency of dry steam. It is no part of this article to throw doubts on the accuracy of calorimeter instruments. Doubtless they give accurate results for the steam passed through them, but the crux of steam-dryness testing rests entirely with the sample of steam tested. The calorimeter tells what water there is in the small sample passed through it, but it does not, nor can it ever tell how much water is passing through the main steam pipe from which the sample is taken.

An old steam engineer was recently passing by a boiler which was being tested for the purpose of glorifying the particular mechanical stoker with which the boiler was fitted. The calorimeter test was in progress. "Why," asked the old man of the young experimenter, "do you take your sample of steam from that particular place? Why do you not use this cock which is specially provided and from which these samples of steam are to be drawn?" The reply of the young experimenter was as instructive as it was ingenious. "Because," said he, "the steam came so very wet at that tap and here I get it dry." And does not that reply give away the whole case for the calorimeter test?

From two points on one valve box or casing there was to be drawn steam wet or dry. Both the samples could not represent the truth of the matter. The test was made of dry steam. Yet the pipe was carrying a lot of water and this water was going to be counted unto the mechanical stoker for evaporation. Granted that the steam was not so wet as the one point showed it to be, it could not have been so dry as the other tap appeared to indicate.

All manner of devices and arrangements are put up with the object, or pretense, of drawing a correct sample. A pipe is turned toward the current of steam. It is fitted with a cross piece extending right across the pipe and perforated. An attempt is even made to draw steam through the sampling tube at the same velocity with which it is flowing in the main pipe, so that the correct proportion of water particles may be taken along. If such precautionary guess work is admitted desirable, is it not convincing proof that such sampling must be quite unreliable? No man can possibly say, with the most elaborate means of take off, that the calorimeter is being fed with steam of the quality the boiler is producing. Why, therefore, should the mockery of the test be continued? It was "sprung" on the electrical steam user as a piece of refinement which was demanded by modern conditions, and it has clung on as the obsolete and dangerous vermiform appendix has clung to mankind for long ages after he has ceased to hibernate and require such an addition. Indeed man today often dies of inflammation caused by the very nuts he once stored in the appendix that was made for such food.

But how can the quality of steam be really known which a boiler is giving forth? Plainly and bluntly it cannot possibly be known by any method short of testing the whole output in a suitable calorimeter. This plain statement refers solely to saturated steam. All saturated steam at a given pressure has a given temperature, no matter how wet or how dry it may be. The thermometer does not help us, for steam and water which come out of a boiler together have no temperature difference. But this very fact is a hint toward a certain elucidation of the problem.

Given a thermometer in the boiler steam space and another one of equal readings in the steam pipe, and a superheater in between, and the two thermometers will give, not the percentage of wetness, but that of dryness, and this dryness will always be over 100 per cent., or at least not less than that, if any reliance is to be placed on the figures of the test. One thermometer must read a trifle above the other, and when it does this it is proof the steam is dry. Some sort of a small superheater is therefore necessary if boiler tests are to be made for figures on which the slightest dependence is to be placed. Not one in all the many published boiler-test records is likely to be correct unless some slight superheat at least has been given to the steam.

The proceedings of the technical societies teem with boiler-test figures, books have elaborate tables of test figures, and conclusions are drawn from such figures and theories advanced on no better foundation than the baseless fabric of a vision. Boiler-test figures may be found showing very nearly 90 per cent. efficiency for the boiler alone, apart from the help of the feed heater. As the conjurer says after each of his juggling displays, "Isn't it marvelous?" It is. Any engineer who wishes credence to be lodged in his test figures should endeavor to have his test include for the superheater also, and in view of the present uncertainty as to the true specific heat of steam he should aim only to get a superheat of a few degrees, just sufficient to render it certain that there is superheat. Otherwise, no one who knows will place any value on the figures of his test.

Horatio Allen and the Novelty Works

Sketch of the Career of the Man Who Brought the First Locomotive to America and Became the Head of an Immense Engine Industry

BY EDWARD P. BUFFET

It was Horatio Allen who brought the first locomotive to America, who acted as running-engineer on the first trip, and who later grew to be of the first magnitude as a builder of marine engines.

To understand how he came to import that locomotive we must look back to the time when the Delaware & Hudson Canal Company was pioneering what has since become a tremendous factor of industry, the transportation of anthracite to tidewater. At this time Horatio Allen was a young civil engineer just beginning to make his mark in life.

From Law to Locomotives

He was born May 10, 1802, in Schenectady, N. Y. His father, Dr. Benjamin Allen, a school principal, gave him a good start on the road of learning and at eighteen the boy graduated from Columbia College with high rank in mathematics. Those were days when none of the doors of a college opened directly upon technological walks of life, so that a young fellow who had been mingling on common footing with the rest of the scholastic herd would have been no more likely to have his attention called to engineering as a vocation than today he would be likely to select the profession of a sandwich man as a logical sequence to taking his degree.

It is therefore not to be wondered at that Horatio Allen at first set about reading law, as his later engine-building contemporary, Charles T. Porter, and many others have done, from lack of reason to the contrary if from no more rational motive. But it took him less time than it did Mr. Porter to discover his real adaptedness and switch off upon the right track. So at about the time he cast his first vote he entered the employment of the Delaware & Hudson company. Afterward he spent a year or two upon the Chesapeake & Delaware canal, but near the close of 1825 he was appointed resident engineer of the summit level of the Delaware & Hudson canal under the eminent John B. Jervis. That brings us to the point where we started, when the company was hauling out its coal by canal and when locomotives did not yet exist on this side of the Atlantic.

In Quest of Knowledge and Engines

The performances of the steam locomotive on the Stockton & Darlington road in England were arousing the interest of American engineers, and in particular of Horatio Allen. Though at an age—twenty-five—when most men rightly feel that they must establish their reputation by steady service with going concerns before cutting loose and offering themselves to the world as technical leaders, Allen threw up his job in order to go to England and acquaint himself with what he was convinced would prove the carrying power of the future. But perhaps he already had the situation better in hand than appears, for previous to sailing he received a commission to act as agent for the Delaware & Hudson company, empowering him to procure railroad plates and one or more locomotives for a 16-mile railroad which it was building to connect its mines in Pennsylvania with the canal. One locomotive the company desired as a pattern for manufacture of additional engines in the United States; as an alternative to which plan it might wish to have them all made in England. The ultimate decision was to procure three more. The company agreed to pay Mr. Allen's passage and expenses, permitting him to remain abroad about three months, the whole not to exceed $600.

Railroad plates of the kind mentioned were primitive rails ½ inch thick by 2¼ inches wide at the bottom and 2 inches at the top and 12 to 15 feet long, to be laid on wooden string pieces. It was desired to have the plates rounded if this would not entail too much additional expense. Further, Mr. Allen was asked to report on improvements in coal "wagons," especially as to the size of wheels and manner of connection to the body. Mr. Jervis wrote him a long letter filled with specifications for his guidance.

Visit to Stephenson

Leaving New York in January, 1828, Mr. Allen arrived at Liverpool, where he was cordially received by George Stephenson. The famous trial of the "Rocket" on the Liverpool & Manchester railroad was not destined to take place until October 14, 1829, in the course of which were the discussions still continued between locomotives and fixed engines for the road. The fixed engines would probably have been used on inclined planes in connection with greater or smaller grades, which arrangement seems to have been a favorite one in the early days of railroading and which still was [illegible] to be seen in operation in this [illegible] vogue in Pennsylvania. Locomotives had, however, been in successful service at Killingworth, Eng., as early as 1814, and there were in use on the Stockton & Darlington railroad locomotives of a common type which the instructions from Mr. Jervis favored. In compliance with the instructions of his chief Mr. Allen ordered one of this model from Foster, Rastrick & Co., of Stourbridge. It had four coupled wheels, all drivers, two vertical cylinders of 36-inch stroke, placed at the rear of the boiler, "grasshopper" beams, wooden-spoked wheels and tubular boiler with several large flues. The blankness of the circular space on the front of the boiler was embellished with a lion's head, whence this engine was dubbed the "Stourbridge Lion."

The "Rocket" and Its Predecessors

While Mr. Allen deferred to the [illegible] ideas in ordering one locomotive of that type, he [illegible] by Stephenson's [illegible] to contract with that [illegible] firm at Newcastle, for [illegible] other engines essentially of what later became celebrated as the "Rocket" type. These, when brought to New York, were placed [illegible] in the city, where exhibitions were given with wheels running free of the ground. [illegible] it is the "Stourbridge Lion" which is known as the first locomotive on an American railroad. If the "Rocket" type engines had been put into service at once [illegible] America would have anticipated the proving of that type in England.

First Locomotive Run in America

The "Stourbridge Lion" was held up during the winter of 1828-29 at the [illegible] of the Delaware & Hudson canal [illegible], Honesdale, Penn., [illegible] and in the [illegible] of August, 1829, made its [illegible] trip on the road from the canal into the Pennsylvania woods [illegible]. The [illegible] crossed the Lackawaxen river [illegible] [illegible] of such an engine in service was only 4 to 6 miles an hour, and had it jumped the track at that velocity he might have stepped off upon the ties without losing his cigar. However, he was at the time running without load and may have speeded up the machine enough to startle the beholders.

More than half a century elapsed before Horatio Allen again visited the scene of his exploit, which occasion was marked with lively emotions at the memories it awakened.

Railroading in South Carolina

The month after his epoch-making run, Mr. Allen became chief engineer of the South Carolina railroad. It was then in question whether to employ horse or locomotive traction there, and his counsel in favor of the latter was unanimously accepted by the directors. As he has stated in his pamphlet, "The Locomotive Era," there was no reason to expect any material improvement in the breed of horses, but in his judgment the man was not living who knew what breed of locomotives the future was to place at command.

By his recommendation the gage of the road was made 5 feet, but a similar suggestion that he later made to the Erie road was rejected, to the great disadvantage of modern heavy railroading. A railroad gage is one of the standards which it seems impossible to change and which is snatched at by the anti-metric cranks as an argument against changing any.

Invention of the Swiveling Truck

To Horatio Allen is due a large share, if not the whole credit, of originating the swiveling truck. The light plates on 6x12-inch stringers which then served for rails were incapable of sustaining a heavy weight, the safe load on the Liverpool & Manchester railway being three tons, or even less, per pair of wheels. Hence the limitation of locomotive wheels to four necessitated the use of light engines and entailed correspondingly heavy operating expense in transporting a given quantity of freight. In 1831, Mr. Allen called the attention of the South Carolina railroad directors to this difficulty and recommended the employment of more than four wheels, with swiveling trucks to enable the passage of curves. Consequently he was empowered to place contracts with the West Point Foundry for locomotives built on that principle. The first of these was the "South Carolina," and put in operation early in 1832. A couple of years later a patent was granted to Ross Winans, of Baltimore, for eight-wheeled cars with two trucks. Some such were built or used by the Newcastle & Frenchtown Turnpike and Railroad Company in defiance of Ross' patent claim. This led to twenty years' expensive litigation, virtually involving the interests of all the railroads, and it was not until 1858 that Winans' patent was finally declared invalid. During the dispute recourse was had to evidence that the double-truck principle had been employed before the patent date by Horatio Allen.

The South Carolina railroad locomotives of this type were double-enders, consisting of two engines facing apart and joined by a firebox in the middle. Each boiler was double-barreled and rested on a four-wheeled, jointed, swiveling truck, there being one cylinder to each truck.

John B. Jervis himself was another pioneer in using the truck form of construction and seems to have been at least a close second. The truck idea had, indeed, been foreshadowed as long ago as 1812 in an English patent to William and Edward W. Chapman.

After completion of the South Carolina railroad, Mr. Allen was variously occupied. He married, traveled abroad for two or three years and served as principal assistant engineer of the Croton aqueduct under his old chief, John B. Jervis.

The Novelty Works and the "Novelty"

Horatio Allen's *Lehrjaehre* and *Wanderjaehre* came to a close in 1844, or thereabouts, when he entered, as one of the proprietors, that famous engineering works in New York City with which his subsequent career is identified. He became a member of the firm of Stillman, Stratton & Allen, owners of the "Novelty Works."

About the early part of the thirties, Rev. Dr. Eliphalet Nott, president of Union College, Schenectady, N. Y., who had been active in introducing anthracite for house stoves, invented a steam boiler to run on that fuel and decided to build a steamboat in which to make a test. Besides burning this novel fuel, he proposed to install a novel mechanical equipment throughout, wherefore the boat was called the "Novelty." This name attached itself to a shop which he established to do repair work, etc., on the vessel. It consisted of a wharf and some buildings situated in New York City, on Burnt Mill point, so-called, at the foot of Twelfth street, East river. The "Novelty" herself ran from New York to Harlem. The Novelty Works gradually extended its attention to outside business, and from an equipment of a few tools in a little shed, grew to be the biggest marine-engine building establishment in the country.

Development of the Works

In the early days the business was conducted by Nott & Co., under superintendence of N. Bliss, formerly of the West, the foreman being Ezra K. Dodd, who afterward was made chief engineer of the "Novelty." Later Thomas B. Stillman took charge of the plant and, in 1838, it passed into the hands of a firm including himself, John D. Ward, Robert M. Stratton and C. St. John Seymour. Messrs. Ward and Stillman were the mechanical men of the firm. Among the work turned out were two ocean steamers, the "Lion" and "Eagle," for the Spanish government. Mr. Ward retired from the firm in 1841 and Mr. Seymour not long afterward, Mr. Allen being admitted about 1844. Eventually he secured practical control of the enterprise with the financial aid of Brown Brothers, bankers, Mr. Stillman retiring.

In 1855 the concern was chartered as a corporation with $300,000 cash capital, the corporate title, "Novelty Iron Works, of New York," expressing what had from the beginning been its popular designation. Horatio Allen became its president and dominating spirit.

A Great Old-time Engine Shop

It may be of interest to summarize an account of the Novelty Works given about the time of the war, in order to estimate how progress in similar plants has been made between that period and the era of West Allis and East Pittsburg.

Near the entrance gate, with its porter's lodge and offices, was a large crane for handling shafts, cylinders, boilers, vacuum pans and other ponderous pieces of machinery. To the left was the iron foundry, 206x80 feet, with a wing. It contained four cupola furnaces capable of melting at one heat 65 tons of iron, which could be cast into one mold. There was also another furnace. The foundry blast was led through an underground pipe of 5 square feet sectional area. Some of the foundry cranes were as strong as 20 tons load. Here were made the bedplates for the steamship "Atlantic," weighing 37 tons, and for the "Arctic," 60 tons. In the summer of 1854 there was cast the cylinder of the steamer "Metropolis," of the Fall River line, having a diameter of 105 inches and a length of 14 feet, with 12 feet stroke of piston. Twenty-two people sat down to lunch in the cylinder, with room to spare, and a horse and chaise were driven through it.

The smiths' shop was equipped with thirty forges, hammers and some cranes of large capacity, evidently of gib type. In one case a piece of iron weighing 14,366 pounds had been forged and handled. There were also machine and finishing shops, two boiler shops, etc., each with its appropriate machinery.

The whole establishment was divided into twenty departments, each having its foreman, viz.:

Iron founders, brass founders, machinists, boilermakers, carpenters, coppersmiths, blacksmiths, metallic lifeboat builders, instrument makers, hose and belt makers, painters, masons, riggers, laborers, cartmen, watchmen, storekeepers, patternmakers, draftsmen and clerks. All told, an average number of more than 1000 men were employed, and the work turned out amounted to some $1,330,000 a year. At one time over 1500 men were employed and owing to the scarcity of labor Mr. Allen went to Europe to obtain hands. The works occupied nearly two blocks and included two slips sufficient in size for the largest steam vessels. Machinery for many of the old Collins line and Pacific Mail steamships were built there. In addition to marine work the company turned out a varied line of mechanical products, such as stationary engines, pumps, sugar machinery, steam fire engines, and hydraulic presses.

Allen's Engineering Faith and Practice

Horatio Allen was a firm believer in oscillating-cylinder engines as compared with beam engines for sidewheelers. He wrote a pamphlet, 1867, claiming for these superiority in compactness, lightness, simplicity and application of power. An "objective point" (to borrow a term from a certain Mrs. Malaprop of our acquaintance) seems to have resided in the valve mechanism. An experimental valve gear which Mr. Allen applied to the engines of the "Adriatic" caused so much trouble that it had to be taken out. It employed large conical plug valves with a device for lifting them to be turned, so as to prevent their jamming. It would probably be indulging in unwarrantable panegyric to describe Mr. Allen as a great inventor. But he believed in himself and he disbelieved in Sickels, of whom he considered himself a standing rival, and whose cutoff, C. T. Porter says, he would never allow to be applied at the Novelty Iron Works. The same authority tells us, however, that Mr. Allen, in his later years, when judging at the Centennial, united in an award to Sickels with an expression of cordial admiration.

At the time of the war the Novelty works built engines for several vessels of the Federal navy, including the double-turreted monitor "Miantonomah."

From this period dated a long controversy in the navy upon the economy in using steam expansively. Chief B. F. Isherwood, of the Bureau of Steam Engineering, and others, advocated moderate pressures with moderate ratios of expansion, while their opponents, including E. N. Dickerson, advised high pressures and high expansive ratios. The dispute became so animated that a commission was formed under Government auspices to make tests and, if possible, answer the question. These experiments were carried on at the Novelty works, largely under direction of Mr. Allen, who was of the high-expansion party, but who suspended judgment during the trials.

These investigations lasted so many years that the world grew weary of waiting for the results and the Government tired of paying for them. It seems that the points at issue were not all clearly settled and the results did not go to vindicate the extreme claims of either party. The data collected tend to show that with increased pressure the economical point of cutoff shortens, but that with any pressure the most economical degree of expansion is soon reached and further expansion rapidly grows wasteful.

Subsequently Commodore Isherwood and Mr. Dickerson arranged a series of comparative tests of the "Winooski," with Stevens cutoff and double poppet valve, to moderate pressure and cutting off at six-tenths of stroke, against the "Algonquin," with Sickels cutoff and single poppet valves, to [illegible] pressure and cutting off at one-tenth stroke. The "Algonquin" failed.

The Closing Years

Engineering work flourished during the war and the Novelty works were kept very busy. But their profits were not correspondingly large. The cost of labor and materials was constantly advancing, and since the machinery built was of a sort that often required a considerable time to complete, the tendency was for expenses to exceed the estimates underlying contracts. In later years business slackened. Meanwhile the equipment was growing old and the real estate occupied by the plant had become very valuable. All things considered, it seemed wise to wind up the business, and about 1870 this historic establishment passed out of existence.

Mr. Allen survived the works a score of years. His death occurred within a few hours of the close of the ninth decade of the century, at his home near South Orange, N. J.

Horatio Allen made a variety of inventions, from 1841 to 1875, those among them relating to steam cutoffs and valve gears standing out conspicuously. Toward the close of his life he interested himself in methods of teaching astronomy and constructed a number of instruments for the purpose. He was the author of an elementary book on arithmetic.

During his connection with the Novelty works his eminence in his profession was recognized by a number of outside appointments. Thus, he was consulting engineer for the Erie railroad, the Panama railroad and of the Brooklyn bridge. He also served a term as president of the Erie.

Horatio Allen has been marked by his contemporaries both with criticism and with praise. A tendency to dissent from some of his opinions is manifest in the "Engineering Reminiscences" of Charles T. Porter, who, among other depreciating remarks, animadverts upon Mr. Allen's [illegible] as president of a group of judges at the Centennial.

On the other hand he is spoken of with high commendation by his old friend, M. N. Forney, who upon his death published in the Railroad and Engineering Journal, which Mr. Forney was then editing, and afterward in pamphlet form, a biographic[illegible] with some interesting old documents relating to the early locomotive experiments. Mr. Forney describes him as a man of [illegible]

New Turbine Plant for the Atlantic Mills

Plans for a steam turbine power plant of [illegible] kilowatts capacity have been completed by the management of the Atlantic Mills, one of the largest textile concerns in Rhode Island, and a contract was awarded for a [illegible]-kilowatt Westinghouse-Parsons steam turbine to be delivered about April 1, when it is expected the new station will be ready for the installation of the first unit.

On the extensive property of the Atlantic Mills are several reciprocating engines ranging from 500 to 1500 horsepower. These will be superseded by the steam turbines and electric drive will be substituted for belt drive.

To steam engineers the novel feature of the new power house of the Atlantic Mills is in the selection of a turbine of the noncondensing type designed to give maximum economy when operating against a [illegible] back pressure. All of the exhaust steam, amounting to approximately [illegible] pounds per hour, will be utilized in the various manufacturing processes in which live steam now is used, these processes being for the most part in the dyehouse. This use of exhaust steam is not in itself wholly new, but it is unusual to find a dyehouse large enough to require the exhaust from so large a turbine as one of [illegible] kilowatts. The Atlantic Mills dyehouse, it may be added, is one of the largest in the country.

The noncondensing operation of steam units has been restricted very largely to reciprocating engines, and the operation of a turbine noncondensing is considered exceptional. The Atlantic Mills is one of the first to adopt this method, and it is expected that the saving over the present arrangement of using live steam will be [illegible]

One advantage is claimed for the turbine exhaust [illegible] which is necessary in the processes in which the steam comes in contact with textile goods.

The Alinement of New and Realinement of Old Shafting

By James Lomas

While discussing this subject with a friend of exceptional experience, he ventured the astounding remark that it would be impossible to find a line of shafting in any mill or works in approximately true alinement. There is undoubtedly much truth in his statement.

The importance of shafting being correct in its position, that is, level in its bearings and in a perfectly straight line sidewise the whole length, cannot be overestimated. Those persons of experience who have had to deal with the faults and follies of incorrect and badly executed work, know well the extra cost of maintenance requisite to keep a mill or works in constant operation; overtime for the engineer-in-charge; occasional stoppage of the machinery through needless friction in the bearings; wheels, pulleys and couplings loosening daily, and breaking; extra cost of fuel and labor in the fire room; extra wear and tear of the engines, etc. These are only some of the troubles attributable to shafting not being in alinement.

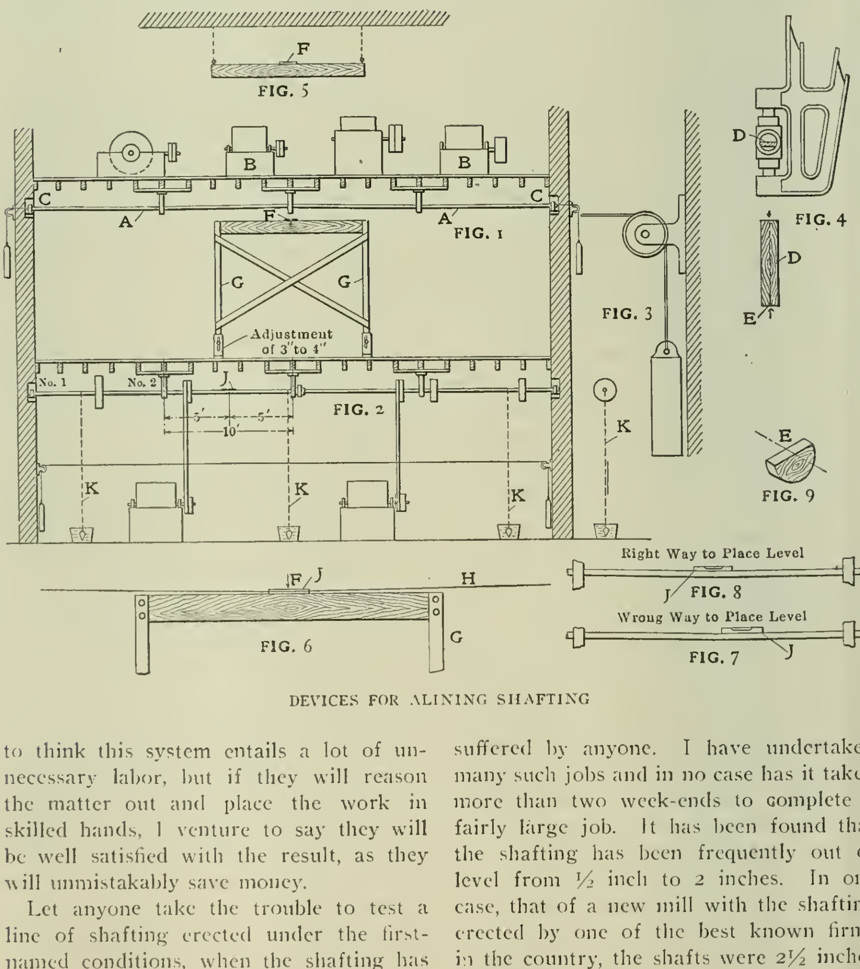
The causes of all these troubles are manifold. On new work the system of erecting generally carried out is unquestionably faulty; and such faults may arise from many sources, such as the settling of the foundations of the building, the warping or twisting of the floors where wood beams have been used, the distortion in structural steel and iron work; and where fireproof floors are constructed either of brick, concrete or similar material and the shafting is erected before the floors are thoroughly set and dry (and this usually takes considerable time), the result of the millwright's labor will be unsatisfactory. As soon as a mill or workshop building is sufficiently advanced in construction to enable the millwright to fix the hangers or brackets he is generally told to do so. Often this occurs before the windows are in their places. The reason for doing this is because there is much to be saved in cost of erection. The room is clear of obstructions and this simplifies the work very much; scaffolding is often at hand and there are many other conveniences which help the work forward. This method, of course, suits the workman, the contractor and the owner, and on first sight appears strictly economical, as it gives a quickly executed and cheap job. But after giving the matter fair consideration it will readily be found to be false economy and an increasing extra expenditure will be requisite until the work is remedied. To illustrate this refer to Fig. 1, where *A A* shows a line of shafting attached underneath a floor, above which a quantity of heavy machinery is being installed. The weight of the machinery has distorted the floor; the shafting, of course, is out of alinement, no matter how carefully the work was done before the heavy machinery was placed in position.

The same thing occurs if a line of shafting is carried on a ground floor through floor stands or pillow blocks, as the floor or foundation is almost sure to settle. Luckily, the remedy is simple if those who are responsible can be led to see it. The logical system to adopt is to allow the mill to be finished and the shafting erected before the machinery is fixed. Then a short time before the machinery is put in operation realine the shafting and make all the bolts, etc., secure; the shafting is much more likely to run under better conditions and for a longer period without attention except the usual oiling and cleaning, etc.

Of course, many people will be tempted to think this system entails a lot of unnecessary labor, but if they will reason the matter out and place the work in skilled hands, I venture to say they will be well satisfied with the result, as they will unmistakably save money.

Let anyone take the trouble to test a line of shafting erected under the first-named conditions, when the shafting has been at work three months, and he will require no further confirmation that the system is entirely wrong. However, under any circumstances it is necessary to have a second alinement to obtain the best results, and if strict economy is to be considered a periodical alinement should be made, say, every twelve months. Of course, the bearings should be under constant examination.

If the reader will study the method of the realinement of old shafting shown in Fig. 2-*J* its simplicity will be apparent, and the cost of putting mill shafting in order will be a mere fraction compared to the advantage gained. Let mill owners think for one moment of the continual loss occurring through the defective condition of their mill shafting, that has probably been working for years without any attention further than the usual oiling. As long as the motive power is sufficient to move the shafting around it is not considered necessary to do anything more until suddenly there is a smash and everything is stopped, sometimes for days. Yet to remedy all this is such an extremely simple matter to the practical man, as will be seen by again referring to Fig. 2-*J*, and the benefits to be derived therefrom need not be further commented on. The work of realining may be done when the mill is stopped for a holiday or at a week-end, and little or no inconvenience need be suffered by anyone. I have undertaken many such jobs and in no case has it taken more than two week-ends to complete a fairly large job. It has been found that the shafting has been frequently out of level from ½ inch to 2 inches. In one case, that of a new mill with the shafting erected by one of the best known firms in the country, the shafts were 2½ inches diameter and the distortion was owing to the steel beams that the hangers were attached to and which were imbedded in a fireproof ceiling; the floor above was covered with heavy machinery. The irregular torsional strain on the shafting was the cause of about a dozen ends of shafts twisting off and the split muff couplings were constantly coming loose. This went on until the whole of the shafting had been realined, although the mill had not been at work more than twelve months.



DEVICES FOR ALINING SHAFTING

Where the shafting is carried in adjustable bearings the leveling is a simple matter, but where nonadjustable fittings are in use the work is much more difficult, still not so much so but that intelligent workmen can deal with it. The best line to use for the purpose is piano wire which, when used as shown in Fig. 3, gives very little deflection or sag. The next best is the strongest line procurable, but fairly fine.

How to Erect and Aline Shafting

Having determined the position and type of hanger, wall bracket, pillar bracket or pillow block to be used, fit the two end bearings in position. Next secure the line as short a distance as possible beyond the end of each bearing. The usual method of so doing is by driving a spike into the wall or other convenient place. The line is carried through the end bearings, pulled taut and made secure. This method is very unsatisfactory, inasmuch as from various reasons considerable deflection or sag occurs; consequently, the line requires to be repeatedly tightened. A much better method is shown in Fig. 3, a bracket with pulley is fixed at each end of the shaft line and the line placed through the end bearings. A weight is fastened to each end of the line (see Figs. 1 and 2). Thus the line is kept taut without further trouble.

At this stage it will be necessary to get the line level from end to end, having placed in each end bearing a strip or float, made as per Fig. 4, and secured the bearings so as to hold the strip firm with the central line marked H on the strip parallel to the line (cord or wire) that the rest of the bearings are to be lined by. Then proceed to fix the straight-edge, the center of which must be exactly at half distance between the end bearings. This point is very important, for if placed at an unequal distance between the end bearings, the deflection of the cord will mislead the erector. The straight-edge may be carried by a cord attached to each end and hung from the ceiling, see Fig. 5-F or a temporary frame made as per Fig. 6-F, whichever is the most convenient under the circumstances. Having carefully leveled the straight-edge, adjust the two fixed hangers so that the cord will be parallel to the straight-edge. Then, having made that secure, notice the deflection in the cord H, Fig. 6, and a simple calculation will show the relative position of the central hanger.

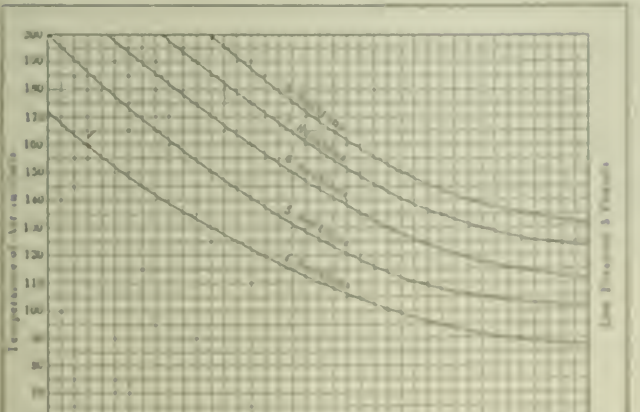
Next, fix the central hanger, making allowance for the deflection of the cord line; having made this secure, place a wood center as per Fig. 9-E in the middle of this center bearing to support the cord line. There will then be very little deflection on the cord line in the intermediate distance between the central and end hangers. The rest of the hangers may then be fixed in position and made secure. Having fixed such hangers in position the shafting may then be placed in the bearings, the couplings fixed in their position and made good, having made everything all right by fixing the caps on the bearings, etc. The shaft may be revolved to insure it being properly placed in the bearings before the leveling is done. The spirit level I should be a reliable make, 18 inches to 2 feet long, and adjustable. When using it on the shaft it should be exactly central between the bearings, as there will be some deflection in the shaft, and if tested on one side of the center between the bearings, the center will be misled. See Figs. 7 and 8.

If the work has been carefully carried out up to this stage, it will be found that very little adjustment will be necessary. The next thing to do is to take a wooden rod having marked on it the plumb line on the shaft level, take it at a convenient distance from the floor, say 3 or 4 feet. On each, drop a cord line from each end of the shaft with a heavy plumb bob or weight attached and let the latter rest in a pail of water. See Fig. 4-E. This insures steadiness of the plumb line. Then carry the strait line, Fig. 3, the whole length of the shaft and adjust it so as to be about 1/32 inch clear of the dropped line at each end. Then by dropping a plumb line from each bearing as shown in Fig. 2-E, begin at No. 1 and lay out all a line with the same plumb line until the whole have been erected.

In practice it is found where the space is filled with machinery it is necessary only to carry out the aforementioned instructions, excepting that a scaffold or other contrivance may be required above the machinery. In erecting nonadjustable hangers on brackets, the adjustment is obtained by using wood or other packing pieces between the faces of the bracket and the beam, making the work much more difficult. Yet the instructions given herewith generally are applicable, except that each bracket or hanger should be leveled by resting the straight-edge on its underside and spanning the next, beginning at No. 1 and proceeding to the end. The straight-edge should not be less than 10 feet long, 10 to 12 inches wide and 1½ or 1¾ inches thick and the two edges will be exactly parallel.

Heating Power of Steam Coils

The amount of heat transmitted per square foot of heating surface from steam coils naturally depends upon the difference in temperature between the steam on the inside and the air upon the outside. But the air temperature close to the pipes is largely influenced by the rate of flow across the surface. When the air remains practically stagnant the condensation will be but a fraction of a pound per hour per square foot, but as the velocity increases so also does the condensation, which is a direct measure of the heat which is transmitted, until the condensation will rise to two pounds per hour for the same surface.



CURVES SHOWING EFFECT OF STEAM COILS IN HEATING AIR area. Manifestly the higher the velocity the more rapid will be the rate of transmission; hence the primary advantage of the blower system of heating under which the air is compelled to pass rapidly across the surface of exposed steam pipes.

The ultimate temperature given to the air passing across a stack of steam coils must depend not only on the steam pressure, but on the initial temperature of the air and above all on the arrangement of the pipes. The less the depth of the heater or the distance across which the air passes the greater will be the condensation per unit of surface, but the less will the temperature of the air be increased. Intensity of temperature with a given steam pressure can only be obtained by depth of heater.

These relations are not generally known with exactness except by those directly interested in the manufacture and installation of such apparatus. Special interest, therefore, attaches to the accompanying curves from the catalog of the Massachusetts Fan Company, Watertown, Mass. Without going into details of construction or conditions these suffice to show that minimum velocity and maximum depth of heater are essential to intensity of temperature. Between these extremes lies average practice with heater depths ranging from four to six sections (16 to 24 pipes) and velocity from 1200 to 1800 feet per minute.

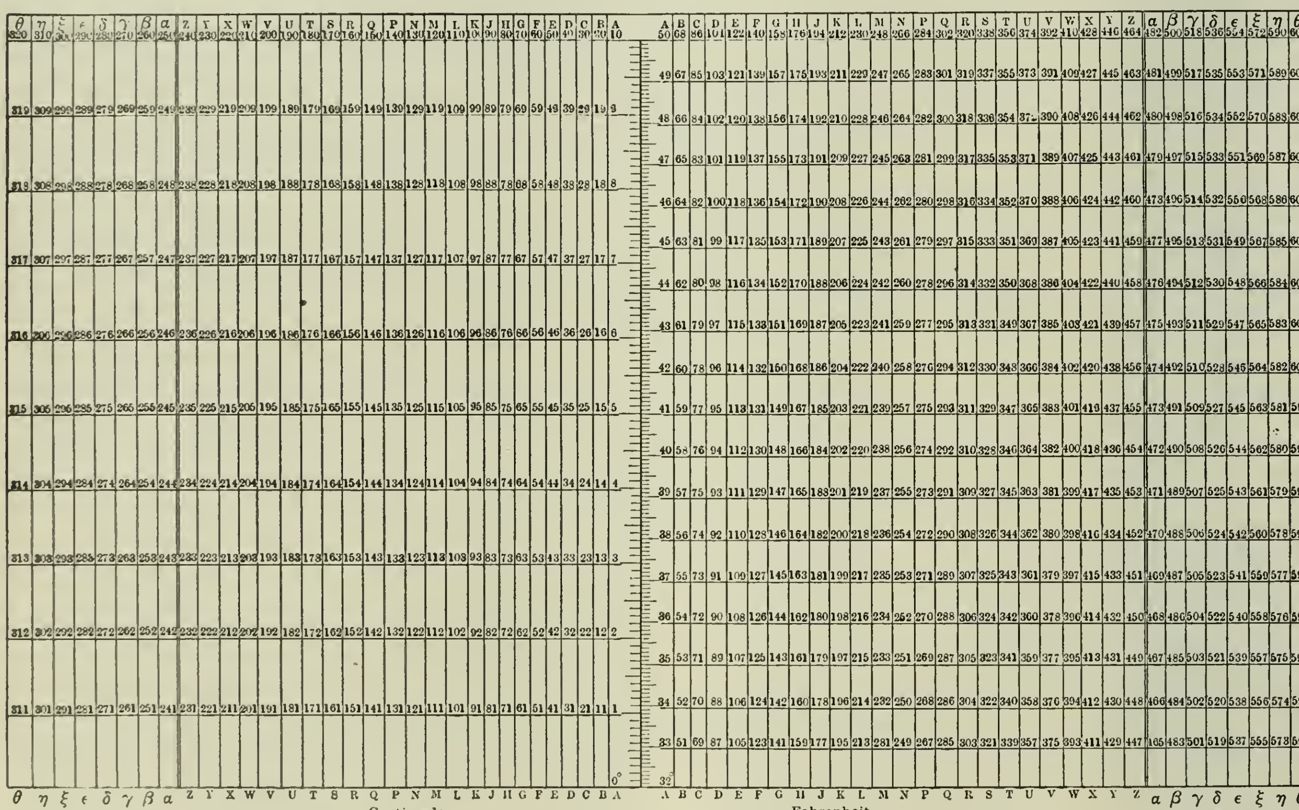
Scale and Table, Giving Epuivalent Graduations of the Fahrenheit and Centigrade Thermometers*

By M. T. Hand

The accompanying scales and chart are intended to give at a glance, without any calculation, the equivalents between any degree or tenths of a degree of the Centigrade and Fahrenheit thermometers. In the center of the chart is shown a double scale divided into degrees and tenths of a degree. The scale on the right is the Fahrenheit thermometer scale and that on the left is the Centigrade thermometer scale. It will be noted that from the graduations of the Fahrenheit and Centigrade scales each portion of the Fahrenheit scale, advancing by 9 degrees from the freezing point, has a coincident portion of the Centigrade scale advancing by 5 degrees. The chart is based on this duplication of scale. It is necessary, therefore, only to lay out to any scale nine equal divisions, subdivided into tenths if desired, using this as the Fahrenheit scale, and then dividing the space on the other side of the vertical into five equal divisions, subdivided into tenths, to have the corresponding equivalents of the Centigrade scale.

In order to make the chart symmetrical and easy to read a scale of 4½ inches for 9 degrees Fahrenheit was used and then doubled. The reproduction is on a reduced scale, of course. Instead of extending this scale in a vertical line, the recurring points on each scale have been placed on a horizontal line, i.e., the point showing 9 degrees above freezing on the Fahrenheit scale or 41 degrees Fahrenheit actual reading, has on the scale as laid out the same relative position as 59 degrees Fahrenheit, 77 degrees Fahrenheit, 95 degrees Fahrenheit, etc. Also 5 degrees Centigrade has the same relative position as 15 degrees Centigrade, 25 degrees Centigrade, 35 degrees Centigrade.

To use this chart the whole degrees of either the Fahrenheit or Centigrade thermometers are found opposite each other in corresponding columns on either side of the scales. For example, 185 degrees Fahrenheit, which is found in column *J* of the right-hand side, has its equivalent in column *J* of the left-hand side directly opposite, namely, 85 degrees Centigrade. For tenths of a degree of either thermometer the corresponding tenths of the other thermometer are read directly from the scale, i.e., if the example had been to find the Centigrade equivalent to 185.5 degrees Fahrenheit, the whole degrees would have been read as stated from the chart,



SCALE AND TABLE GIVING EQUIVALENT GRADUATIONS OF THE FAHRENHEIT AND CENTIGRADE THERMOMETERS

*Copyright, 1908, by M. T. Hand.

while the graduation of the right or Fahrenheit side of the scale, five divisions above the horizontal line marked 185 degrees Fahrenheit, is at once seen to be opposite the graduation equivalent to 0.28 degree on the Centigrade scale. Therefore, 185.5 degrees Fahrenheit equals 85.28 degrees Centigrade. To familiarize the reader with this process several examples and answers are given below.

Examples

Change 296.8 degrees Fahrenheit to Centigrade: 296 degrees Fahrenheit is found in the right-hand chart column *Q*. In the left-hand chart column *Q*, and nearest the horizontal line opposite, is found 147 degrees Centigrade, while on the scale on the left-hand side and across from the graduation corresponding to 0.8 degree Fahrenheit above the horizontal line marked 296 degrees Fahrenheit is found the graduation to give 0.11 degree Centigrade. The total result is, therefore, 296.8 degrees Fahrenheit equals 147.11 degrees Centigrade.

Change 200.3 degrees Centigrade to its equivalent Fahrenheit reading: 200 degrees Centigrade is found in the left hand chart column *V*. In the right-hand chart column *V*, on the horizontal line opposite, is found 392 degrees Fahrenheit. As the top of the scale has been reached, return to the bottom for the fraction of a degree above 200 degrees Centigrade, and accordingly across from the graduation corresponding to 0.3 degree Centigrade at the extreme bottom of the scale is found the Fahrenheit scale graduation 0.54 degree Fahrenheit. Therefore, 200.3 degrees Centigrade is equal to 392.54 degrees Fahrenheit.**

Change 411.5 degrees Fahrenheit to Centigrade: 411 degrees Fahrenheit is found in column *X* on the right-hand chart. In the left-hand chart column *X* is found 211 degrees Centigrade on the horizontal line nearest opposite the horizontal line indicating 411 degrees Fahrenheit, but this line is above the Fahrenheit reading it is desired to transpose. It is, therefore, evident that the whole degree Centigrade corresponding to 411 degrees Fahrenheit is not 211 degrees Centigrade, but 210 degrees Centigrade. Then read the fractional part of the Fahrenheit temperature directly across from the 0.5 degree Fahrenheit scale as 0.81 degree Centigrade. Therefore, 411.5 degrees Fahrenheit is equal to 210.81 degrees Centigrade.†

A little practice will enable one to immediately make these transpositions from one thermometer reading to the other.

A "Valveless" Engine

By W. H. Booth

A novelty in engine work appeared at the Olympia exhibition of motor cars in London recently. It was described as a valveless engine and was of French origin. Actually, however, it was not a valveless engine, but was a curious adaptation of the slide valve with movable seat, of which one may read in Rankine. This particular adaptation is only rendered practicable by reason of the petrol engine being single-acting with an open-ended cylinder. Conceive of a cylinder with a bore about ½ inch larger than the piston, leaving an annular space between the cylinder and piston of ¼ or 5/16 of an inch. Into the closed end of the cylinder projects the cover, the projecting boss being of the same diameter as the piston, so that there is a deep annular space around the projecting boss.

In the cylinder, fitting closely one inside the other an easy working fit, are a pair of ground cylindrical shells longer than the cylinder and of such a thickness that while the smaller one fits nicely within the larger, the former acts as the cylinder for the piston and the larger one slides nicely inside the actual cylinder. The smaller shell projects farthest outside the open end of the cylinder and has upon it a pin attachment for a pivoted valve rod. The larger shell is a little short and has a similar attachment. The two are caused to work up and down by eccentrics on a shaft driven from the crank shaft of a 1:2 chain gear, so as to suit the Otto cycle of a petrol engine. Both shells project into the space about the cover projection.

The cylinder has an inlet port nearly halfway around it, a little below the cover projection, and an exhaust port at the same level nearly half around the opposite side of the cylinder. The inner shell has similar ports, also at the same level, and the outer shell has similar ports, but the exhaust port is larger than the inlet port. Both shells project up into the cover annular space, and the combination forms an annular slide valve with movable seat, thus securing with a short travel the operations of fuel inlet, compression, explosion and expulsion in the four-stroke cycle. Great saving is made over the ordinary [illegible] of valves.

To the ordinary motor car man [illegible] a mechanical [illegible] and that he [illegible] is a bad thing. It is curious that this should be so, for the gas engine was always held to have taken a new lease of life when the valves became [illegible] and the old slide valve dropped out. And the steam engine for highly superheated steam is not considered to be of any use unless it is fitted with valves of the [illegible] order. And here is the last word in petrol engines with two shells and the long rubbing surfaces and it is [illegible] because it is to cut out the [illegible].

So far [illegible] are saying everywhere that practically there were but two innovations in all that great space, since last year. One was that shell valve system and the other was [illegible] the adaptation of the Joy valve motion to the steam engine of the White steam car. The engine, which is compound, has the cylinders brought very close together so that there is a stiff, short crank shaft by reason of the [illegible] of the [illegible], rendered possible by the Joy gear. There was one other steam car in that big show besides the White (American) and the Turner (English) steam cars. This is the Rutherford. It does not seem a great number as a start for the eventual supremacy of the steam car which some, not without good reason, believe will occur. But it will need to move quickly, for motoring is not, I believe, so firmly established in certain directions as some people think. It is largely a flashy business, the sport of the wealthy, and very little more progress in the direction of the art of flying, as shown possible by the Wright brothers, may turn the craze for the last new thing in the direction of flying. Flying is an accomplished fact, and nothing is likely to prevent a very considerable advance during the next two years. Flying machines will become safer and anyone with room to house one and money to work it will be able to fly, with probably but little more risk, if so much, as when riding in a high speed motor car.

In certain quarters the flying machine is regarded as all important for war purposes. It may be of some service—I would prefer the word observation—in such a connection, but it will not be much good as a serious weight carrier and the day has gone by when a quick passenger would be valuable, for there is too much [illegible] about for that. Flying will be the hobby of the rich, and people who live by the roadside will welcome the change. There will be accidents at first, but chiefly to the riders themselves. But we are sorry to see so able a [illegible] and engineer as one of the Wrights coming to harm, for their achievement is very great. Not only have they solved the flying problem, they have shown that the machines can come to earth gently. This has [illegible] the doubts of many who, while believing flight to be possible, had fears that the alighting problem was not [illegible].

[illegible], the cylinder head of one of the engines in the [illegible] building, Boston, Mass., blew out and the flying pieces struck the other engine and "[illegible] it out of commission."

**Use especial care in reading from the bottom of the chart to add the total number of tenths corresponding to the Centigrade graduation, i.e., 0.9 degree Centigrade is equivalent to 16 tenths plus on the Fahrenheit thermometer scale, so that 200.9 degrees Centigrade is equivalent to 392 degrees Fahrenheit plus 1.62 degrees Fahrenheit or 393.62 degrees Fahrenheit.

††Use care when reading from the bottom of the Centigrade chart not to read 1 degree too high. The degree readings corresponding to the horizontal line at the extreme bottom of the chart have been omitted to avoid confusion by finding the same reading in two different columns.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 we printed and circulated 1,836,000 copies of POWER.

Our circulation for January, 1909, was (weekly and monthly) 160,000.

February 2........... 40,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

More Frequent Internal Inspection

Because a steam boiler is covered by an insurance policy is no ground to believe that it is safe to operate for twelve months without an internal inspection. Nevertheless, this is a view held by some engineers and more steam-plant owners.

An insurance policy covering a boiler risk is a mighty good document for two reasons: it demands the payment of damage losses, and practically insures a safely operated boiler because of the inspection feature which accompanies it.

There is no need of going into the question as to what the inspection of boilers amounts to; it is already known. However, the importance of frequent inspection is, in most cases, greatly underrated, not only by the engineer, but also by the insurance companies, although one company at least is sitting up and taking notice of its desirability. The practice has been to make three inspections each year, two external and one internal. While the external inspections are efficient as far as they go, they do not reach the vital parts of the boiler.

There are hundreds of engineers who never know whether the safety valve and the steam gage operate together until the inspector makes his quarterly visit. This is because the engineer has no means of checking up his steam gage for accuracy. The fact that the lever of a ball-and-lever safety valve is marked 100 at a certain point is no assurance that the valve will blow off at 100 pounds gage pressure. The external inspection takes in these matters and is, therefore, of value, especially in the smaller plants; but the internal inspection is the kind that counts most for safety and economy.

One inspection company which formerly made a practice of making two external and one internal inspections yearly, now not only makes the same number of external inspections, but has adopted semi-yearly internal inspection instead of annual. Surprising as it may seem, the cost of repairing defective boilers under the old method of inspection exceeded the losses due to violent explosion, and these losses are confined to ruptures and not mere bagging which results from scale, oil, etc. The twice-a-year internal inspection has so reduced these lesser losses that the company has found that although it costs more to operate the inspection department, due to the increased duties of the inspectors, the saving made in avoiding expensive repairs amply compensates for the extra work and expense involved. The insurance company is not the only party benefited, as the steam-plant owner is, under this new system, doubly sure that his boilers are kept in good condition, regardless of the qualifications of his engineer.

What is sauce for the goose is sauce for the gander. If the making of two internal inspections is a paying proposition to the insurance company it is a good thing for the engineer. True, most engineers do not yearn for the task of inspecting boilers, but it is a duty that must be performed, and if properly carried out is a remunerative investment, not only in dollars and cents but in ease of mind.

A perusal of the reports of boiler-insurance companies for a year will present a startling array of facts, and the most significant of all is the faulty condition of boilers, due to scale, etc., which good management and frequent inspections would have prevented.

There will doubtless be some opposition on the part of the steam-plant owner against the so-called hardship of cutting out a boiler twice a year for internal inspection and while, to some, it may be time and money ill spent, to the great majority it means the saving of time and money spent in repairs, when of a nature not covered by the risk.

In the steam plant not covered by an insurance policy, nor under the jurisdiction of a State inspector, it is the duty of the engineer-in-charge to keep his boiler in a safe condition. He has to say whether the boiler shall be internally inspected twice a year or not. The responsibility is his.

Turbine Condensers

We present in this number, among our leading articles, an abstract of a paper on "Surface Condensation for Steam Turbines," by Professor Josse, director of the engineering department at the Technical High School at Charlottenburg. This paper has already been commented on in our correspondence columns and has excited considerable interest. The curve sheets and table have been converted into English measures and are of more than passing interest.

To manufacturers and users of condensers this paper is of especial value, giving as it does additional data regarding the transfer of heat through tubes from steam to water, supplementing the excellent work of Weighton, Stanton and Morison in England, Ser and Joule in France and Hepburn in America.

The investigation of the heat transference between air and water is put out in excellent shape for use, as is also the problem of taking care of the air leakage into the condenser. The details of the wet-vacuum pump, as illustrated, show a development of the suction-valveless air pump somewhat different from similar pumps in the United States, and the manner of introducing the noncondensable vapors to the barrel of the pump is new. The piston speed of this pump, 260 feet per minute, would be considered quite too high for good results in this country, necessitating very light valves and valve springs.

Professor Josse's condensers are small

compared with surface condensers for turbine work as we know them, and Weighton's experimental condensers were even smaller. It is unfortunate that none of the larger condensers, say from 5000 to 10,000, or even 15,000 square feet of surface, has been tested to the point where the vacuum fell off from lack of ability to condense the steam, as otherwise an opinion might be formed as to the value of the coefficient of heat transference U under the condition obtaining in surface condensers of commercial size for turbine work.

Professor Josse's statement that the surface-condenser outfit for turbine work may cost thirty to sixty per cent. of the cost of the whole turbine plant, which presumably applies to marine work in Germany, is more than surprising.

Loss in Alternating Current Wires

When electric current passes "through" a wire the passage involves two losses, one of pressure or voltage and the other of energy, the latter being the consequence of the former. If the current is of the "direct" class and reasonably steady in value, the proportion of the applied pressure used up in forcing the current through is exactly the same as the proportion of the applied energy wasted by the resistance of the wire. That is to say, if the "drop" in the circuit is ten per cent. of the applied voltage, ten per cent. of the applied energy will be lost in forcing the remaining ninety per cent. through the circuit; if the "drop" is two per cent., then two per cent. of the applied energy will be used up in overcoming the resistance of the circuit, and so on.

When the current is either an alternating or a rapidly pulsating direct current such as some of the early arc-lighting dynamos yielded, the percentage of energy loss rarely equals the percentage of pressure "drop" in the circuit. The lower the power factor of the complete circuit and load, the greater will be the difference between the percentage of energy loss and that of pressure "drop," because a low power factor is due to a counter-electromotive force generated in the windings of the load apparatus and self-induced by the current in the circuit wires. The farther apart are the wires of a circuit, the greater will be its self-induction and the lower its power factor.

The practical moral of the foregoing explanation is that alternating-current circuit wires should be located as close together as the pressure and insulation will permit, and that the percentage of energy loss in a motor circuit, which is easily figured, is no criterion of the voltage drop, which is not easily figured and has an important influence on the torque of an induction motor. The motor torque varies as the square of the voltage at the terminals of the machine; consequently, an excessive drop in voltage in the circuit wires may reduce the torque of a motor seriously.

Natural Resources

On Friday, January 22, the Government closed the presentation of its case against the anthracite railroads. The hearing will be resumed on February 16, in New York, when the defendants will open their side of the case.

The Government has offered in evidence a table of statistics showing that of the 70,000,000 tons of coal produced, only about twenty-one per cent. was produced by independent operators, and about two-thirds of this is in the hands of the railroads by contract.

Have we learned the lesson of the coal fields?

Who could have foreseen, when Col. George Shoemaker brought a load of the black-rock fuel into Philadelphia and nearly got into jail for trying to sell it, that in about one hundred years the transportation and industries of the country and the comfort and well-being of the people would come to depend upon it more than upon any other one factor? Who could have foreseen the enormous possibilities of a perpetual corner in anthracite coal, and with what derision would a forecast of the present situation and an appeal to forestall it have been met.

And yet we are passing through another period of absorption of public resources by private interests. The possibility of electrical transmission has endowed water powers hitherto of little or no value with great earning capacities. While there might have been some difficulty in establishing a governmental or communal ownership of the coal fields, the constitutions of most of the States and of the United States itself establish the right of the people to the use of natural streams. The people should be very guarded in surrendering that right, and we notice with pleasure that the President has vetoed several bills transferring the public holdings in such properties to private interests. This policy should not be continued to a point which will discourage needed development, but such grants when made should be so guarded and restricted as to secure the immediate development of the site as opposed to speculative holding, and the supply of power therefrom to the public at prices which will pay a fair profit upon the actual investment.

A few years will see a large proportion of the industrial power of this country generated by falling water. [illegible] per cent. [illegible] Without such measures and restrictions the country [illegible]

[illegible] as it is now in [illegible]

Power from Niagara Limited

Although the ordinary discharge of the Niagara river is about 222,000 cubic feet per second, and it is commonly held that by utilizing the total fall between the lakes 7,400,000 horsepower are available, or 4,000,000 at the falls, it has recently been decided by this country and Canada to limit the total amount of water used for power purposes. A treaty has been drafted to this effect and doubtless will soon be ratified. Agitation on this subject has been rife for some time and arguments for the side of the power companies, appeals from the lovers of natural splendor, views of the hotel men and transportation companies and, finally, the economic aspect of the navigation on Lake Erie, have all been given due consideration and the result has been to limit the total amount of water used by the power companies in Canada to 36,000 cubic feet per second and those on the American side to 20,000 cubic feet, it being the opinion of the engineers of the International Waterways Commission that this amount would not be detrimental to the scenic effect.

In the foregoing perhaps the navigation should have been given first place, for it is reported that every 10,000 cubic feet per second of water [illegible] by the power companies lowers the level of Lake Erie by one inch. With large amounts engaged in the carrying trade [illegible] of draft represent a [illegible] of tons in freight capacity, and for this reason probably more than any other the amount of water for power purposes was restricted to [illegible] cubic feet per second. The treaty expressly provides that the level of Lake Erie shall be maintained, allowing, of course, for the natural fluctuations of the level.

During 1907 the mean discharge was [illegible] cubic feet per second, where the average for fifteen years previous to January, 1903, and to April 30, 1908, the discharge was [illegible] cubic feet per second.

From the scenic side of the question it would seem a hardship to limit the available supply of water to so small a percentage of the total, and at first sight it would appear to be sentimental extravagance on the part of Government [illegible] [illegible]

Receiver Pressure Regulation for Compound Engines

In plants where low-pressure steam is used for heating or industrial purposes and where the amount of steam so used is less than the exhaust from the engines, it is often economy to use a compound engine, taking the low-pressure steam from the receiver. In such cases it is difficult by hand regulation of cutoff in the low-pressure cylinder to hold the receiver pressure constant, as the demand for steam or the load on the engine varies.

To secure this result, Charles T. Main, engineer, of 45 Milk street, Boston, Mass., has devised two forms of pressure regulator which have been installed in many plants on cross- and tandem-compound engines. The two types are used as best meets conditions. The advantages claimed to be secured are more uniform pressure in the receiver than is possible by any other means, thus giving a uniform steam supply, and saving of fuel by avoiding the blowing off of steam through relief valves or the supply of high-pressure steam to the receiver through reducing valves.

In Type A regulator, Fig. 1, there is a small cylinder *C* in which is a piston *P*, with the receiver pressure admitted to the cylinder below the piston. Above the piston the cylinder is open to the atmosphere. The piston rods *R* and *R'* connect with the arm *A*, and through this move the trip rods of the valve gear *T* and *T'*. To the rod *R* is connected the arm *B* and on this arm are hung two weights *W* and *W'*.

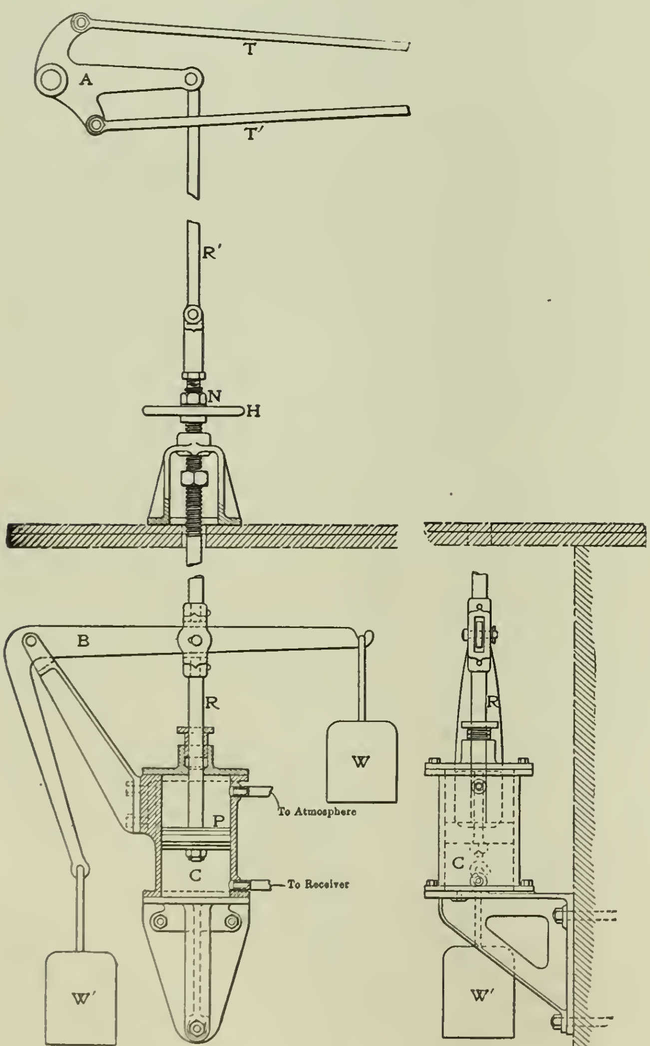

FIG. 1. TYPE "A" RECEIVER PRESSURE REGULATOR

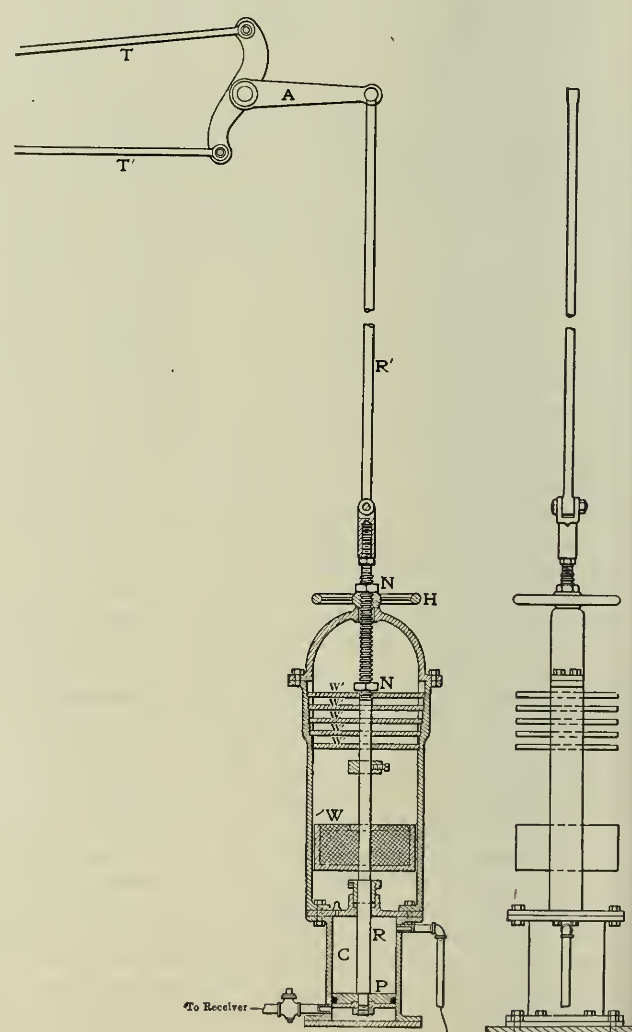

FIG. 2. TYPE "B" RECEIVER PRESSURE REGULATOR

When the pressure in the receiver increases, it raises the piston and increases the cutoff in the low-pressure cylinder; when the pressure falls, the weights bring down the piston, thus decreasing the cutoff in the low-pressure cylinder.

The weight *W* determines the lowest pressure to be carried in the receiver and the weight W'', as it swings from the vertical under pivot, balances the variable pressure from the shortest possible cut-off to full stroke on the low-pressure cylinder.

The hand-wheel H is used to get a long cutoff when starting up the engine, also to fix the minimum cutoff, or if desired to run with fixed cutoff. The nuts N and N' can be set to limit the range of cutoff.

Type B regulator works on the same principle, but has a series of weights W'', which are lifted in turn as the rod R rises. The weight W' determines the lowest receiver pressure and weights W'' balance the variable pressure through the extreme range of cutoff.

A Novel Design of Indicator

We illustrate herewith a novel design of steam-engine indicator, the joint invention of George A. Mower, of 147 Queen Victoria street, London, and James F. Gill. In this device perforated diagrams are obtained, the perforations being produced by the passage through the paper of an electrical current.

The apparatus comprises a cylinder A, piston B and calibrated springs C, as in the ordinary type, but as it is only necessary that the piston shall move to a very small extent, the cylinder A is made correspondingly short. Fixed rigidly to the piston B is a light metallic rod or

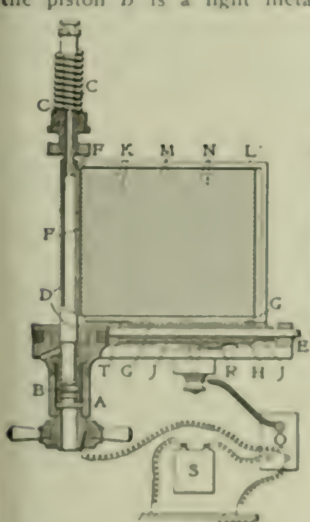

FIG. 1

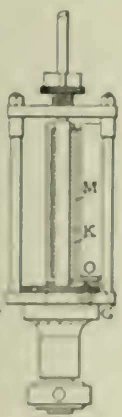

FIG. 2

FIG. 3

tube D with a series of short teeth F forming electrical contact points at equal intervals along its length. The teeth F are formed integrally with the piston rod D.

The laminated plate K is mounted on the frame of the indicator in an electrically insulated case L and is composed of a series of alternate strips of metal foil M and insulating material N. This laminated plate K is so disposed that the contact points F on the piston rod D just barely touch the edge of the laminated plate K. The series of metal-foil strips M is approximately the same in number as the contact points F on the piston rod D, but they are slightly differently pitched so that (as in a vernier scale) a limited movement of the piston will cause the

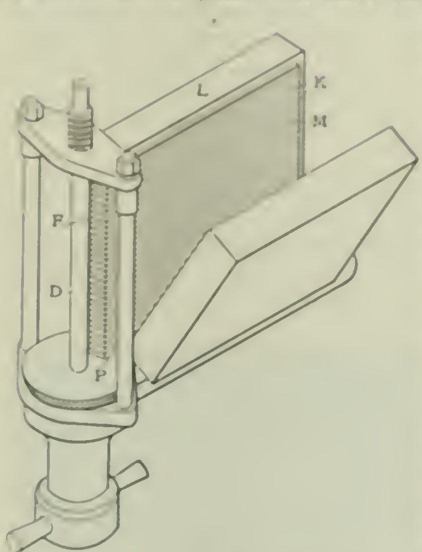

FIG. 4

metal strips M to be electrified in succession, one of the series of contact points F making electrical contact with one of the series of metal-foil strips M; thus as the piston moves up through its limited amount of travel the point of electrical contact will move through a large range on the plate K.

A similar laminated plate O of approximately the same size as the plate K is secured thereto by means of a hinge P and spring, so that it lies on the plate K with its conductors all at right angles to those on the plate K. A second metallic rod E arranged at right angles to, and with contact points G similar to those on the piston rod D, but insulated from the frame T of the apparatus, is arranged to move through a limited distance and to make electrical contact with the metal-foil strips on the second plate. The contact points G are on a tube H insulated from the rod E by the ebonite or other nonconducting sleeve J. This second rod E is connected through suitable reducing gear to the piston of the engine to be indicated. An electric-sparking coil Q with a safety spark gap is connected so that the current therefrom passes through the spring R [illegible] to the tube H and contact points G on the second rod E, thence to one of the metal-foil strips in the second laminated plate O, according to the position of the engine piston, thence to a metal-foil strip M in the first laminated plate K and out through the contact F on the piston rod D and casing of the indicator, thence to earth and back to the coil through the battery S.

To take a diagram: Open the apparatus as shown in Fig. 4, place a flat piece of any suitable paper between the two laminated plates K and O, secure them by the spring clip, attach the reducing gear to the piston of the engine and turn on the indicator cock, switch on the electricity and the current will flow, and its disruptive sparking action will pierce holes in the paper which is the only impediment in the path of the current. The position of these small holes will correspond to the intersection of the two conductors at right angles which are electrified at the same instant, thus producing a diagram from which may be obtained a true record of the variations of pressure in the engine cylinder. If this perforated diagram is placed on a page of a book and an inked roller passed over it, the diagram will appear, its boundaries being defined by small dots.—*Mechanical Engineer.*

Wagner Induction Motor Starter

The accompanying engraving illustrates the type of starting apparatus built by the Wagner Electric Manufacturing Company, St. Louis, Mo., for use with squirrel-cage polyphase induction motors of more than 5 horsepower. The starter is of the autotransformer class, with the transformer inclosed in one iron case and the switch inclosed in another which is oil-filled. The transformer is provided with a number of sub-voltage taps giving different percentages of full voltage, and from which any desired tap may be se-

[illegible]

lected, the permanent wiring to the switch after one or two trials under actual running conditions.

The switch, as will be noted from an inspection of the illustration, is of the drum type, [illegible] mechanism is equipped with a quick-action make-and-break [illegible] to the minimum the possibility of arcing between the [illegible] starting the motor the handle is moved always in the one direction. It may be turned back to the "off" position only from the first starting position; after once passing the first starting position it cannot be carried to the "off" position except by moving it through all of the succeeding positions.

In the "off" position the transformer and motor are both dead. Upon turning the operating handle into the first starting position the motor is connected to the sub-voltage tap of the transformer, with the fuses short-circuited; the connections thus established cause the compensator to deliver sufficient pressure to start the motor with minimum line disturbance. Turning the handle to the second position connects the motor to the full voltage and disconnects the autotransformer, the fuses being still short-circuited. Finally, in the third or full running position the fuses are cut into the circuit. This starter may be used in connection with any standard make of squirrel-cage motor. It is built for two- and three-phase work at any of the standard voltages.

Dinner to N. A. S. E. Officers

Friday evening, January 22, the Chicago Association of the N. A. S. E. gave a dinner to the officers of the national body at the Boston oyster house. The dinner was entirely informal, as it was arranged simply because of the officers' presence in Chicago on business connected with the association.

John F. McGrath, of No. 28, was master of ceremonies, and all the distinguished visitors were asked to say a few words to the assembled members and friends. The speakers were introduced in the following order: Fred J. Fisher, of Los Angeles, Cal., national president; Joseph F. Carney, of New York, past national president; William J. Reynolds, of Hoboken, N. J., national vice-president; Royal D. Tomlinson, of Milwaukee, past national president; John W. Lane, of Chicago, editor of *National Engineer*; John A. Kerby of Cincinnati, E. J. Lee of Albany, N. Y., J. H. Van Arsdale of St. Louis, W. W. McLane of Boston and Alfred Johnson of Chicago, trustees; F. W. Raven, of Chicago, national secretary. Nearly two hundred members participated in the enjoyment.

Hoboken Association No. 5, National Association of Stationary Engineers, will hold its annual entertainment and ball at Odd Fellows' hall, on February 9. The committee has prepared a first-class entertainment, and it is expected that the event will be up to the usual high standard.

Silk City Council No. 18 (Paterson, N. J.), Universal Craftsmen, Council of Engineers, will hold its annual entertainment and reception on February 12. A good time is assured.

Technical Education

By H. Addison Johnston

The trouble with the ordinary technical graduate is that when he gets his diploma, and can play three scales and "Home, Sweet Home" on the engineering piano with one finger, he thinks he is second only to Paderewski. He forgets, or rather he has never realized, that long experience in actual construction is necessary before he can safely and surely apply his mathematical theories to everyday work.

The engineering school does teach a man a whole lot about *how* to build engines, that it is very essential that he should know, but the only way to learn *to build* engines is to build engines. In this connection, hear the sad story of Jones:

Jones was a young, quite recent, technical graduate, and what he did not know about engineering was not worth knowing. Jones had not specialized particularly on thermodynamics, but he thought he knew something about it, and there is no doubt that he passed his examinations. Jones was great on accurate calculations; nothing worried him so much as leaving off the decimals; why, he could figure out the proper diameter of a staybolt to nine places of decimals and tell the probable error and all that. Jones was a very decent fellow, but one thing he hated, and that was to notice those awful, inaccurate, rule-of-thumb methods which prevailed in some shops. Why, in one shop Jones had visited, instead of having the last batch of bolt iron properly tested as to its elastic limit, ultimate tensile strength and resistance to shear, and calculating the allowable stresses and figuring a factor of safety, the superintendent had just casually remarked that he "guessed six five-eighth bolts would do for that there flange," and that was all there was about it. It was simply shocking that such practices were allowed in this scientific age.

Well, one day, at the club, Jones was comfortably explaining to the company the beautiful accuracy of scientific mathematical calculation as compared with the unreliable guesswork of cut-and-try schemes, when an acquaintance, Brown, by name, who was in the gas-engine business, asked him if he could give any simple, accurate method of calculating the compression pressure in a gasolene-engine cylinder when the percentage of clearance was known.

"Why, certainly," said Jones, swallowing the bait whole, quite pleased at the opportunity to be of assistance. "The pressure of a gas varies inversely as the volume, 'Mariotte's law,' you know. Pressure multiplied by volume before compression equals pressure by volume after compression, like this," and he stepped to a small blackboard and wrote:

$$P_1 V_1 = P_2 V_2.$$

"Oh! I see," said Brown, who knew something of mathematics himself, even though he was a practical man. "Well, just for an example, what would a pressure gage show the compression to be on an engine with, say, 20 per cent. of the total cylinder volume as clearance?"

"That's easy," replied Jones. "The normal air pressure is 14.7 pounds, and we call the total volume 100; then the clearance will be 20." Then he laid out the following:

$$P_1 = 14.7. \quad V_1 = 100. \quad V_2 = 20.$$

$$P_1 V_1 = P_2 V_2. \quad P_2 = 73.5.$$

"There, that's it: 73.5 pounds compression."

"Must be something wrong," said Brown. "I saw an engine with 20 per cent. clearance tested and it had 110 pounds."

Jones checked over his figures. "Can't find anything wrong with the figures; must be the equation that's wrong. Um—um. Say! that equation is wrong. I have got the isothermal instead of the adiabatic equation. You see the air gets hot when it is compressed and that runs the pressure up. I should have written the equation this way:"

$$P_1 V_1^{1.41} = P_2 V_2^{1.41}.$$

"I guess this will bring it out about right."

Jones always carries a little table of logarithms in his pocket and pretty soon he said, rather dubiously: "That works out to 142 pounds compression; seems about as far out too high as the first one was too low."

"Well, put it on the board beside the other, anyway," said Brown. "After awhile we'll average them up. Looks to me, though, that you forgot to subtract 14.7 from your figure to get the gage pressure. You've got the absolute."

"Why, so I have," replied Jones. "Never thought of that; but, say, that first figure was too high by the same amount. It should have been only 58.8 pounds. The last one looks a little better now, though; 142 — 14.7 = 127 pounds compression gage. That engine you saw must have had leaks in it."

"No it didn't," said Brown. "But it strikes me the Prof. John Perry says that 1.41 is too high for air; 1.37 is the proper figure."

"Well, perhaps it is," said Jones, looking slightly worried. "I'll work it out."

Jones works out again:

$$P_1 V_1^{1.37} = P_2 V_2^{1.37}.$$

$$P_2 = 119$$

pounds gage.

"Getting closer," said Brown. "But that's too high yet; now I come to think of it, some other fellow says that 1.33 is the proper figure to use instead of 1.37."

Jones works out once more:

$$P_1 V_1^{1.33} = P_2 V_2^{1.33}.$$

$$P_2 = 111$$

pounds gage.

"There, that's right," he exclaimed. "Your pressure gage must have read a pound too low."

"Perhaps it did," replied Brown. "But it seems to me that you have missed something. You see there is always a slight vacuum in a gas-engine cylinder at the end of the suction stroke. The piston moves out so fast that the air cannot get through the valve quick enough to keep up the pressure. I don't suppose the pressure would be over 14 pounds in some engines when the piston started on the compression stroke."

Jones said nothing, but worked it out with the new value for p_1:

$$P_1 V_1^{1.3} = P_2 V_2^{1.3}.$$

$$P_1 = 14 \text{ pounds}; \frac{V_1}{V_2} = \frac{100}{20} \quad P_2 = 106$$

pounds gage.

"This is rotten," said Jones. "It's getting worse."

"We've only a few more left," said Brown. "Have you ever noticed that these mechanically operated inlet valves do not close until the piston has moved back about 5 per cent. of the compression stroke? You did not take that into account."

"Oh, well, I'll work it out a few times more," said Jones, crossly. "That 5 per cent. loss will just about have the effect of increasing the clearance to 21 per cent. instead of 20 per cent.

$$P_1 V_1^{1.3} = P_2 V_2^{1.3}.$$

$$P_1 = 14. \quad \frac{V_1}{V_2} = \frac{100}{21}.$$

$$P_2 = 97$$

pounds gage.

"Jones, there's another thing we did not take into account," said Brown. "There's a whole lot of hot exhaust gas in the cylinder that's going to warm up the charge and send the pressure up a little."

"Yes," snapped Jones, "and now you mention heat, I suppose the cold fresh charge will be warmed by contact with the warm cylinder walls, to begin with, and the hot compressed charge will be cooled by contact with the warm cylinder walls, to finish with, and little drops of gasolene will make some vapor and raise the pressure, and little leaks around the piston will lower the pressure, and if you know any more little variable constants or constantly varying variables, why spring them now."

"Cheer up," said Brown. "Don't get worried. Just add up all the half dozen results you've got and strike an average."

Jones worked out

$$\frac{127 + 119 + 111 + 106 + 97}{5} = 112$$

pounds gage.

"Just about right, eh?"

"Well, almost for the engine I saw," said Brown, getting up to go.

"Hold on!" cried Jones. "how the deuce do you figure your compression space to get the right pressure?"

"Well, I'll tell you," replied Brown, "though it's a secret and I wouldn't have it leak out for anything. When we get out a new type of engine we open our mouth and shut our eyes and make a real good guess; then, if the pressure doesn't suit, we juggle the length of the connecting rod or the depth of the cylinder head until it does."

Alfred R. Wolff

We present herewith a likeness of the late Alfred R. Wolff, whose death, on January 7, was announced in the January 19 number. As previously stated, Mr. Wolff was one of the foremost heating

THE LATE ALFRED R. WOLFF

and ventilating engineers in the United States. He was a charter member of the American Society of Mechanical Engineers. In 1880 he started a general engineering practice at 88 Park Row, New York, removing in [illegible] to the [illegible] He took up the designs of power, heating and ventilating plants and established a practice which extended over a period of twenty-eight years. He was a member of the Engineers' Club. Mr. Wolff's practice of consulting engineer for power-plant, heating and ventilating installations has been taken over by Messrs. Nygren, [illegible] Tenney and Arthur K. Ohmes, under the firm name of Nygren, Tenney & Ohmes, with offices in [illegible] building, corner of Fulton and Nassau streets, New York City.

Marine Engineers' Convention

The thirty-fourth annual convention of the National Marine Engineers' Beneficial Association was held in Washington, D. C., during the week beginning January 18, with headquarters at the Ebbitt house. There were about one hundred delegates in attendance. The reports showed the organization to be in a prosperous condition. The National Marine Engineers' Supplymen's Association, also in session at the Ebbitt house, entertained the delegates and guests during the week with trolley rides, theater parties, etc.

The leading social feature was a smoker held in the ballroom of the New Willard hotel, at which there was an attendance of about four hundred, including many Government officials. The entertainment was first-class in every particular, the entire company going from New York City especially for this occasion. On Wednesday afternoon the visitors were received by President Roosevelt, who was present at the meeting and congratulated the members of the association upon their high standing in the engineering world. The President shook hands with each visitor.

On Thursday the following national officers were elected: W. F. Yates, president; [illegible], first vice-president; W. P. [illegible], second vice-president; C. N. [illegible], third vice-president; George A. [illegible], secretary; [illegible] Jones, national treasurer; W. D. [illegible], [illegible], E. J. Houghton, advisory board; [illegible] Smith, trustee. The election of officers of the supplymen's association resulted as follows: Herbert [illegible], president; John W. [illegible], vice-president; [illegible], secretary-treasurer.

Combined Associations, N. A. S. E.

The seventh annual entertainment and ball of the Combined Associations of the National Association of Stationary Engineers of Manhattan and the Bronx, New York, was held at the Grand Central Palace Saturday evening, January 23. The attendance was larger than ever before. The hall was beautifully decorated with streamers, floral and flag effects. An [illegible] vaudeville performance was given, after which the hall was cleared for dancing. [illegible] Dancing and [illegible] many [illegible] being [illegible] of the [illegible] Besides [illegible] were [illegible] prominent engineers and [illegible]. There were [illegible] of the leading engineering [illegible] on the list of patrons.

The officers of the Combined Associations are: Fred [illegible], chairman; J. R. [illegible], vice-chairman; [illegible], treasurer; J. [illegible], secretary. The grand success of the [illegible] was due to the [illegible] combined, earnest efforts of the officers and the several committees, who deserved the hearty praise bestowed upon them.

Eccentric Firemen's Ball

The fourteenth annual entertainment and ball of the Eccentric Association of Firemen, Local No. 56, I. B. of S. F., of New York, was held at Grand Central Palace on Saturday evening, January 23. The large and prettily decorated hall was filled to its capacity. A vaudeville performance preceded a long dancing program, and goodby's were said after a most enjoyable night. This event always attracts many people prominent in the engineering world, and besides these there were present a number of distinguished guests, including J. Pierpont Morgan and daughters, William K. Vanderbilt, Postmaster E. M. Morgan and wife and Lewis Nixon.

Business Items

Schuchardt & Schutte have removed their New York offices and warerooms from 136 Liberty street to the West Street building, 90 West street.

Arthur Hoyt Bogue has resigned as general manager of the Atlas Preservative Company of America and has opened an office as manufacturers' direct representative at 142 Pearl street, New York.

Jersey City Association No. 1, N. A. S. E., wishes to get manufacturers' catalogs, samples, etc., for its meeting room. Such catalogs should be sent to John T. McEntee, secretary, 295 Third street, Jersey City, N. J.

John P. Cosgro, who during the past few years has spent considerable time in the southwestern part of this country and the northern States of Mexico, has been appointed district manager of the Allis-Chalmers Company, with offices in the El Paso & Southwestern building, El Paso, Tex.

Henry I. Lea, who has been associated with the Emerson McMillin and the Dawes syndicates, the Western Gas Construction Company and the Westinghouse Machine Company, has opened an office in Room 616, The Rookery, Chicago, Ill., as gas engineer. He will design, construct or manage gas works and make examinations and reports.

Cyrl J. Atkinson, designer of the Atkinson gas producer, which has been manufactured by the Industrial Gas Power Company, lately severed his connection with that company, and is now located with the Dornfeld-Kunert Company, of Watertown, Wis., which is building under his management and supervision improved forms of his gas producer, both of the suction and pressure types.

The copartnership heretofore existing between Frank B. Williams and George H. Williams, doing business under the firm name of I. B. Williams & Sons, Dover, N. H., has been dissolved by mutual consent, George H. Williams retiring. The business, that of making leather belting, will be carried on in future under the same firm name by Frank B. Williams, who assumes all outstanding obligations.

The Minneapolis Steel and Machinery Company has been given the contract for furnishing the new engine for elevator "D" of the Consolidated Elevator Company, Duluth, Minn. They will install a 26- and 52- by 48-inch vertical tandem compound Twin City Corliss engine, with flywheel 16 feet in diameter grooved for twenty two 2-inch ropes. The entire engine will be completed by April.

The National Tube Company has just issued a handsome pamphlet under the title of "Shelby Steel Tubes and Their Making." After a brief review of the history of the art, the seamless process is described step by step, illustrated by numerous half-tone reproductions of photographs of the processes and the product in the various stages. It is beautifully printed upon heavy plate paper and will make an attractive and interesting addition to the library of an engineer.

Edward C. Brown, manager of the Hawaiian office of the Dearborn Drug and Chemical Works, at 42 Queen street, Honolulu, is making an extensive oriental trip of three or four months, during which he will visit Japan, the important seacoast cities of China, Australia, the Philippines, Java and other important islands in the Pacific ocean. Mr. Brown has most successfully handled the Dearborn company's business in the Hawaiian islands since that department was opened some ten years ago.

The Lagonda Manufacturing Company is distributing an interesting booklet of twenty-four pages on "The Scale Question." The booklet gives numerous facts about steam-power plant economy and protection and will interest all who own or have charge of boilers, economizers, condensers, etc. Among the new Lagonda products described therein is the Weinland air-driven wing-head cleaner. This machine is a miniature rotary engine which goes into the tube and rotates the cleaning head in much the same manner as a turbine does, but is claimed to be more powerful. The booklet will be sent to all who write to the Lagonda Manufacturing Company, Springfield, O.

New Equipment

It is said the McCook (Neb.) Electric Light Company is planning to rebuild its plant.

The Mammoth Spring (Ark.) Electric Light Company will rebuild its burned plant.

E. C. Bowman, Birmingham, Ala., contemplates the construction of a cold-storage plant.

The Houston (Tex.) Electric Company is planning the installation of additional equipment.

The Carthage (N. Y.) Electric Light and Power Company is planning to install another generator.

The citizens of Glasgow, Mont., voted to issue $50,000 bonds for water works. J. J. Mullins, town clerk.

The Ocala (Fla.) Ice and Packing Company will increase the capacity of its ice and cold-storage plant.

G. W. Cavanah, town clerk, Sebree, Ky., will receive bids until Feb. 15 for constructing water-works system.

J. Fletcher, owner of the electric-light plant at Wolsey, S. D., contemplates installing a new engine and generator.

The Ennis (Tex.) Ice, Light and Power Company contemplates installing a 200-horsepower boiler and engine.

The Valley Electric Company, New Brighton, Penn., is planning the installation of a 500-kilowatt turbine unit.

A new electric-light plant is to be built at the De Pauw University, Greencastle, Ind. R. L. O'Hara is president of board of trustees.

The City Council, Barberton, Ohio, is said to be considering the purchase of a new air compressor for the water-works plant, to cost about $8000.

The Lincoln (Ill.) Railway and Light Company has under consideration the question of installing a steam-heating plant using exhaust steam.

It is reported that a new dynamo and engine will be installed in the Municipal electric-light plant at Quincy, Fla. B. A. Puckett is manager.

The Skagit River Power Company, Denver, Colo., has completed plans for the construction of a 100,000-horsepower plant. E. M. Riggs is president.

A Low-Head Hydroelectric Development

An Interesting Plant at Milford, Maine, to Develop 12,000 Horsepower under a Head of 20 Feet, and Generate Three-phase 2200-volt Current

BY S. RICE

Low-head water-power developments are, as a class, of much greater importance to the country than those of any other type, both because of their numerical superiority and from the fact that the conditions which render them possible are more frequently met with near large manufacturing centers, where the current generated may be used, than are conditions necessary to high or medium heads, which require the vicinity of mountains, hills or unusual geological formations such as exist at Niagara.

At Milford, Me., there has been placed in successful operation one of the most interesting of the low-head power developments to be met with anywhere in the United States. The source of power is the Penobscot river, which flows in a group of lakes in Piscataquis county, not far from the Canadian border, and flows in a general southeasterly direction to

FIG. 1. THE DAM AND POWER HOUSE AT MILFORD

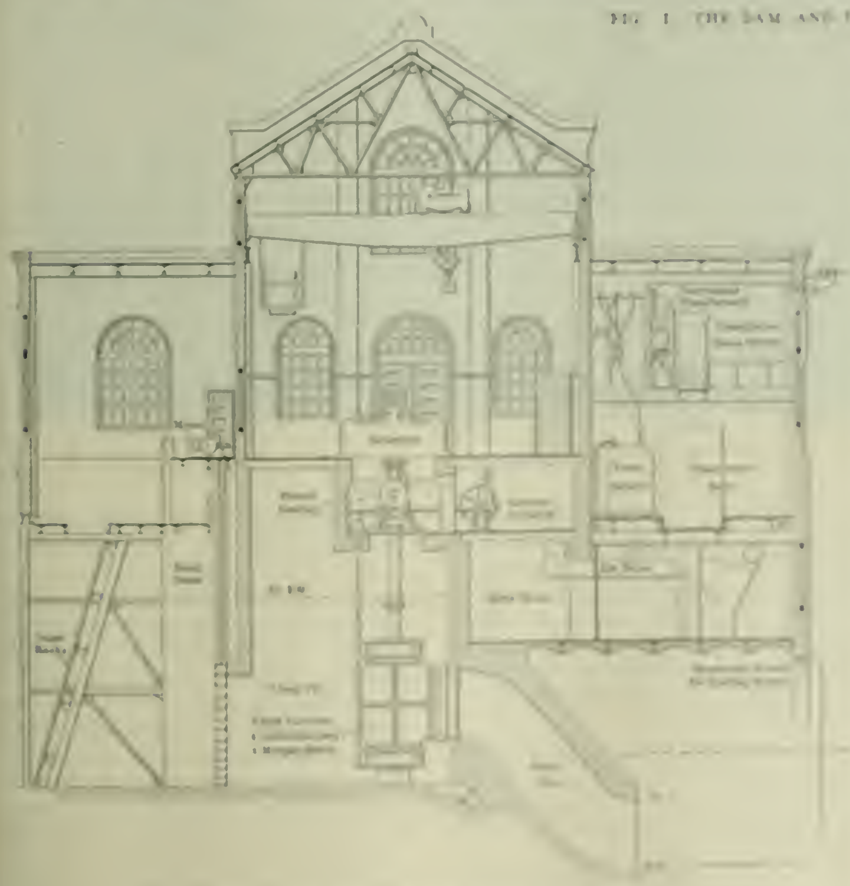

FIG. 2. SECTION OF POWER HOUSE THROUGH [illegible]

Penobscot bay, draining in the upper reaches a territory of about [illegible] square miles.

Near Millinocket, about [illegible] miles up the river from Milford, the Great Northern Paper Company has constructed a dam, where about [illegible] horsepower is developed under a [illegible]-foot head and used to operate electric generators to supply current for motor drive throughout the company's mills. The [illegible] made by damming the Penobscot river at this point create storage for about [illegible] cubic feet of water, and the Great Northern Paper Company is under contract with the governmental authorities to let down a minimum of [illegible] cubic feet of water per second.

South of Millinocket the highest head of water is found at Milford, where the total fall of the river from the source, as shown by the U. S. Geological Survey, is approximately [illegible] feet, and there the Bodwell Water Power Company has built a plant to develop [illegible] horsepower under the normal working head of 20 feet. The immediate cause of erecting a central power station at this point was the opportunity to contract to [illegible] to be furnished the [illegible] Manufacturing Company located at [illegible], about [illegible] miles distant, but there are quite a number of paper mills and other industrial establishments in the vicinity of Milford, and the manufacturing city of Bangor is situated on the river 10 miles below; so that there was every prospect of being able to dispose continuously of the full available quantity of current, and this expectation has been realized.

Across the river from Milford, in the vicinity of Old Town, are two woolen mills and a pulp mill, water for which is taken from the river through a canal discharging below the new dam; but the amount of power diverted by this means is not enough seriously to affect the Bodwell company's project.

Concrete Dam

The dam built by that company extends 1000 feet from the new power house to the abutments of the canal above mentioned on the western side of the river. This is of solid concrete construction, 12 feet wide on the crest and varying from 14 to 32 feet at the base. This latter difference is accounted for by the irregularity of the bed of the stream, necessitating stronger and wider foundations in its deeper parts. The spillway extends the entire length of the dam, and there are no openings with the exception of a 25-foot log sluice next to the power house and adjoining the dam on the eastern side and a fishway 30 feet at the bottom and 10 feet at the top, which extends between the log sluice and the power house. These are controlled by steel gates, motor-operated.

Power House

The power house is located at the easterly end of the dam on the Milford side, being constructed of concrete as far as the generator floor and having brick walls above that level. It has a length of 225 feet 10 inches and a width of 84 feet 8 inches and is divided into three main parts. The central part, with pitch roof, contains the hydraulic turbines and governors and the electric generators; the up-stream aisle contains the rack and flume gates and the down-stream aisle houses the auxiliary electrical machinery and other apparatus.

Up to elevation 115, which is 15 feet above the crest of the dam, or datum, the foundations and walls are of concrete. All walls above this elevation are of brick surrounding a steel frame. There are two sets of racks, outer and inner, the former being placed a short distance up stream from the power house. These are built of structural-steel frames, securely braced, and extend 6 to 7 feet above the crest of the dam. The general construction is clearly shown in the side elevations of the power house. The steel gates are motor-operated. All of the rigging is so arranged that there are no gears or other appliances liable to be clogged or have their operation interfered with by ice or other débris that may be carried through the racks. Water enters to each turbine through a separate flume, the walls of which are of concrete reinforced with steel. Discharge is directly into the river below the dam.

FIG. 3. THE GENERATORS AND EXCITER UNIT

The Turbines

The hydraulic turbines are built for operating at their best efficiency under a head of 20 feet and a speed of 150 revolutions per minute. Under these conditions the flow of water through each is at the rate of 483 cubic feet per second, with delivery of 875 horsepower. Each turbine has two 45-inch runners of the Francis type, mounted on a heavy vertical shaft and with central discharge casing connected to a draft tube built of reinforced concrete. Every portion is easy of access for inspection and repairs. The water flow is regulated by movable vanes, operated by vertical shafts and levers from the piston of an oil-pressure governor.

The head under which these turbines run will be increased, perhaps as much as 5 feet, by the raising of the head water, and it is also expected farther to increase the head by improvements in the river below the power plant, bringing the tail

FIG. 4. ONE OF THE ALLIS-CHALMERS TWIN TURBINES

water down nearly or quite to the top of the outlet of the draft tubes and making the ordinary working head from 25 to 27 feet. The dam was built heavy enough to have the required hight added, and grooves were left in the top of the structure for bonding. The wheels are built for operating at their best efficiency under a head of 20 feet at the speed above noted; but with a head of 25 feet the percentage of efficiency will not be materially reduced. Under a 14 foot head normal speed is also maintained and the output is relatively high. All parts are so proportioned that, when running under the full contemplated head of 27 feet, the machine will stand the operating stresses within a liberal factor of safety.

As a water power is of highest economy when the energy developed from the natural resources available is the largest under all operating conditions, a lowering of 6 inches, or 30 per cent., of the available head will cause serious reduction of the capacity of the plant, if the turbines are not designed with careful consideration of such conditions. The speed of the 875-horsepower units being specified as 150 revolutions per minute, this must also be maintained at the low head of 14 feet caused by backwater in the river at time of flood, and it is here that the turbines should develop as much power as possible.

While it is not difficult to design a turbine to meet the requirements of speed and power at 20 feet and at the same time show a good efficiency, it calls for more than ordinary engineering skill also to obtain satisfactory results under the reduced head of 14 feet. It must be borne in mind that when tests are conducted in the flume at Holyoke to prove the efficiency of the turbine, such tests have to be made at a head which does not vary much. It is, therefore, an easy task to design a runner which shows up nicely at Holyoke, while it is questionable whether such a runner will give in operation a result which is the most satisfactory commercially. Many engineers believe that they secure a high grade wheel when they note on the test sheet that the efficiency exceeds 80 per cent., and quite often this very turbine will not be as good an earner of money in the plant as another one which probably showed less efficiency at Holyoke, but was designed to be better adapted for the commercial-operating conditions. From this point of view the special turbines at Milford were designed, and it is not surprising that their performance has given satisfaction and an unusually high efficiency obtained.

Between each turbine and generator, in the basement above the wheel, is a thrust bearing carried by a cast-iron base ring grouted into the concrete arch over the turbine pit at elevation 107. Each of the bearings originally used with the first of the units to be installed consisted of two cast iron disks with an annular groove to which oil was supplied at 225 pounds pressure. This made an excellent bearing but was expensive to maintain and entailed too great risk in operation, as an accident or wrong manipulation by an operator, resulting in derangement of the mechanism, might not only cause the pressure to drop or be lost entirely, but would cause every unit running at the time to be put out of commission, entirely ruining the disks the moment they came in contact and tying up the plant most effectually until each unit had been dismantled and the defect repaired.

After a brief operating experience, during which disaster was several times avoided by a close margin, it was decided to equip all of the units in the station with oil-bath bearings, which, being self-contained and floating in oil, not only require very little attention and no auxiliary apparatus and consequently reduce the number of operatives necessary, but also eliminate any danger from a sudden shut-down and effect a saving of over [illegible] per cent. in oil. The starting up of the first unit with which the new oil-bath bearing was equipped, full load was put on the machine within a few minutes' time and the unit has been in continuous operation ever since, at decreased temperature, with no change of oil.

For each of the turbines in this station there has been provided a vertical oil-pressure governor, so arranged as to be visible either from the switchboard or any portion of the main floor. These governors can be controlled by electric switchboard connection, automatic regulation by flyballs or hand regulation. They are driven from the wheel shafts through bevel gears, shafting and link belting. Each governor is cylindrical in form and made up of two chambers, the upper being an oil and the lower a pressure chamber; the latter has an oil gage and a pressure gage, so that the volume of air and oil and existing pressure are always in plain view, and it is provided with an adjustable safety valve. Between the two chambers lies a horizontal differential cylinder, the piston of which is directly connected to the regulating shaft.

The oil pump is of the rotary type and placed in the oil reservoir. It is self-lubricating and is connected by a shaft projecting through the casing, directly with the turbine. The chain which forms a part of the connecting mechanism is easily detached. The flyballs, which are designed as a sensitive but absolutely static apparatus, are tested and carefully adjusted to the required percentage in change in speed. They are driven by

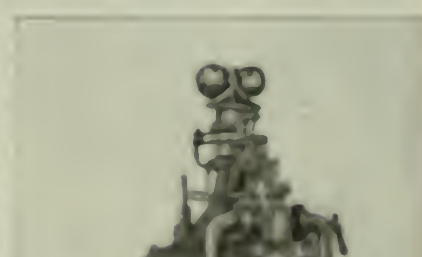

FIG. 5. ALLIS-CHALMERS GOVERNOR

means of a bevel gear located in the oil reservoir and can be started or stopped by means of a friction-clutch coupling, without stopping the pump. The regulating valve is not rigidly connected to the floating lever of the flyballs, but is balanced.

Generator Equipment

The generator room contains [illegible]

of the power plant and is 36 feet wide. Room is provided for 12 alternating-current generator units of 750 kilowatts capacity each and one 300-kilowatt exciter unit, the distance between units being 16 feet. Another exciter of 200 kilowatts capacity is driven by a three-phase, 2200-volt induction motor and placed below the switchboard gallery in the same bay.

The generators are of the revolving-field type, three-phase, 25 cycles, delivering current at a terminal pressure of 2200 volts. Excitation is 120-180 amperes at 125 volts. The switchboard is of blue Vermont marble and located in a gallery 15 feet above the floor. It consists of the usual complement of generator, feeder and exciter panels and special regulator and auxiliary-circuit panels. For all 2200-volt connections oil switches are used. They are located in concrete cells on the thrust-bearing floor directly underneath the switchboard. The power transformers, designed to step up from 2200 to 22,000 volts, are placed in the basement of the south bay, and in the room above are two banks of instrument transformers. The station is served by a 25-ton Niles crane, electrically operated, and is heated by the blower system, a motor-driven Sturtevant blower being placed in a subbasement under the transformers.

FIG. 6. SWITCHBOARD GALLERY

Miscellaneous Improvements

By W. H. Wakeman

Fig. 1 illustrates the governor of a Putnam engine, with its substitute for a dashpot, which is designed as follows: The column of this governor is hollow and contains a rod which connects the inner ends of the fly-ball arm to the hollow casting *A* that is pivoted to the lever *B* and is carried by a shaft, one end of which rests in the bearing *C*. The cap on this bearing is lined with leather instead of babbitt metal, and it is held in place and clamped on the shaft by one cap screw. When the governor balls rise, *A* falls, and *vice versa*, thus causing the shaft to turn slightly in the bearing *C*. As it does not move freely it offers resistance to rapid changes in the position of the governor balls; therefore, it is a very good substitute for a dashpot.

The leather lining is durable but, of course, it wears slowly, and when it becomes too loose the engine races. To remedy this defect it is only necessary to tighten the cap screw. One day this engine raced when starting up, which was very unusual, and applying the natural remedy made no improvement because the cap was what would be called "brass bound," if it were on the crank pin of an engine; therefore, it could not be tightened until repaired. To turn out the cap screw, remove the cap and take out the leather lining was a short job, and as it would take several minutes to fit a new leather lining into place, a piece of writing paper was fitted into the cap and the leather put back. This was sufficient to give the cap a hold on the shaft, and provided enough friction to control the governor perfectly. The advantages of this method are that it required less than five minutes to do the job, and the perfect fit of the leather on the shaft was not disturbed. From present indications it will probably last a year.

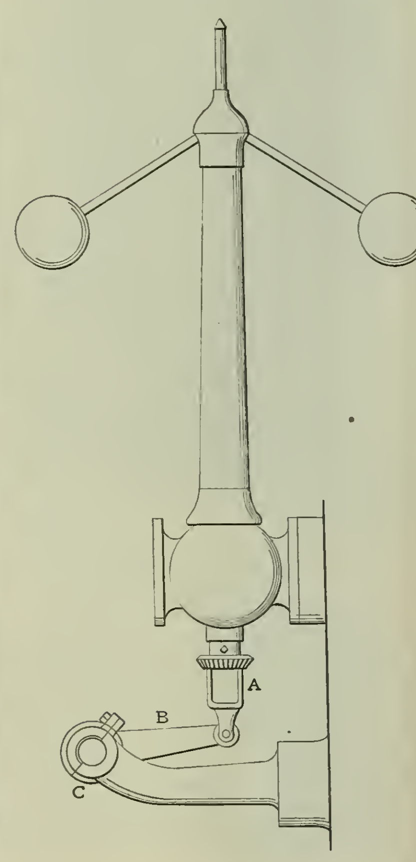

FIG. 1

The two pump governors shown in Fig. 2 are designed for 1½-inch pipe. The vertical central pipe is 2 inches, with a cross at its terminal, into each horizontal outlet of which a 1½-inch nipple was screwed, followed by a valve as shown. The connection between this valve and the pump governor on each side was originally 1½ inches, but proved to be too large for smooth running under existing conditions. A sediment catcher is located below the cross, also a trap for removing the water of condensation.

These governors control two duplex pumps, with 7½-inch steam pistons and 6-inch water cylinders, taking water under 20 pounds pressure and raising it to 45 pounds. As the area of a 6-inch circle is 28 square inches, and the actual pressure per square inch to be overcome by steam pressure is

$$45 - 20 = 25$$

pounds, the total resistance exclusive of friction is 700 pounds. The area of a 7½-inch circle is 44 square inches; therefore, it requires

$$700 \div 44 = 16$$

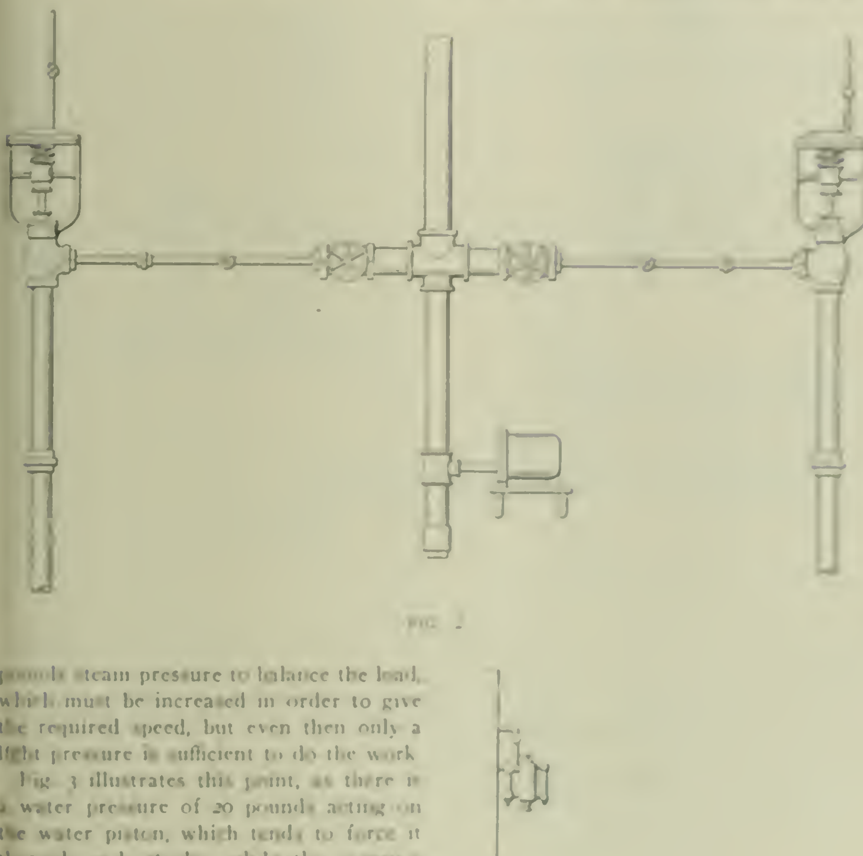

FIG. 2

pounds steam pressure to balance the load, which must be increased in order to give the required speed, but even then only a light pressure is sufficient to do the work.

Fig. 3 illustrates this point, as there is a water pressure of 20 pounds acting on the water piston, which tends to force it through each stroke, while the pressure on the opposite side is 45 pounds; therefore, only the difference is to be provided for. If the steam pistons of these pumps were 6 inches in diameter, the required pressure would be 25 pounds, and if they were only 5 inches it would be 37 pounds, which is about one-half of the boiler pressure. This would be more satisfactory for service in general, and for this case in particular. Only drip cocks are provided for the steam cylinder of each pump, and there is no drip pipe for the frame.

The 1½-inch pipe between the cross on one side and a governor on the other was taken out, bushings which reduced the openings to the right size for ½-inch pipe were substituted and a suitable connection as shown was made for one pump. The service rendered proved to be so much better that a similar change for the other soon followed, and both are now giving satisfaction. The reason for this is that when a large quantity of water was used, causing a sudden reduction of pressure, the governors responded quickly, giving a full charge of steam to the cylinders, as the pipe was large enough to supply the necessary quantity. The re[illegible]

[illegible] tolerated in that place.

The governors respond now as readily as before the steam pipes were reduced, because they depend on the water pressure, but the quantity of steam that can be admitted in a given time is much less than formerly; therefore, the pistons do not start quickly enough to cause pounding in the water cylinders and pipes, yet [illegible]

[illegible]

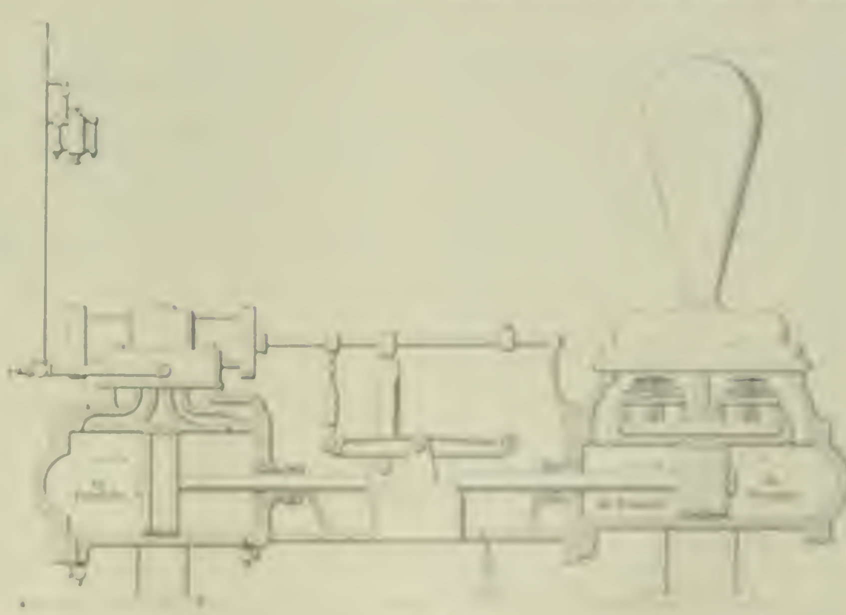

FIG. 3

[illegible]

small space with other valves and several pipes, making it inaccessible for cleaning and repairs. The overflow pipe was originally of small size and made as short as possible, with few fittings. Air would sometimes be trapped in this pipe, and thus prevent water from flowing away freely, causing it to spill on the floor and cause trouble. To prevent this action the pipe was increased from ⅜ to 1 inch, and a tee used in place of the first ell, as shown under the main lever. As the upper outlet was left open the air escaped freely, yet the water did not overflow, because the tee was as high as the small reservoir provided.

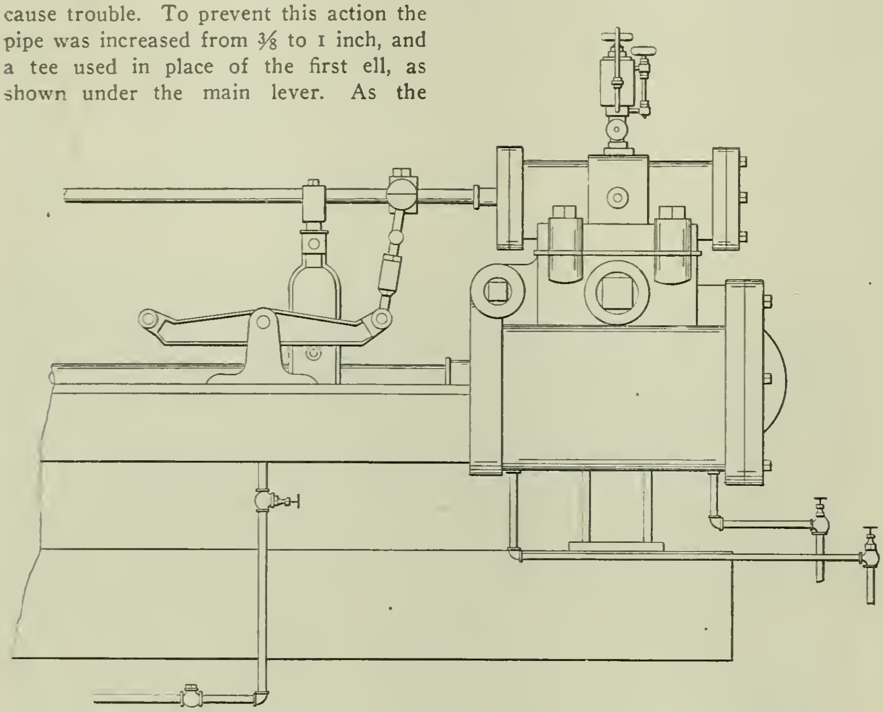

FIG. 4

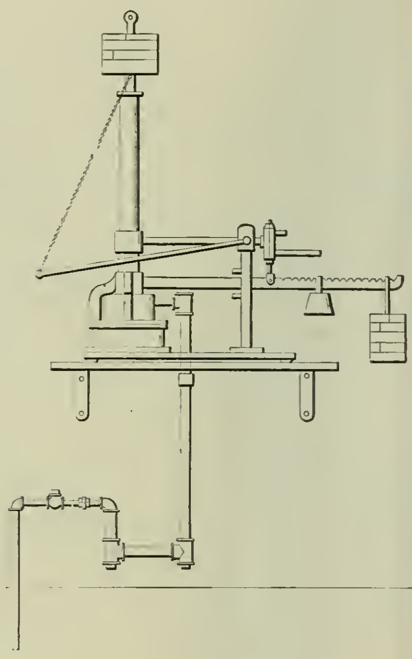

FIG. 5

The original small pipe became filled with sediment from the water used, at a point beneath the floor, but this objection was removed by making a pocket above the floor, using 1-inch tees and suitable nipples for this purpose. Two plugs were provided, the threads coated with graphite, and they were screwed in only lightly in order that they may be easily removed when the trap thus formed becomes filled with sediment. These are located high enough to admit of setting a pan under them to prevent staining the floor with muddy water when the pipe is washed out.

Fig. 6 illustrates a tilting steam trap located where it receives the discharge from three long drip pipes, which discharge water from different parts of a heating system. Sometimes this part of the system is noisy because the water resulting from the condensation of steam is warm in one drip pipe and cold in another; therefore, one kind of water hammer is the result. By throttling the discharge from the warm pipe, for which a valve is provided, this can be prevented, as it regulates the flow until there is little difference in the temperature of the pipes, resulting in smooth operation.

These three pipes discharge into a vertical header, on the top of which is a ⅜-inch angle valve that is opened one-sixth of a turn. This allows all air to escape to the return pipe, preventing excessive pounding, even when steam is first turned on, and keeping the pipes free from air at all other times; but it does not waste heat, because the return pipe is about 400 feet long, which is sufficient to allow the returning water to become cool; therefore, the small amount of steam that passes this valve, usually under 3 pounds pressure, goes into the feed water and gives it a higher temperature than it would otherwise have.

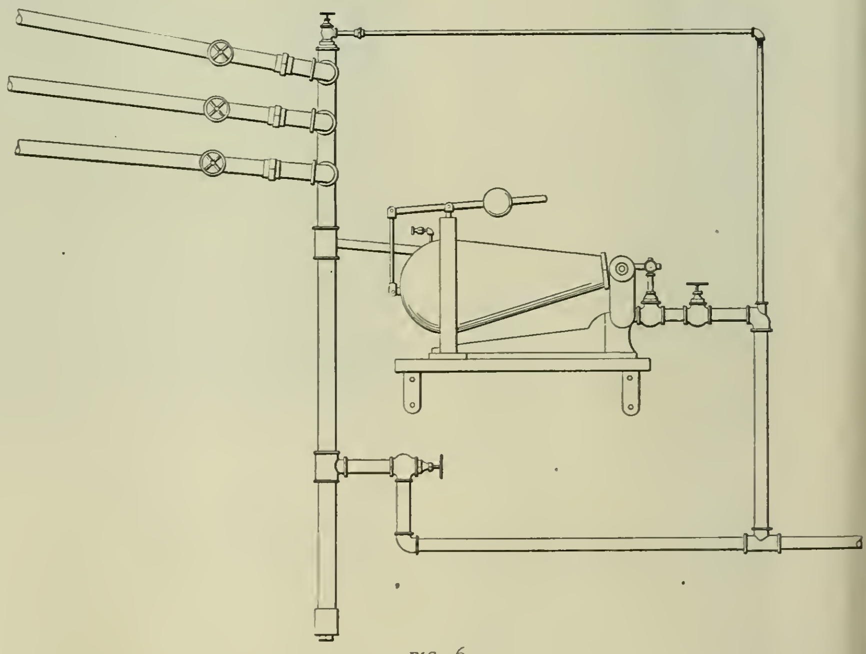

FIG. 6

The outlet from this vertical header to the trap is connected just below the lower inlet, while the bypass, or blowoff valve, is of the angle type, located lower down, with a dead end or pocket still lower, formed of the same pipe; consequently, if the incoming water contains sand, scale from the inside of the pipes and other foreign matter, it will lodge in this pocket instead of going into the trap. When pressure is off from the heating system, a plug at the lower extremity is unscrewed and all sediment removed. It is surprising to note how quickly such a pocket will fill with sediment. This arrangement of drip pipes, etc., was devised to take the place of connections that did not give good results on account of poor design and inconvenient operation.

Modern British High-Speed Steam Engine

Current British Practice, Giving Efficiencies, Methods of Governing and Lubrication and Principal Details of Standard Makes

BY JOHN DAVIDSON

The high-speed engine is largely used in England for all purposes, and it may safely be said that more high-speed engines for use on land are manufactured in England than in any other country in the world. The majority of these engines are for use at home, but a great number are sent abroad, English productions in this direction being used in almost every country.

The term "high-speed" is somewhat misleading—although no doubt generally understood—but "quick revolution" is a more correct definition of the type of engine under consideration, as it is high speed of revolution only which makes these engines differ from any other type. All engines running at speeds exceeding 120 revolutions per minute are generally spoken of as high-speed engines, and they are in general use running at speeds up to 700 revolutions per minute for the smaller powers, whereas the speed of the largest engines usually does not exceed 200 to 250 revolutions per minute.

Piston Speed

The piston speed of the engines is not much in excess of that of slow-speed engines, except in the case of the larger powers. The early high-speed engines were made with short strokes, and consequently with low piston speeds, but during the last few years there has been a tendency to increase the strokes and piston speeds. This has most probably been brought about by the necessity for economy in design necessitated by keen competition. In many instances the strokes have been increased 25 per cent. and the piston speeds accordingly increased 25 per cent. It will be readily seen that from almost the same weight of material 25 per cent. more power is then obtainable.

As illustrating general practice of the leading high-speed engine builders in England today the following table is given:

I.H.P.	Revolutions per Minute	Piston Speed
50	600 to 700	500
100	550 to 600	550
200	500	675
500	350 to 375	750
750	325	775
1000	300	800
1500	200	900
2500	160 to 180	1000

The Early High-speed Engine

Although the high-speed engine was first introduced for dynamo driving, it is now in use for almost every purpose, rapid strides having been made during the last few years despite the competition of the steam turbine. Even mill owners have at last recognized the simplicity, reliability and economical working of the enclosed type of engine for driving their mills, but the slow-speed Corliss engine has such a firm hold, and has done so well, that it will be many years before any other type of engine will be largely used. A number of mills, however, are now driven electrically, and as many of them have their own generating plants, another field for development is opened for the high-speed engine.

The early high-speed engines were of the single-acting type, as made by Brotherhood, Willans and others, but this class of engine has been entirely superseded by the double-acting forced-lubrication type of engine. Double-acting engines, with ordinary gravity lubrication, when running at high speed of rotation, are most unsatisfactory and will soon knock themselves to pieces, whereas the single-acting engine with its parts always in constant thrust overcame all these difficulties, but it was an expensive and inefficient engine.

FIG. 1. STEAM CONSUMPTION OF A TRIPLE-EXPANSION HIGH-SPEED ENGINE

The introduction of forced lubrication, however, did away with the necessity of single-acting engines and although large numbers of these engines were made after forced oiling was first brought into use, all engine builders of today use forced lubrication and double-acting engines, and none of the single-acting type is manufactured.

Advantages of the High-speed Engine

High-speed engines have many advantages over the slow-speed type. These may be summarized as follows:

A smaller engine is required for a given power, and thus it occupies less space, and reduces the cost of the engine somewhat. Smaller foundations and buildings are required; this again reduces the cost. The high-speed engine is of the simplest type manufactured, is reliable and is subject to a minimum of wear.

It may appear somewhat exaggerated to say that there is considerably less wear in a high-speed engine than in a slow-speed engine, but nevertheless it is a fact that with high-speed engines of the best makes less adjustments are required than with any slow-speed engine ever built. This is no doubt principally due to the fact that all the wearing parts of high-speed engines are large, and the system of lubrication is most perfect. These points will be more fully considered later, but as a proof of the statement just made with regard to wear, a few particulars are given below of a [illegible]-horsepower three-crank engine after running 7 years, 12 hours per day and 300 days per year:

[illegible]-HORSEPOWER THREE-CRANK ENGINE

Crank pins, greatest wear, inch	[illegible]
Main bearings, greatest wear, inch	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]

After [illegible] years running the wear on parts of a [illegible]-horsepower two-crank compound engine are given below:

[illegible]-HORSEPOWER TWO-CRANK ENGINE

[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]
[illegible]	[illegible]

These are not isolated experiences, but are commonly found almost everywhere. It might here be mentioned that all [illegible] [illegible] and that together with [illegible] and the necessary perfection of workmanship put into the engine, accounts for their success.

Again, high-speed self-lubricating engines require much less attendance, and it is common practice to put one man in charge of from four to six high-speed engines in a generating station. This is only rendered possible by the automatic system of lubrication adopted, and is rarely found possible in the case of slow-speed engines.

Economy

There are also many points in their favor as regards economy, and actual tests of modern engines have shown that high-speed engines have at least as high economy and efficiency as any other type of engine manufactured. In Fig. 1 is shown the consumption of steam per indicated and per brake horsepower of a high-speed triple-expansion mill engine working with steam at a pressure of 175 pounds per square inch and exhausting into a condenser having a vacuum of 26 inches, the steam being superheated 100 degrees Fahrenheit. These are the ordinary present-day conditions as regards steam pressure and vacuum for ordinary slow-speed mill engines, so it will at once be seen that the results obtained leave little to be desired. A consumption of 11.8 pounds per brake horsepower, or 10.9 pounds per indicated horsepower being equal to the best Corliss engine results, and owing to the high efficiency resulting from the forced lubrication and throttle governing, the economical performance at light loads is relatively much better than in the case of slow-speed engines.

The type of engine cylinder, viz., piston-valve cylinders, also renders the use of superheat practicable, and great advantages are thereby obtainable. In Fig. 2 is shown the percentage of gain due to superheat ranging from 0 to 200 degrees Fahrenheit on a high-speed triple-expansion engine. From this curve the advantages of superheat are apparent, and 150 to 200 degrees Fahrenheit are quite suitable for high-speed engines. At 200 degrees Fahrenheit the saving in steam consumption is no less than 26 per cent., and although this cannot be counted as total gain, a large percentage of economy is derived from the use of superheat.

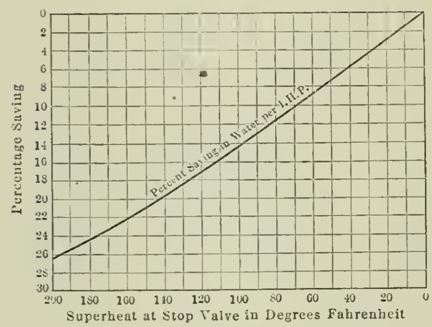

FIG. 2. GAIN FROM SUPERHEAT

Methods of Governing

The method of governing small high-speed engines is most generally by means of a plain centrifugal governor fixed to the crankshaft and acting directly on a throttle valve. In the case of lathe engines several makers are now fitting a governor which at light loads controls the speed of the engine by throttling, and at heavy loads by altering the degree of expansion in the high-pressure cylinders. This has been found the most economical method of governing. In the early days of high-speed engines, many makers used crankshaft governors which acted directly upon the steam-distributing valve and controlled the speed of the engine by altering the cutoff throughout the whole range. This type of governor is largely used in America, and with great success for medium-speed engines, but for high speeds it has been found impracticable and of very little advantage, except perhaps for small engines. The method adopted for governing by expansion in the case of heavy loads only, will be described in detail later.

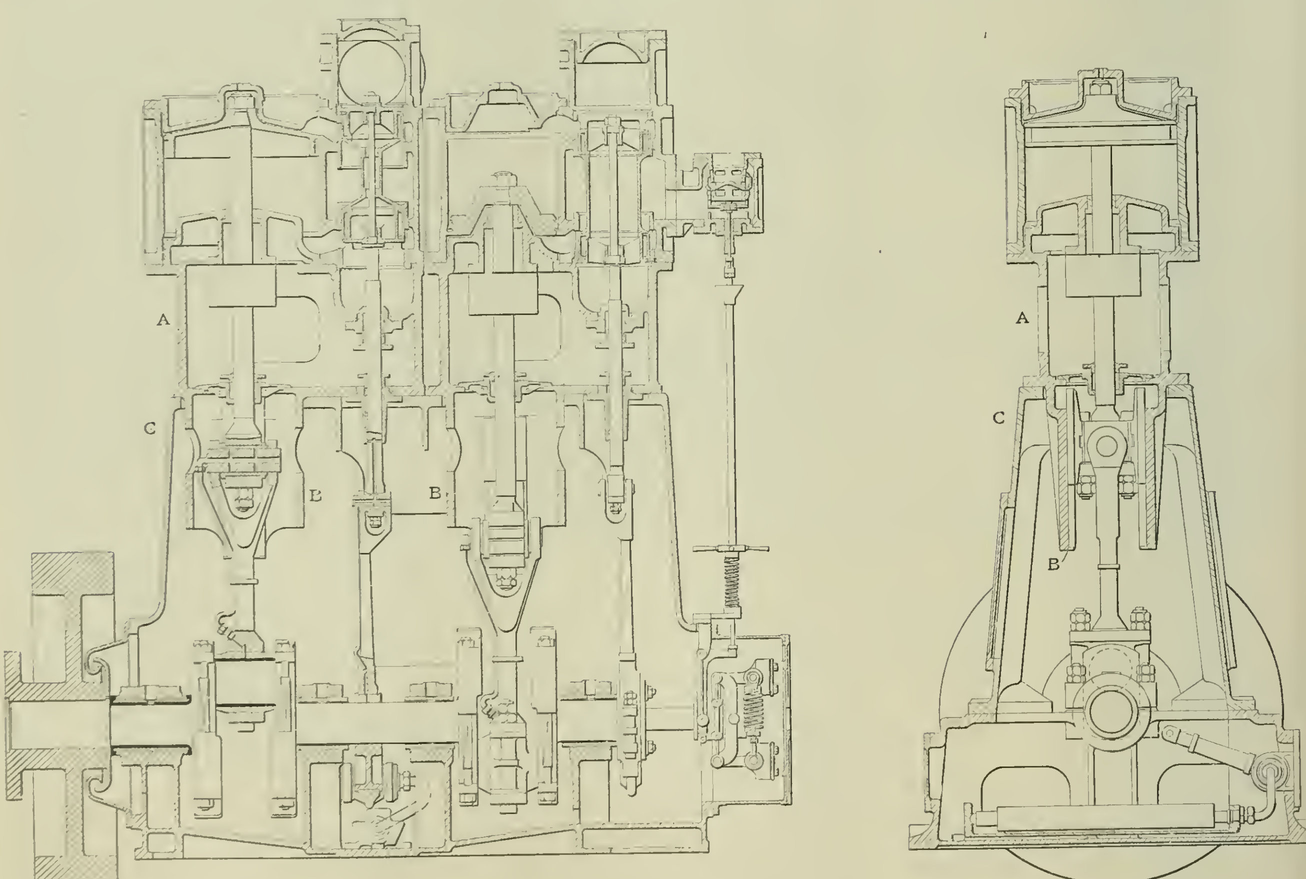

FIG. 3. BROWETT-LINDLEY VERTICAL ENGINE

Standard Type of Details

High-speed engines are built in all the usual varieties, viz., simple, compound and triple-expansion, and the principal British makers build engines in standard sizes up to 3000 indicated horsepower.

Cylinders. Piston valves for all cylinders are universally used, these being the only satisfactory type to suit all conditions of steam pressure and superheat. The cylinders are simple. In the case of two- and three-crank engines, each cylinder with its line of parts is usually quite independent of the other, that is to say,

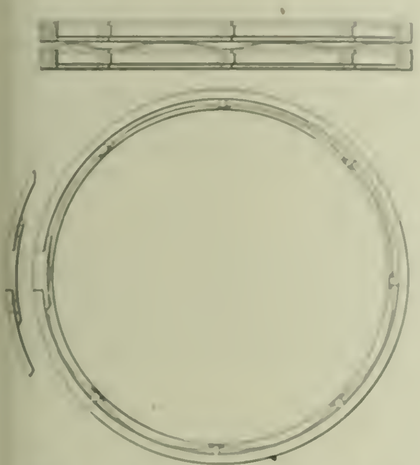

FIG. 4. TYPE OF PISTON RING IN COMMON USE

the cylinders are not stayed together in any way. This leaves each engine entirely free to be centered over its own crank, and also prevents distortion owing to unequal expansion due to the temperature of the steam. Steam jacketing has been tried, and no benefit being derived, it has been abandoned by most makers.

It may be of interest to note that all builders of this type of engine appear to have now adopted one standard design of engine, which consists of four main parts, viz., cylinder, distance piece with which is formed the crosshead guide, frame and bed or base. The arrangement referred to will be clearly seen by referring to Fig. 3, which shows in section the type of two-crank compound engine as manufactured

FIG. 5. ADMIRALTY TYPE OF RING

by Browett, Lindley & Co., Ltd., of Manchester, for powers ranging from 30 to 1000 horsepower, and this may be taken as typical of the best standard British design. In this engine the cylinders are supported their full length, but quite independently of each other, by a casting *A* with which is formed the lateral guides *B*. In this distance-piece casting are formed large openings, both back and front, to give easy access to the piston rod and valve-spindle glands. Above the guide, that is, at the top of the frame *C*, another set of stuffing boxes are fitted to prevent leakage of water from the cylinders getting down into the engine base, and so mixing with the oil in the crank chamber. The distance between these two glands is usually made a little more than the stroke of the engine, so as to prevent oil being

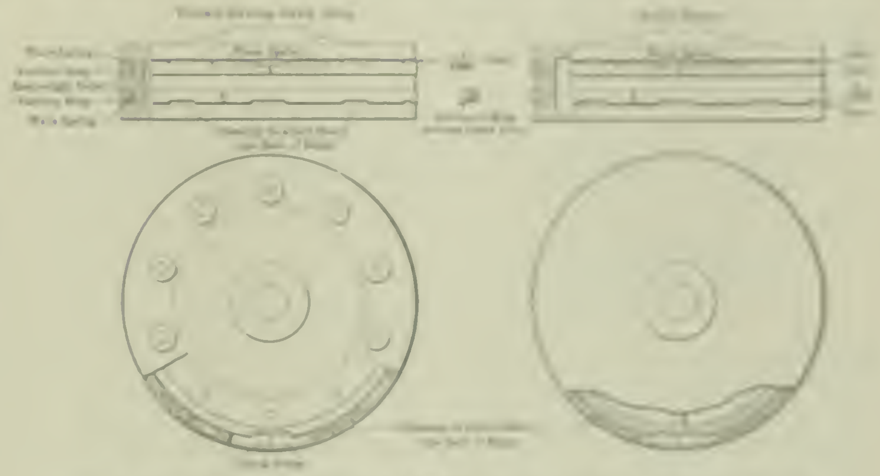

FIG. 6. [illegible] PISTONS SHOWING PATENT CHECK RINGS AND WAVE SPRINGS

carried up the rod and being drawn through the stuffing box into the low-pressure cylinders, when the engines are worked condensing.

It will be noted that the distance-piece casting also forms the bottom cylinder cover, and as this cover and the crosshead guide are bored out at the same setting and the cover afterward turned on a mandrel fitted into these two machined portions, the guide is self-centering when the cover is fitted into the cylinder.

Pistons. The design of pistons for small engines does not call for any comment, but the low-pressure pistons of compound and triple-expansion engines are usually made of wrought or cast steel. The type of piston ring almost universally used on account of its suitability for quick reversals, is one which consists of two cast-iron rings, Fig. 4, similar to the ordinary Ramsbottom rings, both being placed in one wide groove. Between these two rings is placed a strong wave spring, which keeps them against the piston flanges, and behind each ring another wave spring is fitted, which presses them against the cylinder walls. By suitably proportioning these springs excellent results are obtained. These rings, however, are not suitable for high-pressure cylinders when superheated steam is used, and most makers then adopt a restrained type of ring which is prevented from expanding beyond a predetermined amount by suitable locking tongues, pieces or lugs formed at the joint of the rings. For this purpose the Admiralty type of ring, shown in Fig. 5, has been largely used, and also the type of ring shown in Fig. 6. In this case, as will be clearly seen, check pieces are formed on the rings at the joints, and these engage with suitable recesses formed in the piston or carrier ring, as the case may be. A wave spring is also fitted to each ring to keep it against the piston [illegible] [illegible] The outward pressure is obtained by giving the rings a slight initial spring, and by allowing the steam free access behind the rings. The rings are thus steam expanded, but excessive outward pressure is prevented by the check pieces. These rings are practically self adjusting, owing to the very slight wear of the check pieces, and are working satisfactorily with steam superheated up to 300 degrees Fahrenheit.

Piston Valves. As already stated, the type of steam-distributing valve universally used is the piston valve, and what may appear surprising is the fact that almost all engine builders use either solid piston valves or valves fitted with solid floating rings. This type of valve, simple as it may appear, is very satisfactory and

FIG. 7. SIMPLE ARRANGEMENT OF [illegible] [illegible]

with the best of manufacturing [illegible] [illegible] results are to be obtained.

Valves with springs or adjustable rings are rarely used, although found to have a tendency to [illegible] [illegible] for the best [illegible]. The piston valve possesses many advantages, among which may be mentioned its simplicity and the accuracy with which it can be [illegible] owing to it being perfectly balanced. It is the usual practice to fit liners of hard, close-grained cast iron in the cylinder-valve chests for all except the smallest of engines. For compound engines up to 400 indicated horsepower, one valve placed between the high- and low-pressure cylinders is generally used. The arrangement is shown in Fig. 7, and it is certainly a very simple engine, only one valve and gear being required.

Motion Work. The marine type of crosshead and connecting rod is used by all builders, all wedge and cotter adjustments having given place to the simple cap and two bolts. For engines up to about 600 horsepower the crosshead and piston rod are usually forged in one piece, but for larger powers the two-bearing crosshead of the marine type is generally adopted so as to make it easy to withdraw the piston rods and crossheads, which would otherwise be a difficult matter. The design of these details is shown in Figs. 8 and 9.

The piston rods and crossheads are usually made of high-carbon steel, 0.4 to 0.5 per cent., mild steel being used for the connecting rods. The crosshead bushings are made of phosphor bronze, and these working in conjunction with hardened-steel crosshead pins of ample size, are very durable. The crank-pin bushings are lined with white metal in every case. Cast-iron crosshead slippers are always used. Experience has shown that even with the most perfect system of lubrication, large bearing surfaces are necessary; consequently the pressure per square inch is very low. General practice shows the maximum pressure per square inch on crosshead pins to be 900 pounds; on crank pins, 350 pounds, and on crosshead slippers, 40 pounds.

Although the piston speeds of these engines are by no means low, there has been very little tendency to cut down the weight of the parts. In the early engines the parts were made as light as possible, but apparently experience has shown that there is no necessity for this, and that it is far more advisable to make the parts of ample strength and thus to a great extent prevent buckling, should there be a slight rush of water into the engine. With a view to decreasing vibration, connecting rods are made of considerable length compared with the stroke, the average practice being between two and three-fourths to three times the length of the stroke. A few firms, however, make their connecting rods as long as three and one-fourth times the stroke.

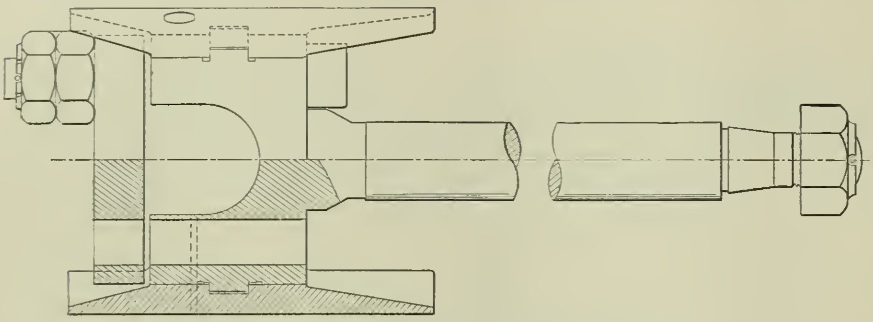

FIG. 8. CROSSHEAD AND PISTON ROD FORGED IN ONE PIECE

Valve Gear. The gear for driving the valves consists simply of an eccentric keyed to the crankshaft, driving the valve spindle through an eccentric rod in the usual way. In small engines the valve rods, together with the crosshead, are made in one piece, and the guide is generally formed by swelling out the valve rod at the bottom end, this working through a long bushing. The design of valve-rod end is similar to that of the piston rod, viz., marine type, a pair of phosphor-bronze bushings being fitted and made adjustable by cap and bolts. Eccentrics are made of cast iron, the latter being in all instances lined with antifriction metal.

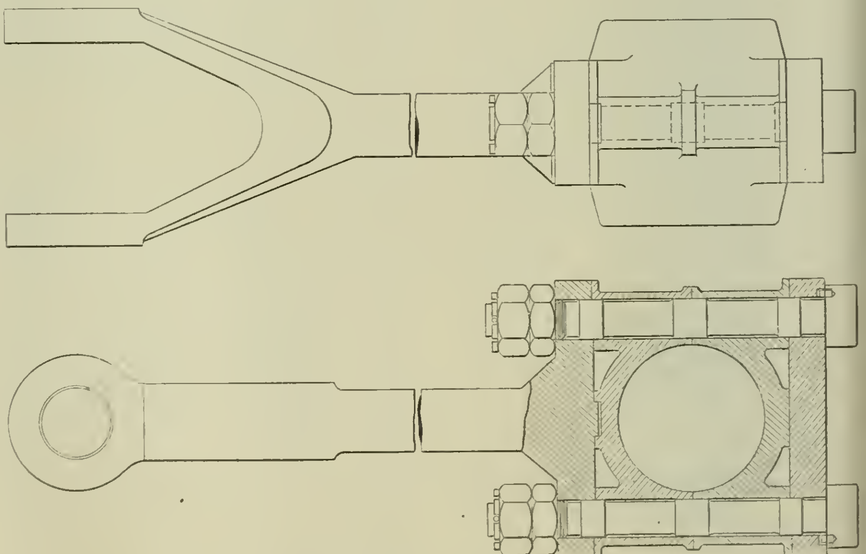

FIG. 9. TWO-BEARING CROSSHEAD OF MARINE TYPE

Main Bearings. The standard practice regarding these appears to be plain bushings of cast iron lined with antifriction metal, the bed with its caps being bored out to receive them. One large firm, however, does not fit loose bushings to the main bearings at all, but simply lines the bed and cap with antifriction metal, afterward boring the lining out in place. Gun-metal bushings for the main bearings are not fitted by any of the large firms except when specified.

It has been found in practice that cast-iron bushings are preferable, and when heating occurs due to foreign substance getting into the bearings, or want of lubrication caused by neglect, cast iron is less liable to close in than gun metal. It is the general practice not to fit liners to any of the bushings, but simply to adjust them, metal to metal, when the main-bearing bolts are tightened hard down. Owing to the ample surface provided in the main bearings of these engines and, as already stated, the excellent system of lubrication, adjustments are very rarely required and certainly not for several years.

Crankshafts. Crankshafts are made from solid forgings of Siemens-Martin acid steel to specification equal to that of Lloyds except for the largest-sized engines, in which case the crankshaft is sometimes built up of three equal parts, couplings being formed solid at the end of each portion. It is more general, however, to make shafts for engines up to 2000 horsepower in one solid piece. The strength of the shafts is somewhat greater than of shafts used in slow-speed practice, but this is principally brought about owing to the necessity for large bearing surfaces. To provide for this, with the ordinary type of shaft, would necessitate a great length of engine, and no advantage would be gained thereby. The pressure per square inch on the main bearings of engines rarely exceeds 200 pounds, this being calculated on the maximum pressure obtainable, as measured from the indicator diagram. This in most instances is the determining factor for the size of the crankshaft.

Flywheels. Owing to the high speed of rotation, the flywheels are necessarily of small diameter, the maximum speed on the rim usually not exceeding 6000 feet per minute. These wheels are made in plate form and never with arms, this design being most suitable for such small diameters and much stronger than could possibly be made with arms. Owing to the great number of impulses per minute, it has been found that wheels of a fairly good fit and simply keyed on soon work loose, and the practice today adopted by all firms of repute is to make the shaft a forcing fit for the wheel, the latter then being forced on by hydraulic pressure. In the case of large engines, if this system is adopted, the crankshaft and flywheel become a very unwieldly piece of machinery for transit, and owing to this it is usual to form a coupling solid with the crankshaft and carry the flywheel between this coupling and the coupling of the dynamo or extension shaft carrying the wheel in the case of rope driving. This arrangement was first introduced by the late Mr. Willans and it has the advantage of making a very simple flywheel casting. The flywheel practically consists of a heavy rim with an inner plate or rim suitable for attachment to the coupling.

Oil Throwers. In engines of the forced lubrication type there is a great amount of splash inside the crank case, although none of the working parts are allowed to dip into the oil. It is therefore necessary to provide means for preventing the oil leaking out at the point where the crankshaft comes through the engine base. In the early engines stuffing boxes and packing of every description were used with more or less success, but it has been found that by making a ring of the design shown in Fig. 3 oil leakage is entirely prevented. The arrangement is simple and at the same time perfectly effective. At the governor end of the engine there is no necessity for the crankshaft to come through the casing, and this is generally closed in by an oil tight door.

Causes of Engine Failure

By R. C[illegible]

When an engine gets a dose of water in the cylinder while running at full speed and, as a result, becomes more or less fit for the scrap pile, it is plainly seen that an unusual force was unexpectedly brought into action and it is interesting to look into the case a little closer and see "how it happened." The force in itself is, of course, the kinetic energy of the moving parts of the engine, principally the flywheel, the size of the energy depending on the weight of those moving parts and the velocity at which they were moving at the time of the accident. A hundred-pound weight resting on the floor does not possess energy, but in picking it up and placing it in a higher position a certain amount of work has been expended on it. This amount of work is now stored, so to speak, in the weight in the form of potential energy as long as held stationary at this higher level, but if allowed to drop back to the floor this potential energy is changed into kinetic energy and, in striking the floor, does the same amount of work as was expended in lifting it to a higher level. The same with a steam engine; when steam is admitted to the cylinder on starting up, a certain amount of work is done by the steam in bringing the engine up to speed, part of which is used to overcome friction and should not here be considered; the remaining part goes to give to the moving parts of the engine a certain velocity. As long as the engine is running at uniform speed the work done is simply stored in the moving parts in the form of potential energy, but the moment a sudden load or some obstruction, as water in the cylinder, tends to reduce the velocity of those moving parts, this stored-up or potential energy is instantly brought into play in the form of kinetic energy trying to overcome the resistance offered, the size of the force thus brought into action depending on the time during which the change occurs. In a heavy engine with a ponderous flywheel this force can easily be imagined, but consider a little 22x22-inch affair with light balance wheels, say 66 inches in diameter, running at 271 revolutions per minute. Suppose the face of the wheel rim is 14 inches and of an average thickness of 1 inch. If we disregard all the other moving parts and consider only the two wheel rims the weight of these would be

$$2 \times 66 \times 3.1416 \times 1 \times 14 \times 0.2[illegible] = 1486.606$$

pounds. With 271 revolutions per minute we get a velocity of

$$\frac{66 \times 3.1416 \times 271}{12 \times 60} = 78$$

feet per second, nearly. The available kinetic energy of the two wheel rims is then, according to the formula

$$\frac{W\ v^2}{2\ g} = \frac{1486.606 \times 78 \times 78}{2 \times 32.16} = 140,617.398$$

foot-pounds, where W = the weight of the moving parts, v = the velocity and g = gravity, 32.16. The action of this stored-up energy depends on the nature of the resistance to motion. As water is practically incompressible, if a volume of it should happen to fill the space between the piston and the cylinder head during the compression period of the stroke, when there would be no outlet for it, the action would be identical to the force of a blow. To determine the force of this blow it is necessary to know the time required to bring the moving parts of the engine to rest, if they actually come to rest, which is not at all likely, it resulting in only reducing the velocity the amount of reduction must be known. As such figures are not available, suppose for an instant that the different parts of the engine are of sufficient strength to withstand this blow, i.e., actually to stop the engine without straining the different parts beyond the elastic limit; but that the strain, such as bending of the spokes in the wheel, torsion in the shaft and compression of connecting rod and piston, allows of a movement at the wheel rim of, say, 3 inches or ¼ of a foot from the time the piston brought up against the solid body of water until all parts are at rest. The force developed at the wheel rim would then be the kinetic energy divided by the distance through which it acts in feet, or

$$\frac{140,617.398}{\frac{1}{4}} = 562,469.592$$

pounds. In the sketch diagram shown suppose this force is active at the end of a lever [illegible] feet in length (the radius of the wheel). As the crank pin is only 11

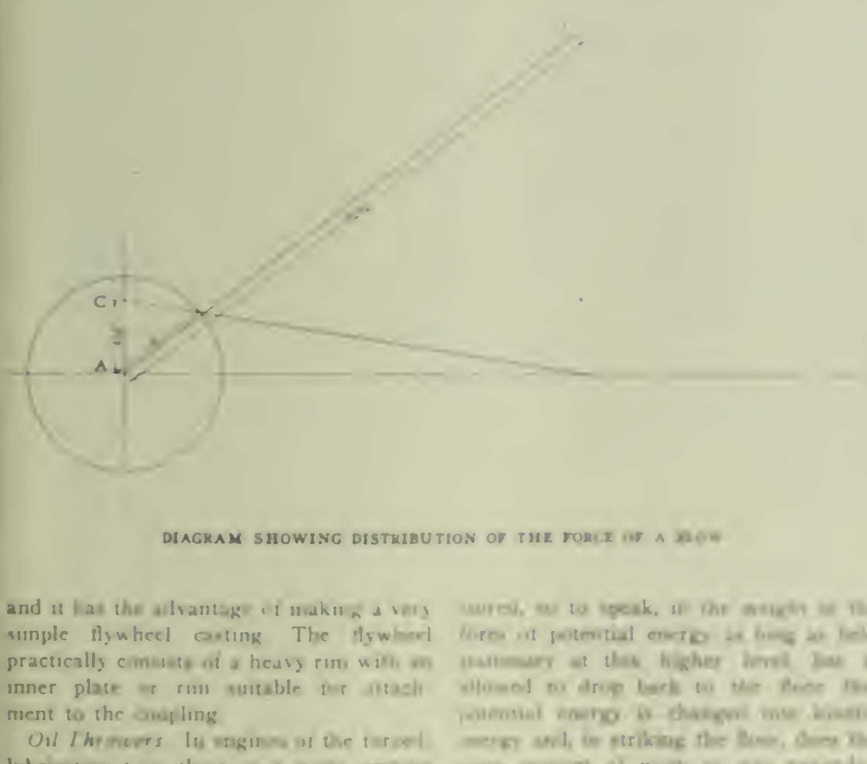

DIAGRAM SHOWING DISTRIBUTION OF THE FORCE OF A BLOW inches from the fulcrum of this lever, the force at this point is correspondingly greater and, the crank and connecting rod forming a toggle joint, the force or pressure is distributed toward the shaft journals as well as against the cylinder head, which explains the broken journals or split and cracked frame which are often a result from a dose of water in the cylinder. Considering the thrust against the cylinder head alone, if the crank should be in the position shown in the diagram, the distance *C A*, which we get by prolonging the line representing the connecting rod until it intersects the vertical center line, would be about 4½ inches. The thrust on the head would then be

$$\frac{562{,}469.584 \times 32\tfrac{1}{2}}{4\tfrac{1}{2}} = 4{,}062{,}280.329$$

pounds, or

$$\frac{4{,}062{,}280.329}{12 \times 12 \times 0.7854} = 35{,}918.233$$

pounds per square inch, all on the assumption that the engine was strong enough to withstand the shock. No engine, however, is built to do so and some part is smashed long before the full kinetic energy has been developed.

Cost of Producing Electricity

E. A. Ashcroft, in a paper recently presented to the Faraday Society, estimates the cost at which electricity can be produced in a 5000-kilowatt plant as £8 6s. 6d. per kilowatt-year for steam, £6 18s. for gas engines and £7 4s. for oil engines. The items are fuel, labor, upkeep (comprising maintenance and depreciation) and capital charges. He divides water power into two classes: first-class powers yielding an even supply all the year round without high cost of regulation or of development, with which sort of a plant he estimates that a kilowatt-year can be produced for £2, made up of fuel, 6s.; upkeep, 8s.; capital, 13s.; royalties on rights, 13s. The cost for water powers of the second class he estimates at £5 6s. per kilowatt-year, made up of fuel, 8s.; upkeep, 13s.; capital, £4 2s.; royalties on rights, 3s.

Mr. Ashcroft was quite aware that water powers of his first class are not often met with. He mentions a development near Vacheim on the Sogne Fjord capable of yielding 7500 kilowatts, or 1000 horsepower, which can be developed for less than £5 per horsepower, including payments for dam rights. At Meraker, near Trondhjem, 3000 horsepower had been sold at £1 5s. 6d. per electrical horsepower on a seven-year contract, and at Notodden (the Birkeland Nitrate Works) the price was £1 8s. per horsepower for 3000 electric horsepower. Water power is being more closely studied than it used to be; several governments, Swiss, Bavarian, Würtemberg and others, have now taken up the problem quite seriously.

A New Departure in Flexible Staybolts*

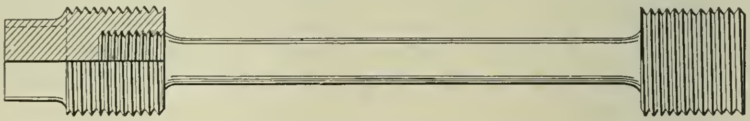
The increasing size and pressure of boilers makes this subject of vital importance to those who are responsible for the management of that type of boiler in which the firebox is stayed by a large number of bolts.

In recent years some form of flexible staybolt, that is, one having a movable joint, has been very extensively used in the breaking zone of locomotive boilers, but their high cost and the difficulty of applying them, their rigidity from rust and scale and the fact that their use throws an additional service on the adjacent bolts because of lost motion has militated against their more general use.

It is well known that staybolts fail not because of the tensional loads upon them, but from flexural stresses induced by the vibration resulting from the greater expansion of the firebox sheets than of the outside sheets; but notwithstanding the general acceptance of this theory, engineers have designed staybolts solely with respect to the tensional loads. It is quite general practice to recess the bolts below the base of the threads and this has effected a slight reduction in the fiber stress, but practically no effort has been made to design a bolt to meet the flexural stresses or even to calculate their magnitude. The stress increases in direct proportion to the diameter and decreases as the square of the distance between the sheets.

It is obvious that the remedy does not lie in the use of a slow-breaking material, but in the employment of a material of sufficiently high elastic limit to meet the conditions of service. It is also possible to reduce the diameter of the bolts greatly by the use of such a material, thus proportionately reducing the fiber stress in flexure.

Staybolt material, however, must possess sufficient ductility to enable the ends to be readily hammered over to make a steam-tight joint and to afford additional security against pulling through the sheets. To meet these conditions the bolt shown herewith has been designed, of the same grade of steel as that used in the manufacture of springs. It is oil-tempered and will safely stand a fiber stress of 100,000 pounds per square inch. Its high elastic limit makes it possible to reduce the diameter to ⅜ or 7/16 of an inch, or even less. The ends are of soft steel and it is thus possible to apply and head up the bolts in the usual manner.



FLEXIBLE SPRING-STEEL STAYBOLT

Tests were made of such a bolt in comparison with ordinary iron bolts by clamping one end of the bolt in a machine and revolving the other end through a radius of 3/16 of an inch, the specimen being 6 inches long from the end of the right head to the center of the rotating head. A tensional load of 4000 pounds was also applied to the bolt. A 1-inch iron bolt having an actual breaking strength of 32,500 pounds and weighing 20 ounces broke with 6000 such vibrations. An iron bolt ⅞ of an inch in diameter, having an actual breaking strength of 24,500 pounds and weighing 15 ounces, broke with 5200 such vibrations, while a spring-steel stem bolt, 1 inch in diameter at the end and 7/16 inch in the stem and with an actual breaking strength of 32,000 pounds and weighing 10 ounces, withstood 500,000 such vibrations without breaking. On some such bolts the test was continued to a million vibrations without failure. The paper contains a calculation to show that with staybolts spaced 4 inches apart and with a temperature of the inside sheet of 400 and of the outside sheet of 100 degrees, the expansion between two bolts will be 0.0079 of an inch and each bolt will deflect 0.00395 of an inch. This amount of deflection will stretch the usual type of bolt beyond the elastic limit. In practice, however, one bolt may hold rigidly, throwing the entire deflection on the adjacent bolts, or neither bolt may deflect and the sheet will then buckle. The author figures that under the conditions assumed and supposing the bolts to be rigid, the sheet would buckle ⅛ of an inch, which must ultimately lead to a crack in the furnace sheet. If, however, the bolt deflects, allowing the sheet to normally expand, the latter will be relieved of the extraneous load.

A bolt of sufficient flexibility to deflect under the forces following expansion and of material which will not be stretched beyond the elastic limit in resisting these forces will greatly assist in reducing the cost of boiler maintenance by eliminating broken staybolts and reducing the stresses in the furnace plates. If, in addition, the bolt has a smaller diameter, the life of the furnace plate should be farther increased, as such bolts will interpose less obstruction to the circulation of the water in the water legs.

*Abstract of paper by H. V. Wille presented before the American Society of Mechanical Engineers.

One advantage in using large boiler units is the reduction in heat units lost by radiation per pound of coal burned and pound of water evaporated.

The Installation of Direct-Current Motors

Plain Directions for Setting Up and Operating Motors, with Some General Rules, Observance of Which Will Insure Excellent Results

BY R. H. FENKHAUSEN

When installing motors of any type, one of the first requirements is a knowledge of the proper size of wire to use. Many excellent wiring tables have been compiled for this purpose, but in case none is available the following formula will give the correct size:

Let *c.m.* = Circular mils in required size,
D = Distance in feet one way,
I = Current in amperes at full load.

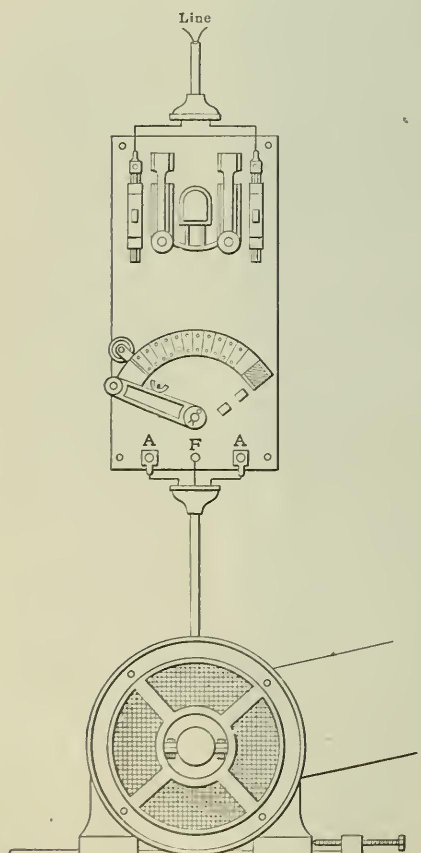

FIG. 1

V = Volts lost in line,
21.5 = Constant = resistance of a two-wire circuit 1 foot long, of wire 1 mil in diameter.

$$c.m. = \frac{I \times D \times 21.5}{V}$$

Example: Twenty-five amperes at 110 volts must be transmitted 300 feet with 5 per cent. drop; 5 per cent. of 110 volts is 5.5 volts. Substituting the known values for the corresponding letters of the formula:

$$\frac{25 \times 300 \times 21.5}{5.5} = 29{,}318.$$

This is the required cross-section in circular mils, and it will be found by reference to Table 1 to fall between Nos. 5 and 6 of the standard sizes; either of these sizes will be close enough for practical use, or one wire may be run of each size for closer results.

The full-load current taken by various motors may be obtained from Table 2, calculated by the formula

$$I = \frac{H.P. \times 746}{E \times e},$$

where
I = Current in amperes,
H.P. = Rated horsepower of motor,
746 = Watts in 1 horsepower,
E = Voltage of circuit,
e = Efficiency, varying from 50 per cent. in very small motors to 95 per cent. in large motors, 87 per cent. being an average efficiency for moderate-sized machines.

The result obtained by use of this formula should be increased by 25 per cent. at least, to allow for overloads on the motor.

The wiring may either be run open or inclosed in iron conduit, but around industrial plants open work will usually give better satisfaction when large-sized wires are to be run, owing to the greater facility in installing the wires and accessibility when repairs, alterations or extensions are to be made to the distribution system.

Separate Supply Circuits Desirable

Separate circuits should be run for motors; if they are supplied from lighting circuits the rush of current at starting will cause disagreeable fluctuations at the lamps. This applies particularly to elevator and other motors requiring frequent starting and having widely varying loads. In cases where the 110-220-volt three-wire system is used to supply both lamps and motors, no motors larger than ¼ horsepower should be connected to the neutral and one main wire, or serious unbalancing of the system will result.

The supply line to each motor should terminate at a starting panel containing the fuses or circuit-breaker, main switch and starting or speed-regulating rheostat. The fuses should be of the inclosed type and their proper capacity may be ascertained in the same manner as that of the line wires, except in such cases as where a starter with an overload release is used or where a circuit-breaker is used in addition to the fuses. In these cases the fuses are not intended to blow unless the

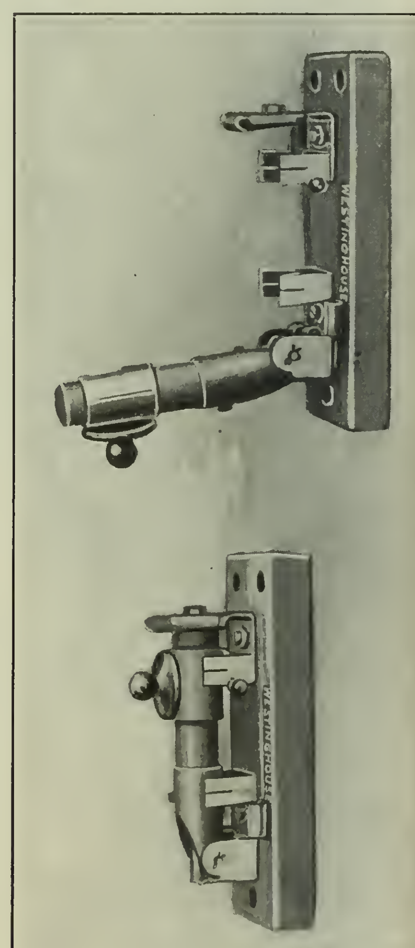

FIG. 2

overload-release or circuit-breaker should become inoperative, and therefore they should be of greater capacity than when they are used as the only safety devices. Table 3 gives the fuse ratings recommended by one of the largest controller manufacturers in the United States.

Switches and Connections

All switches for currents in excess of

25 amperes should be of the quick-break type, as the arc drawn by opening a direct-current circuit is much more destructive than one formed with alternating current. Self-contained motor panels carrying all necessary apparatus are on the market and their use is advisable, where the slight extra cost will not be a detriment. Fig. 1 shows such an installation. Fig. 2 shows a cheap but reliable single-pole carbon circuit-breaker recently placed on the market, and intended as a substitute for fuses. It is made in capacities up to 75 amperes at 250 volts, on direct current, and when installed one in each lead of

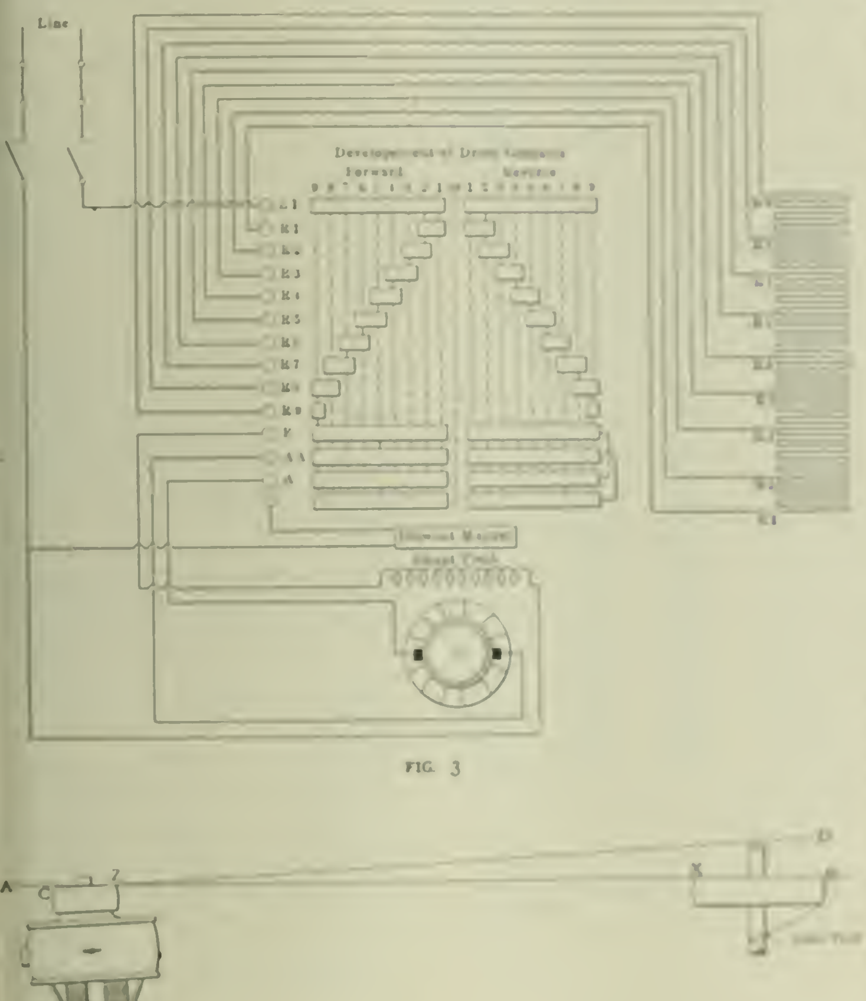

FIG. 3

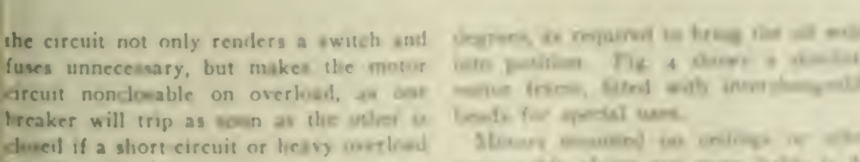

FIG. 5

the circuit not only renders a switch and fuses unnecessary, but makes the motor circuit nonclosable on overload, as one breaker will trip as soon as the other is closed if a short circuit or heavy overload is still on the line.

Fig. 3 shows complete connections for a motor with regulating and reversing controllers. When a large machine is driven separately by its own motor an ammeter should be connected in its circuit and mounted on the motor panel in order that the operator may avoid overloading the motor, by observing the ammeter indications. If this ammeter be of the record-ing type it will give a valuable record of the time the machine is idle, the load fluctuations and the manner in which the controller is handled; this will usually make the operator more careful, with a consequent decrease in power and repair bills.

Motor Frames and Location

The "heads" or journal brackets of nearly all motors are bolted on with four bolts or some multiple thereof, which allows the same motor to be mounted on the floor, wall, or ceiling simply by rotating the heads through 90 degrees or 180 degrees, as required to bring the oil wells into position. Fig. 4 shows a standard motor frame, fitted with interchangeable heads for special uses.

Motors mounted on ceilings or other inaccessible places are more liable to be neglected than if placed where they can be easily inspected; therefore, motors should, if possible, be located in a clean, dry and well-lighted place where any accumulation of dirt or grease will be readily noticed by the attendant. When a motor must be set close to a wall, the pulley side should always be away from the wall; this will not only make the commutator and brushes more accessible but allow the belt to be laced where it is out of the way. When locating a motor, especially a larger one, do not forget that it may be necessary to dismantle it for repairs some day, and leave room to remove the armature without shifting half the machinery in the shop; also bear in mind that the load that a motor can safely carry is governed by the allowable heating and that, therefore, a motor inclosed in a box without ventilation will only carry about three-fourths of the load that could be carried if the motor were given proper ventilation. The ratings of open, semi-inclosed and wholly-inclosed motors illustrate this very effectively. Because of the poorer ventilation of the two latter types they are given lower ratings by the manufacturers than open motors of the same size and windings.

Setting Motors on the Foundations

The frames of 120-volt to 250-volt motors should be insulated from the ground, but on circuits of 500 volts or over the motor frame should be well grounded to prevent injury to the attendant in the event of a ground in the motor

FIG. 4

winding. Before attempting to bolt a motor to its foundation one should make sure that the foundation is perfectly true and level, then locate the slide rails as close as possible, setting them with the adjusting screws at opposite ends, as illustrated in Fig. 4, but do not bolt them down. Place the motor in position on the rails and line it up with the driven pulley. A silk line should be procured and be tied of a bolt, stretched across the face of the driven pulley, as indicated by the line A—B, Fig. 5, one man holding the line taut at the point A and the other signaling to him when the line barely touches at the point B. The line is now secured at A and the motor moved until both edges of its pulley just touch the line. Some men go this far and call the motor lined up, but if satisfactory results are desired a line should be placed around the edges of the motor pulley and be tied of a bolt stretched away from the driven pulley. The line C—D shows the result (exaggerated), which must be corrected by shifting the motor around until the lines A—B and C—D coincide. If the two pulleys are of different width, an allowance of one-half the difference in the faces must be made when lining up.

After the motor is lined up the rails should be bolted down and the motor moved toward the driven pulley as far as possible before taking the belt measurement, which will allow maximum adjustment before it becomes necessary to shorten the belt. Whenever possible the driving stretch of the belt should be the lower one. The pulleys should be as far apart as conditions will allow; the belt may then be left slack and a large arc of contact with the pulleys obtained, decreasing the wear on the belt, bearings and shafting and materially reducing the friction loss of the drive and the motor current in consequence. The belt should preferably be endless, but under no consideration should a belt fastening be used that is thicker than the belt itself; if it is, a disagreeable jar will be felt each time the joint strikes the motor pulley. In putting on an endless leather belt care must be used not to run the belt against the laps; otherwise the thin edges of the laps will gradually loosen until the pulley catches them and rips the belt apart. Before starting a motor be sure that the bearings are filled with a good quality of engine oil, and see that all oil rings rest on the shaft and turn with it. If the brushes are not fitted to the commutator a piece of sandpaper should be held around the commutator with the rough side up and the armature rocked back and forth until the brushes are properly fitted, after which they should be set on the neutral point. The "no-load" neutral point is usually located at the factory by chisel marks on the rocker arm and frame. For reversing the motors the brushes should be set exactly on this point, but for nonreversing motors they should be moved back slightly in the direction opposite to the rotation of the commutator, until sparkless commutation is obtained with full load. When reversing motors are heavily loaded running in one direction and only lightly loaded when reversed, "back lead" should be given the brushes for the direction of rotation in which the motor is heavily loaded.

Starting Up and Shutting Down

In starting up, first close the main switch and then slowly cut out the resistance until full speed is reached. If the motor runs in the wrong direction it must be shut down and the brush leads reversed. In series- or shunt-wound motors, either the brush or the field connections may be reversed to change the direction of rotation, but for compound-wound or interpole motors, the brush connections alone may be changed; otherwise there is danger of reversing the series or compensating windings. For this reason it is well to adopt the rule of changing the brush connections, regardless of the kind of winding. If the series winding of a compound-wound motor is reversed, the application of a heavy load to the motor is liable to cause the series-field winding to overpower the shunt winding and possibly cause the reversal of the motor, with disastrous results. A sure test for the series-field connections is to put a light load on the motor and then short-circuit the series-field winding. If the speed of the motor increases the connections are correct, but if the motor slows down the series winding is reversed and should be changed immediately.

When shutting down a motor do not pull the rheostat arm away from the retaining magnet, but open the main switch and the rheostat will release as soon as the motor slows down. Many operator are puzzled by the fact that the retainin magnet does not release the rheostat arn until the motor speed has dropped abou 50 per cent. This is due to the fact tha the retaining magnet is energized by th counter-electromotive force of the arma ture, which also keeps the shunt-fiel winding excited, until its speed is no lon ger sufficient to hold up the voltage.

The shunt-field circuit of a motor mus never be suddenly broken, even thoug the armature be stopped, as the sudde opening of a highly inductive circuit, suc as that of a shunt-field winding, causes a induced voltage greatly above the norma voltage at the terminals of the winding, the circuit is broken very quickly, an this may puncture the insulation of th motor windings. If the circuit must b broken it should be done by graduall drawing an arc until it breaks. Mo motor starters are so connected that th field winding discharges the induced vol age through the armature and resistanc when the rheostat arm flies to the "off position.

Curing Warm Bearings

In case the bearing of a motor becom too warm do not stop the machine, b cause the babbitt will contract and gr the shaft and necessitate rebabbittin keep the machine running slowly, with th load off, and keep pouring cool oil on th bearing until it cools down to a sa working temperature. The motor ma then be stopped and the bearings shou be removed and any slight roughness c the shaft or bearings removed with a fi or scraper; the bearings should then l calipered and if not too loose may be r placed. If, however, the bearings a badly cut, there is no remedy save r babbitting.

When the fuse or circuit-breaker in motor circuit opens the circuit, the ma switch should be opened the first thin Then the circuit-breaker (if there is on should be closed and again tripped l hand to make sure that burning of th contacts has not rendered it inoperativ The breaker should then be closed (or th fuse replaced) and the motor started usual. If the fuse or the breaker aga "blows," trouble must be looked for the motor, as will be explained in a subs quent article.

In plants where many motors are use, the various departments should divided into routes and these rout should be so laid out that one of th motor inspectors will visit each motor least twice each week. The inspect should carry an oil can and keep all wells filled to the proper hight, being car ful to remove the side plugs when fillin in order to avoid getting the wells t full. He should also inspect the bearin and by testing the air gap satisfy hims that they are not dangerously worn. T commutator should then be inspected a if necessary smoothed down with sandpaper (never emery cloth), after which the brush tension should be tested by raising each brush from the commutator, being careful that all brushes of the same group are in contact with the commutator before raising any brush of that group. If the commutator needs lubrication it should be lightly touched with a clean, slightly oily rag (never use waste) and the surplus oil immediately removed with a dry cloth.

Lubricants for Cylinders

By John M. Sewell

A perfectly smooth surface exists only in theory. With the most modern appliances it is possible at the best to produce only a comparatively smooth surface and when two surfaces of this kind come together in sliding contact, their roughness is evidenced by the frictional resistance to the motion and the wear of the surfaces in contact. The interior surfaces of the cylinders fitted with the reciprocating pistons, together with pistons themselves, form excellent examples of surfaces in sliding contact. Lubricants are used to reduce both the frictional resistance and wear. This is accomplished by interposing a thin layer or film of the lubricant between the two moving surfaces, filling up the minute depressions and preventing the very small projections of one surface from engaging with and dislodging similar projections on the other surface.

The question of cylinder lubrication is an attractive one, and it is one that is extensive in its scope. However, for the purpose of discussion, all cylinders requiring lubrication may be grouped under four heads or classes: First, the cylinders of the steam engine; second, the cylinders of explosive motors or gas engines; third, the cylinders of air compressors and ammonia compressors; fourth, the cylinders of pumps and hydraulic machinery. These classes may be farther distinguished by the position of the cylinder, whether vertical or horizontal.

It has been argued that oil, or its equivalent, need not necessarily be used on sliding surfaces, but that water will serve the purpose. This cannot be denied, for when water is used, it forms a film between the moving surfaces and reduces the friction. But water cannot by any means replace oil or grease as a lubricant.

Water lubricant has been used in several types of engine, but without much success, and in every case where other lubrication is practical, it would be advisable to inquire into the effect on the coal pile before coming to any definite conclusion regarding the economy of that kind of lubrication for use in engine cylinders. It is clearly impossible to avoid the use of some sort of lubrication in a majority of cases, no matter how easily water may work under certain conditions.

The Conditions to be Met

The question is, then, to obtain the lubricant for the existing conditions and no one can tell these conditions better than the man in charge of the machinery, for the conditions are not always the same in all cases. Some conditions to be met with are: First, the iron of which the cylinders are made is different and needs better lubricant; second, the location of the valves may be different, which would make necessary a better kind of lubricant; third, high temperature, due to heat of steam, the heat caused by compression, or the heat generated by the combustion of the charge in the explosive chamber; fourth, water due to the condensation of steam on account of the cooling effect of the cylinder walls; fifth, water retained by the steam and carried over from the boilers into the cylinders, which may often contain many troublesome impurities; sixth, friction due to the pressure of the pistons and valves against the walls of the cylinders and steam chests.

As a consequence of these conditions, a cylinder oil or other lubricant to be valuable must possess the following characteristics: First, it must have a high flashing point or point of decomposition under the effect of the heat; second, it must possess sufficient body to keep the surfaces free from contact under pressure; third, it must be as fluid as consistent with pressure conditions; fourth, it must be capable of resisting the action of the atmosphere; fifth, it must be free from corrosive action upon the metals of which the surfaces are composed. It can therefore be seen at a glance that the conditions cannot be met with any simple lubricant, but must be compounded.

The selection of a cylinder lubricant therefore necessitates a study and long experience of the conditions of the temperature, pressure, speed and condensation, and a great deal of watchfulness. In the first place if you have a poor oil the damage is done before you are aware of it.

It is not an easy matter to determine what lubricant is best adapted for the particular cylinder, but when this has once been determined, this grade should be used persistently, as long as it gives satisfaction. Much of the trouble due to the cutting and scoring of the valves, pistons and cylinders is due to the use of poor cylinder lubricants.

It has come to be a generally accepted statement, upheld by years of experience, that the best lubricant for cylinders is a mineral compounded oil of good body with high flashing point, for a purely mineral oil contains a great number of good qualities which go to make a suitable cylinder compound.

The Different Classes of Oil

Oil is divided according to the sources from which it is obtained into three classes: Mineral oil, such as produced from oil wells and bituminous shale by the process of distillation; vegetable oil; animal oil. Vegetable and animal oils possess certain properties which make them totally unfit for a cylinder compound. They decompose easily and if the atmosphere is warm and moist, the decomposition becomes greatly increased. These conditions of heat and moisture exist in every steam cylinder, and to a certain extent in the cylinder of explosive engines. Hence the use of either of these oils must be regarded as contrary to good practice.

Let us note just what takes place when either of these two oils is used in the makeup of a cylinder compound. Tallow is a compound of stearic acid, or a stearine compound of carbon, hydrogen and oxygen. When it meets with steam or hot water the action of the heat decomposes the tallow to a certain extent and a portion of the decomposed atoms, combined with a portion of the hydrogen and oxygen of the water, form new compounds, so that where originally there were stearine and water, there are now stearic acid and glycerin. This stearic acid being in a free state is now left to attack the metal of the cylinder, which it does with great vigor, pitting the surfaces of the cylinder, pistons and valves until they are ruined or, as in many cases, to such an extent that the cylinder is blown to pieces. The same action would take place if palm, vegetable or lard oils were used. For in palm oil we get palmitic acid and in the lard or vegetable oils we get oleic acid set free. Both of these acids would attack the cylinder just as stearic. These disadvantages precluding the use of fatty oils leaves the field open chiefly to mineral oils.

As previously stated, mineral oils for lubrication are obtained from crude oil by the process of distillation. The heavy oils used for cylinder lubricants are those left in the stills after the distillation is almost complete; they represent the least volatile components of petroleum. When a quantity of crude oil is placed in the still and subjected to the action of the heat, the first product vaporized and driven off is crude benzine. This product is from 100 to 300 degrees Fahrenheit. If the temperature is then raised, a second series of distillates will be formed, including illuminating oils. These are driven off by raising the temperature from 300 to 575 degrees. There then remains in the still a thick heavy residuum [illegible] from which paraffin [illegible] lubricating oil and [illegible] it is common to use [illegible] the following [illegible] cylinders, and the lubricant [illegible] to some of the engines [illegible] where a greasy lubricant can be used with efficiency.

Specific Gravity and Viscosity

At first the ordinary lubricant oils were obtained from the residuum by further heating and distillation, but this destroyed many of their valuable lubricating properties. At present, this residuum is treated in a vacuum, or in superheated steam, which prevents decomposition of the distillate and preserves its lubricating properties. The first products of this final distillation are the higher machine oils and the last products are for the heavy machine and cylinder oils. At one time the specific gravity of an oil was made the criterion by which it was judged and selected. That is, the oil possessing the highest specific gravity was thought to be the best suited for cylinder lubrication, but this theory was soon exploded when it was found that some of the machine oils possess more specific gravity than the more viscous oils.

Then viscosity was made the standard of comparison and this to a great extent is the characteristic which influences the selection of oils at the present day. But even this properly cannot be relied upon, for the very reason that the viscosity may not be due to the friction and cohesion of the oil molecules alone, but to the presence of paraffin, in which case its value as a lubricant may be even less than that of an oil of less viscosity but possessing a smaller per cent. of paraffin. Farther than this, the viscosity of an oil changes with its temperature, the higher the temperature the less viscous it becomes. What is desired, then, is an oil the viscosity of which at the actual working temperature will still be sufficiently great to prevent its being squeezed out from between the rubbing surfaces under the effect of the pressure.

Another impurity in oil which lowers its efficiency as a lubricant is sulphur. This may be present owing to the improper methods of refining. To determine whether sulphur is present, heat a very small quantity of oil, say for fifteen minutes, at a temperature of 300 degrees Fahrenheit and then allow it to cool. When cool, compare the color of the treated sample with that of the untreated oil and if the treated sample shows perceptible darkening, it may be safely assumed that sulphur is in the oil.

Requisite Qualities for Cylinder Lubrication

This brings us, then, to a consideration of the qualities of the oils required for lubricating the four kinds of cylinder referred to: In selecting an oil for steam cylinders the viscosity should be proportional to the weight and the speed of the piston. The flashing point must be governed by the steam pressure carried. If this is high, then the oil should have a correspondingly high fire test. The flashing point should not fall below 400 degrees Fahrenheit in any case; and the more animal fat the lower the fire test which ordinarily calls for from 500 to 600 degrees Fahrenheit. It is most difficult to obtain a much higher test. Although cylinder walls of an explosive engine are cooled with water jackets, it is nevertheless a fact that the lubricants are subject to the evaporative effect of the intensely hot gases. To withstand this successfully an oil of high fire test is required, and for general use a pure mineral oil is the best.

For compressor work the cylinder lubricant must withstand not only great heat or cold but, probably, ammonia influences. This means either a high fire test or a low cold test, or both; and the purely mineral oil fulfils these requirements. If ammonia is used it is imperative that only pure mineral oils be used, since any animal oil in conjunction with ammonia will form soap, which in turn will cause no end of trouble in the machine and the condensing coils. Another mineral that is regarded as a good cylinder lubricant is graphite. In a finely divided or flake form it gives an exceedingly smooth skin to the metal-rubbing surfaces and at the same time considerably lowers the coefficient of friction. The main trouble with the use of graphite formerly lay in the fact that it could not be fed into the cylinder like oil, and it could not reach all the surfaces that needed lubrication. This disadvantage restricted the use of graphite for a long time to special cases for emergencies. At first an attempt was made to mix the graphite with the cylinder oil so as to get it into the cylinder at the required points. The difficulty met with, however, was that the graphite would not stay mixed with the oil and would settle to the bottom, in which case it became not only useless as a lubricant, but very troublesome. After much experimenting this difficulty has been overcome by the application of a new principle in the mixing of the graphite and oil.

Properly speaking, two oils are used at about the same specific gravity, but of such natures that they will not mix together, as oils usually do; that is, they repel each other somewhat as do water and oil. In one of the oils, called the developing oil, the graphite is thoroughly mixed and ground until every particle of the graphite is surrounded and incased by a film of oil. This mixture is added to the other oil and the grinding and mixing continued, until the distribution of the graphite is complete and uniform throughout the mixture. It has been found that this compounded lubricant works well in cylinders if properly mixed, with the right quality of oils.

In conclusion, it should be said that there is no part of an engine where so much risk is taken in changing lubricants as in the cylinders. Therefore, it is advisable, where a lubricant is giving good service, not to change a certainty for an uncertainty.

Hudson-Fulton Celebration

We have received a synopsis of the plan and scope of the Hudson-Fulton celebration, which will begin on September 25 of this year and will continue for eight days in and around Greater New York and the following week in the cities along the Hudson river, as far north as Troy, with general participation throughout the State. It will surpass anything ever attempted in any city of the Union.

The commission in charge of the celebration is incorporated and consists of 365 members appointed by the governor of the State of New York and the mayor of the City of New York. Its membership includes the mayors of all the 46 cities of the State and the presidents of 38 incorporated villages along the Hudson. The president of the commission is Gen. Stewart L. Woodford, 18 Wall street, New York, and the presiding vice-president (also acting president) is Hermann Ridder, 182 William street. The headquarters is in the Tribune building, where the secretary, Henry W. Sackett, is to be found. The treasurer is Isaac N. Seligman, 1 William street, New York City.

The purpose of the commission is to arrange for the celebration of the three-hundredth anniversary of the discovery of the Hudson river by Henry Hudson, in 1609, and the one-hundredth anniversary of the successful application of steam to the navigation of the river by Robert Fulton in 1907. Because the two historic events occurred on the same river and their anniversaries came so closely together, it was deemed advisable to postpone the 1907 anniversary and celebrate both together.

The plans for the celebration have been formulated with a view to the international, national, interstate, State and local significance of the events to be commemorated.

Saturday and Sunday, September 25 and 26, will be religious-observance days; Monday, September 27, will be reception day; Tuesday, September 28, will be historical day: Wednesday, September 29, will be general commemoration day; Thursday, September 30, will be military-parade day; Friday, October 1, will be Hudson river day; Saturday, October 2, will be general carnival day in New York City.

In all the cities, October 2 will also be Children's Day, devoted to fetes in public and private parks and playgrounds.

The upper Hudson week, which will begin Sunday, October 3, will be somewhat in the nature of an Old Home Week. Each county has been assigned a day, as follows: Dutchess county, Monday, October 4; Ulster county, Tuesday, October 5; Greene county, Wednesday, October 6; Columbia county, Thursday, October 7; Albany county, Friday, October 8; Rensselaer county, Saturday, October 9.

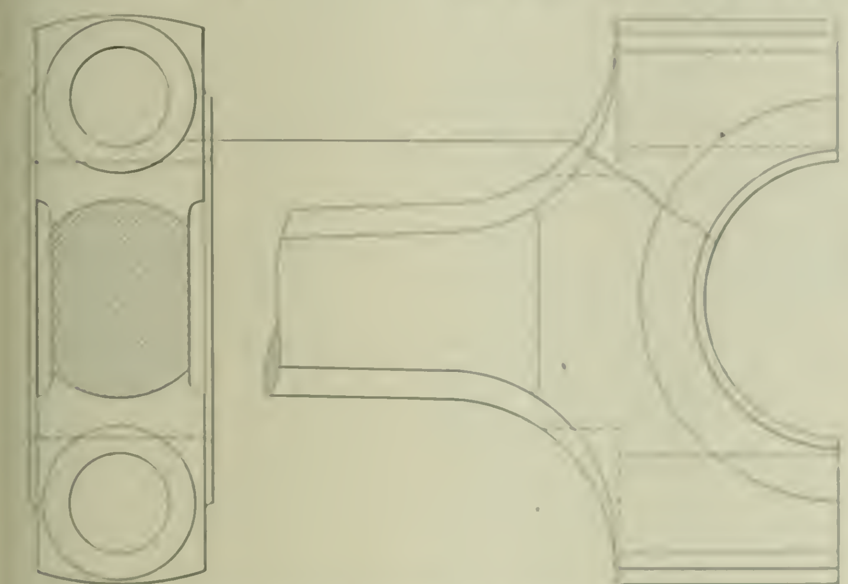
Connecting Rod Design

The accompanying illustration shows the end of a connecting rod which frac-



SHOWING THE FRACTURE IN A CONNECTING ROD

tured in service about as indicated. The side view of the rod presents an appearance of great strength, which on closer inspection is found to be misleading. The shaft blends into the enlarged end with a curve of large radius, but the good effect of this construction is neutralized by the recesses for the bolt heads, which are of such large diameter relative to the width of the rod end that but a slight amount of metal is left on each side to reinforce the weak section.

A thin wall of metal such as this, introduced for the purpose of strengthening a heavy member, in many instances does more harm than good since, while it increases the stiffness of the member, it may for that very reason render it less able to resist shock. The stress developed will be high in the thin portion, and may cause a crack which would not have occurred but for the presence of such a thin web.

In this instance the bolts were made quite large, for the reason that they had been giving trouble by breaking frequently, the break occurring under the head and not, as might have been expected, at the root of the thread. Bolts for such service as this should be made of tough, refined wrought iron or nickel steel, and should be annealed at frequent intervals.

The drawings from which this rod was made showed the cap and bolts in position, from which to study the proportions of parts.

Pittsburg, Penn.

Chute for Handling Wood

I can suggest to J. D. [illegible] a scheme which I have found very successful. Make a chute about [illegible] feet long and 6 feet wide, into which the wood is delivered. As the lower sticks are removed, the wood will keep sliding down.

The great expense would be the grading of the [illegible] road to the top of the chute and the cost of the chute, but it would soon pay for itself.

W. H. H. [illegible]

Philadelphia, Penn.

Boiler Setting

The sketch shows the setting of a boiler in a plant where I am employed. As originally set, considerable smoke and soot were produced on the bottom of

MR. [illegible]'S BOILER SETTING

[illegible]

[illegible]

making the change the smoke and soot have disappeared.

I am not in a position to state the amount of gas that has been saved, because the boiler is connected on a 6-inch main with a number of other burners. However, it is safe to say that there is a saving of gas because of the more perfect combustion.

C. S. Robinson.

Independence, Kan.

An Emergency Packing Ring

The packing ring gave way in a Corliss engine, with no new ones nearer than the factory, and the engine was needed very badly. The type of ring is shown in Fig. 1.

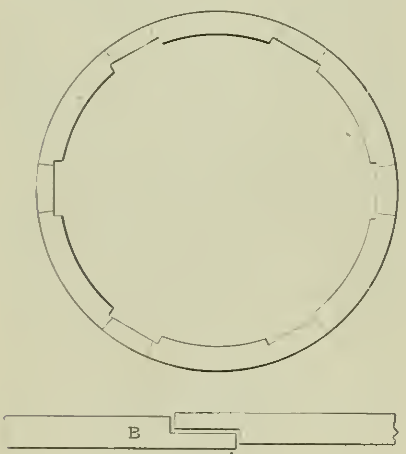

FIG. 1

Such a ring is placed in the slot of the bull ring, and held against the action of coil springs by small pins, which are inserted through holes in the rim of the bull ring, and also pass through holes in the packing ring (not shown in the sketch). These coil springs press outward against a tee-shaped piece of iron,

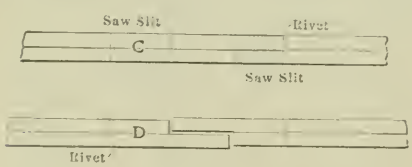

FIG. 2

the stem of the tee being inside the coil spring and the cross piece pressing against the slots shown on the inner surface of the ring. At *B* is shown how the sections overlap, making a steam-tight joint.

To make such a ring as is made at the factory is difficult, but a substitute may be easily made as follows: Two rings are bored and turned to the proper diameter for the finished rings, and the sides machined perfectly true. The two rings are then riveted together forming a single ring. At least two rivets should be placed in what is to be one section of the ring. The ring is then cut with a hacksaw, as shown at *C*, Fig. 2, after which the different sections may be separated as shown at *D*. Slots should be cut on the inner surface of the ring before the ring is sawed into its different sections. Holes should be drilled in the proper places to receive the pins for holding the ring in position on the bull ring while it is being placed in the cylinder. It is hardly necessary to state that after the bull ring is in place the pins must be removed to allow the springs to force the packing ring outward against the cylinder walls.

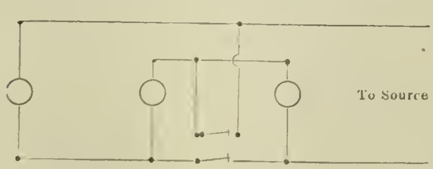
Throwing Lamps in Series and in Parallel

On page 71 of the January 5 issue, E. J. Williams asks for a diagram showing how to throw three lamps from series to parallel and *vice versa*. The accompanying diagram indicates a method using only one double-pole single-throw switch



MR. DURAND'S SUGGESTION

which, on closing, connects the lamps in parallel and on opening puts them in series.

W. L. Durand.

Brooklyn, N. Y.

I am submitting two wiring diagrams by which three battery lamps may be switched from parallel to series and *vice versa*, by means of standard switches.

The diagrams are the same except that in Fig. 1 two four-point pole-changing switches are used, while in Fig. 2 two double-pole double-throw knife switches are used. In both cases l_1, l_2 and l_3 are battery lamps; *S* and *S* are the switches. Fig. 1 shows the lamps in series using the pole-changing switches; Fig. 2 shows them in multiple, using the knife switches; *a* and *b* are common wires between the lamps.

This arrangement of wiring, for automobile sidelights and taillight makes it possible to economize on battery current while the machine is standing at the curb on the street.

It is required by law and is necessary,

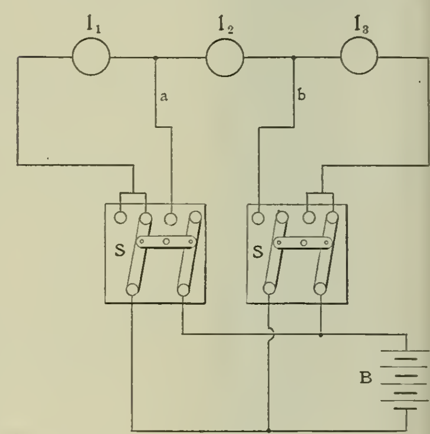


FIG. 1

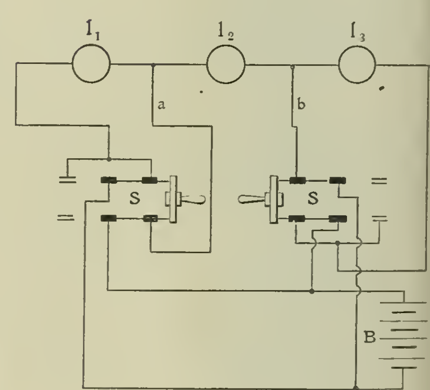

FIG. 2

to prevent accidents, to have these lights burning. When the lamps are thrown in series they draw only one-third the amount of current as when in multiple; however, the candlepower is reduced in the same proportion, but it is only necessary to have a light even though it is not brilliant. A special lever switch mounted on the dashboard of the automobile would be ideal for this wiring scheme.

J. E. Washburn.

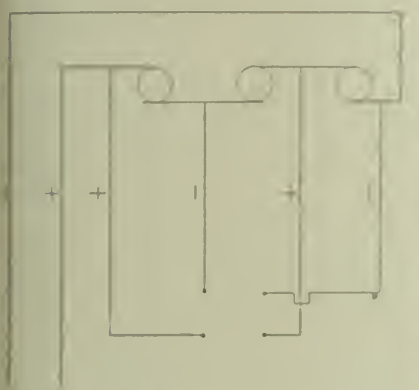
Cleveland, O.

I think the sketch herewith will solve Mr. Williams' problem, using the same source of current. If he wishes to use two different currents, however, he may employ a double-point double-throw knife switch. The switch shown in the sketch is a double-point single-throw switch.

JAMES F. DRYDEN.

Pocomoke, Md.

I inclose a rough sketch of a method



MR DRYDEN'S SOLUTION

MR. BENJAMIN'S DIAGRAM

which could be extended to any number of lamps, but would evidently be most desirable if only a few were needed.

As shown, the lamps are in series; if the switches were closed they would be in parallel.

C. A. BENJAMIN.

Philadelphia, Penn.

Effect of Scale in Boilers

If the furnace temperature of boilers averages 2000 degrees Fahrenheit, it is quite clear that the escaping gases would be 240 to 300 degrees higher before scaling than after scaling, if it were true that the scale caused an increase of from 12 to 15 per cent. in fuel consumption; otherwise, as Hilton Williams inquires, where does the extra heat go? It is very certain that 1/16-inch scale does not cause any such rise in temperature of escaping gases, and that the direct effect of scale on fuel bills is small.

But there is no justification for letting scale form in boilers, as all the deterioration and repairs to boilers arising from scale can be prevented and all the labor of scaling boilers avoided, by the use of an open heater fitted with accessory soda treatment, whereby the scale-forming impurities are arrested at nominal cost, so that the boilers can be cleaned by merely washing out with a hose.

We have installed large numbers of such heater-softeners, with the greatest success with all types of boiler, so that no occasion arises for the use of boiler compounds or tube scrapers, but the fuel saving due to heating the feed with exhaust is far more important than the fuel saving arising directly from scale prevention.

ERITH'S ENGINEERING COMPANY, LTD.

London, England.

Commutator Trouble

In reply to A. L. Baker's letter for commutator advice, I will suggest a few causes that could produce his trouble. It is understood that the smallest details are fully known, but in nine cases out of ten that is where the trouble is found. As he does not say what his load is when the bad sparking occurs, I take it for granted that he is carrying the full load.

As the machine was designed for 250 volts and only 220 volts are being carried, the proper field density is not obtained. The speed should be cut down and the field current increased. If the brushes are radial, see that each set are perfectly so. If they are angle brushes and the commutator runs against the toe, take the holders off the studs and reverse them, making the commutator run against the heel of the brush. See that there are the same number of commutator bars between the sets of brushes, and adjust the rocker arm to get the proper lead for sparkless commutation. No amount of adjusting will help if the trouble is in the brushes. Have the brushes work free in the holders and do not have them too long. A brush a little too short will work better than one too long. Adjust the tension on the brush springs to hold the brush snug to the commutator. If the line voltage drops at full load, adjust the shunt resistance to get the correct voltage [illegible].

From the nature of the trouble, I should not think it was in the armature; however, it would be well to test for opens and grounds if such has not been done. I am inclined to think the trouble is a weak field if the brushes and lead are absolutely correct.

L. E. [illegible]

[illegible], Ala.

Compression

I have often read articles for and against compression as a means of economy in the use of steam. Some engineers say they have tried it, but they do not show indicator diagrams taken with no compression while they do show diagrams taken with what they call medium compression. I judge by these diagrams that engineers are inclined to expect too much from a slight change in the closing of the exhaust valve, say 2 or 3 inches before the end of the stroke.

The accompanying sketch shows very plainly what may be expected at two points of closure. I divide the cylinder into ten equal parts, and assume one of these parts to be equal to the clearance and steam passages, designated by the space A A.

FOR [illegible] COMPRESSION

In practice the exhaust pressure is, say, 2 pounds above the atmospheric line D. Suppose the exhaust valve closed at three-tenths before the end of the stroke; the pressure would be [illegible] pounds when the piston has arrived at the end of its stroke. The pressure at the first and second points is also shown. What might be expected if the exhaust valve closed at one-half stroke is also shown.

Taking this as a standard of comparison for the compression had on an ordinary engine, how do the cards generally illustrate compression? They do not show compression to an extent that would make any difference in the [illegible] [illegible] [illegible] [illegible] pounds by compression [illegible] [illegible] all of the points, that is, compression, admission, cutoff and exhaust, [illegible] [illegible].

[illegible], Tenn.

Do Crank Pins Always Wear Flat?

An old crank of the center-crank type was brought into the machine shop. It had evidently been in use for a long time, for the crank pin was worn so small that the owner felt that it was no longer safe. One of the men measured the crank with his calipers and then told another of the men to measure the flat spots on the pin and tell which way the crank turned.

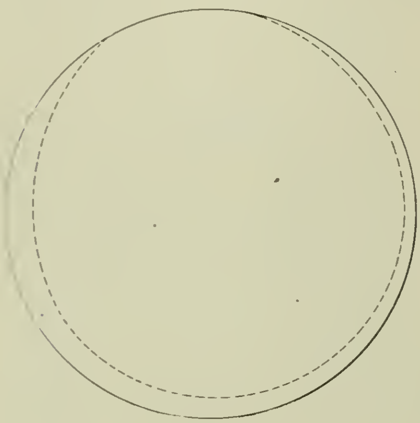

FIG. 1

That seemed tolerably easy to do, and the man took his calipers and went to the crank. A glance at the pin and bell showed which side of the pin received the pressure, for the pin was badly out of center with the bell, but the most careful calipering failed to show that it was out of round; neither could any flat spots be found.

In a discussion which had taken place about the wear of crank pins, the apparent fact that pins would always wear out of round had not been questioned, but the talk had been confined to the ultimate shape and position of the results as compared to the original position of the pin. The same question came up in another place some time later. A crank pin was examined that measured ⅜ inch closer to the bell on one side than on the other, and yet this pin was round as far as the ordinary measurements could detect.

The usual assumption is that crank pins should wear flat, and the assertion is often made that they do wear flat in steam-engine practice. The cranks referred to were from small steam engines of not over 40 horsepower, but for some reason they were round.

If it is proper and natural for a steam-engine crank pin to wear flat, it would seem even more natural and proper for a gas-engine crank to do so. I measured some worn gas-engine cranks to see how they wore. One from a 40-horsepower engine had been in hard service for about four years. It had run dry, had become cut several times and had been redressed by filing. It was practically ¼ inch smaller than when new. Two experts measured it carefully with a micrometer and pronounced it out of round not to exceed 0.002 of an inch.

One from a 20-horsepower gas engine had been in use for thirteen and one-half years. Measuring with a scale from the pin to the washer that had been faced on the bell to give the brasses a bearing showed that the pin was a full ⅛ of an inch nearer to it on one side than it was on the other, yet the micrometers showed that the pin was round within 0.0015 of an inch. This pin was 7/32 smaller than the original size.

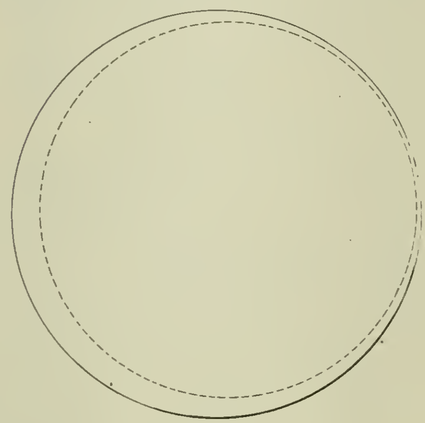

FIG. 2

A crank from a 15-horsepower gas engine had been in use more than ten years. It was more than ¼ of an inch smaller than the original size. It was 3/32 of an inch removed from its original center and was practically round, being out but 0.001 of an inch. These pins had not been carefully used and should have shown the effects of wear in a marked and unmistakable way.

It takes constant attention and careful work to have pins turned on center-throw cranks so perfect that the micrometer will not find any variation from round. Pins were measured on cranks where the engines had always received good care, and where there were no signs of cutting, and they were found to be round. Pins have been pronounced out of round by men who were not skilled in using measuring instruments, when experts found the trouble in the men and not in the cranks.

Pins from side-crank engines, if taken out and revolved on the original centers, often will not run true where the brasses bear, but this does not prove that they are not round there any more than it would prove that an eccentric is not round because it does not run true when put on a mandrel that causes the hole to run true. It may be that crank pins on larger or smaller engines than these mentioned will show different results, and it may be that engines designed differently may also do so, and if such is the case it will be interesting to know it.

In Fig. 1 the full circle represents the original pin and the dotted lines represent the shape it was thought it would assume from wear and its position in relation to the original. In Fig. 2 is shown in outline the original pin, the dotted circle representing the pin, which has been worn round but not flat.

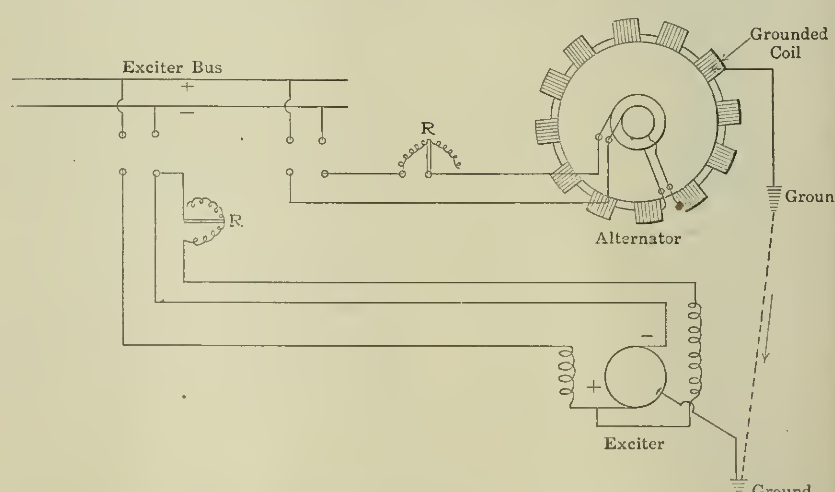
Oil City, Penn.

Trouble Caused by a Ground

The equipment in the generator room of a paper-mill power plant consisted of three 500-kilowatt three-phase 440-volt revolving-field alternators, direct-connected to water turbines. The alternator shafts were extended for driving the exciters and various other machinery. There were two 37.5-kilowatt exciters, belt-driven. No. 1 alternator carried No. 1 exciter; No. 2 alternator carried a low-pressure centrifugal pump, direct-connected and a high-pressure power pump, belt-connected; No. 3 alternator carried No. 2 exciter and the mate to the centrifugal pump. To complete the "mess" there was a gallery switchboard stuck up under the roof and a spiral stairway lead-



SHOWING HOW TROUBLE WAS CAUSED BY A GROUND ing to it. One night I went to the generator room and found the attendant acting rather dizzy. I first thought he had got a series of hurry calls up the winding stairs, but a whiff of his breath was sufficient proof that the stairs were not wholly to blame.

Soon after taking charge I found that the commutator of No. 2 exciter was damaged in a rather peculiar manner, the insulation between the bars being burned all around the outer end, and extending from one-fourth to one-third the length of the bars. A test showed the armature to be grounded and the commutator ran too warm, but the machine generated all right.

One Sunday morning the attendant wished to shut down No. 1 alternator and, therefore, changed over to No. 2 exciter. Soon after doing so he noticed that No. 2 alternator was vibrating back and forth on the base with each revolution of the field. My first impression was that the anchor bolts were loose, but a trial with a wrench showed them to be tight.

As the exciter was known to be grounded, I started testing the alternator field circuit for a ground, and discovered that about one-third of the field coils were warmer than the others. The circuit was then broken between the cool coils and the warm ones and a test showed the ground to be among the cool ones, and the first cool coil proved to be "it." When the coil was removed it was found that the insulation, although very heavy, had been punctured and a hole as large as a quarter of a dollar burned in it, thus grounding the coil on the pole piece.

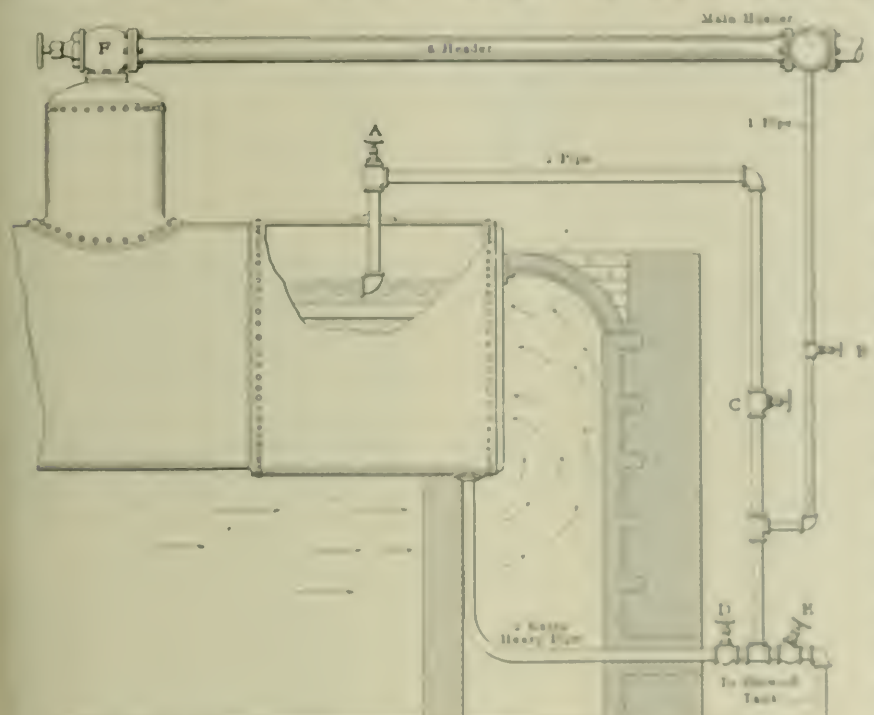
The sketch (on page 290) shows how the trouble occurred. The grounded exciter and grounded coil short-circuited some current from a part of the coils, making them weaker than the others. Undoubtedly the primary cause of the trouble was that at some time the field insulation had been punctured by inductive discharges, and the grounded exciter did the rest.

H. L. STRANGE.

Portland, Me.

A Blowoff Arrangement

The sketch illustrates a blowoff arrangement I have been using for five years. At *A* is a 2-inch angle valve on the scum blowoff, to be used in case of repairs on the blowoff valve. The scum blowoff leads into the boiler at the top and extends down just below the normal water line, with an ell facing toward the front of the boiler. At *D* is a 2-inch gate valve, and at *E* a 2-inch Y valve.



SHOWING MR. FINLEY'S BLOWOFF ARRANGEMENT

While the boiler is in use the valves *B*, *C* and *D* are open and valve *E* is closed. When I blow off the boiler, about every six hours, I close valves *B* and *C* and open valve *E*. When I have blown down enough I close valve *D*, open valve *C* and blow off the scum; then I close valve *C* and open valve *B* in the line leading to the main steam header.

With *B* open, I get practically dry steam, and the circulation in the blowoff pipe removes any mud or particles of scale away from the disk of the valve *E*. With valve *B* open, valve *E* closed and valves *C* and *D* open the condensation in the steam header flows through the 1-inch pipe by gravity and back to the boiler through the blowoff, which causes circulation enough to keep the blowoff pipe clear of mud, etc. I have not been troubled with the blowoff being stopped up in the last five years, and I do not have to renew the disk in valve *E* oftener than once a year. I am using the arrangement on two 125-horsepower return-tubular boilers.

E. R. FINLEY.

Buffalo, N. Y.

Recognizing the Staff

The editorial, "The Line Recognizes the Staff," on page 174 of the January 19 number, is in keeping with the average marine engineer's view of the matter. "Fighting Bob" Evans certainly deserves no little credit for forgetting the usual standing of the navigator so far as to admit that "the man who brought the fleet around the Horn is the man who boiled the water in the fireroom and the man who peeled the potatoes." The effect of this magnificent statement is to a certain extent spoiled, however, by the additional remark that "they have done as much to take it, step by step, as the keen-eyed officer on the deck or the gray-haired captain on the bridge." It would have been more in keeping if the admiral had compared the men boiling the water and peeling potatoes with the men on lookout and at the wheel. Other comparisons could have followed.

Who can explain the antagonism which exists between officers of the deck department as a whole and those of the engine department? Is it that the deck officer lived and had his being centuries before steam propulsion was thought of? Can it be that it exists because the engineer is in a position to command a salary in keeping with his increasing responsibilities and is at present much better paid? Then, again, it might be the engineer's natural aggressiveness that is to blame, or the fact that the engineer's uniform when on duty is a suit of overalls.

That the captain of a vessel seeking an exceptionally nice run is looked and found is due, to a great extent, to the fact that the newspaper men just report callers on the chief engineer, and, at least, we get little information on their doings, whereas the deck officers are easily reached and are ever so prone to talking. Engineers do occasionally get credit, however, as in the case of a vessel completing in New York harbor, when one of the leading papers referred to the quickness of the captain's eye and the smart work of the engineers at the levers in the matter of saving a ship. So let us be thankful for small mercies.

I want to relate a little incident that happened on my ship not so long ago.

We were hustling through the usual routine of boiler-room work in port. There were men cleaning smoke boxes, others wheeling ashes to the boiler-room at work on the furnaces and the hundred other jobs requiring doing in the short time the ship would be in port. Needless to mention, all was noise, dirt and seeming confusion, and myself in the thick of it. As the men were preparing to swing open another smokebox door I was surprised to see them hesitate and look over my shoulder and on turning was even more surprised to see the third mate, Mr. Smitzer, standing watching operations in the company of a stranger. This third mate was one of those men who, having failed in the battle of life, are fond of telling yarns of the time they were "in command," and have no little idea of their importance. He condescended to recognize my presence with a brief nod. I noticed one of my men at this point mutter to his mate and they both grinned maliciously. It occurred to me that Mr. Smitzer had had this same man logged for throwing some scraps of food in the scuppers.

On a question from the stranger Mr. Smitzer approached me with a supercilious air. The conversation that followed was interesting.

"How many boilers have we, Mr.—er —er?"

"Six." This from me.

Smitzer, turning to the stranger, who was listening to my answer, said: "We have six boilers!"

"And, how many fires in each boiler, Mr.—er—er?"

"Eight." This to the stranger, who originally asked the question.

"We have eight fires to each boiler!" This from Smitzer, impressively.

"How many men are on duty at a time?" asked the stranger, pleasantly.

"How many men have we on duty at one time?" anxiously parroted Smitzer, getting ready to enlighten the stranger in my stead.

"Twenty-four."

"We have twenty-four men on duty down here at one time. Think of it! You see," explained the garrulous Smitzer to the stranger, "we have to drive her all the time!" *We* have to!

At this moment the stranger walked across the boiler room to look into the uptake of a clean boiler, Mr. Smitzer staying behind to gaze around him with arms akimbo. Suddenly a startled yell rang out and the stranger and I turned in time to see a great stream of ashes pour from the opened smokebox. The air was filled with ashes and soot at that end of the boiler room and in the midst of it all scrambled the unfortunate third mate.

Of course, I saw to it that the men were severely spoken to, and that some of the ashes were removed from Smitzer's clothes before he returned to the deck. What is the moral? Why, there are several of them.

B. Slattery.

New York City.

Some Vertical Centrifugal Pump Troubles

We have a vertical, centrifugal, belt-driven pump in our plant, used for circulating water. As the sand which freely mixes with the water is very sharp, the casing of the pump is provided with removable liners in order to protect the interior. These linings have to be renewed every six or seven months.

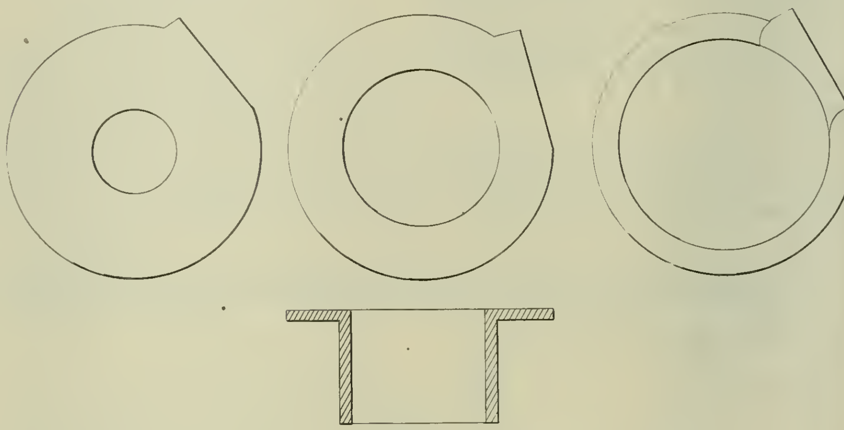


FIG. 1

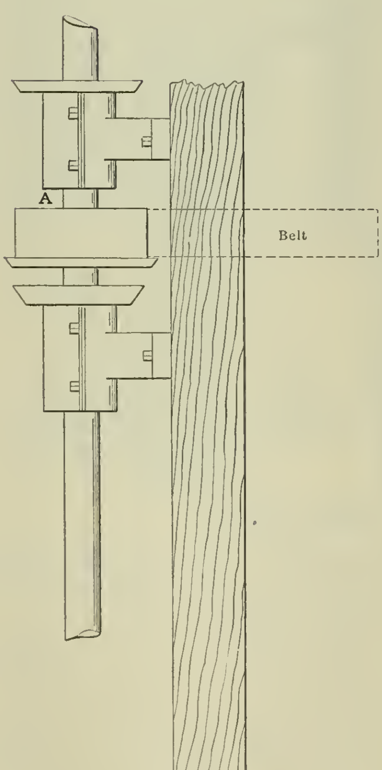

FIG. 2

Referring to Fig. 1, the first two liners are the protectors for the top and bottom of the casing, while at the right is a ring for protecting the sides.

One of the most common troubles with this type of pump is that it may not throw enough water, due to a slipping belt. The pulley on the shaft of a vertical centrifugal pump is usually placed between two shaft bearings, as shown in Fig. 2. If the operator is careless and puts too much oil in the top bearing the oil will run to the pulley, then onto the belt, causing it to slip, and ruining the belt. In order to prevent this trouble we put an oil guard around the shaft at the lower part of the top bearing as at *A*.

At one time the pump failed to pick up water. After disconnecting a flange in the discharge pipe it was found that the pipe was full of sand to the end of the outlet. As there was not ample pressure in the pump to force the sand out of the pipe, it was not able to pick up.

A common trouble experienced with vertical centrifugal pumps is that the impeller will work down, due to the support holding the shaft and impeller wearing or working loose, when the bottom side of the impeller will rub against the lower lining plate, thereby wearing this lining and lower part of the impeller out in a short time, besides causing more friction, which takes more power.

We have a gage at a convenient point on the vertical shaft by which we can see when the impeller is going too low, when it is adjusted again. Here is where an electric motor would be the thing for driving a vertical centrifugal pump, because should the impeller work down too low and rub against the lower lining, or any of the bearings wear, or be carelessly adjusted and out of alinement, the increased friction would be indicated at once by a meter connected to the motor.

H. Jahnke.

Milwaukee, Wis.

Neatsfoot Oil on Belts

In the January 5 number, page 70, Charles Haeusser writes regarding the detrimental effect of neatsfoot oil on belts. We have seven belts in our plant ranging from 4 inches to 22 inches in width, and neatsfoot oil is applied to each with gratifying results. It is in my opinion the best belt dressing one can use.

Joseph H. Jacobucci.

Rawlins, Wyo.

New Method of Equalizing Cutoff

The two sets of diagrams shown in Figs. 1 and 2 were taken from the same Corliss engine. Fig. 1 was taken with the governor as sent out with the engine; Fig. 2 was taken after I had put my improvement on. It will be seen that an even cutoff is obtained on both ends of Fig. 2, even with a variable load.

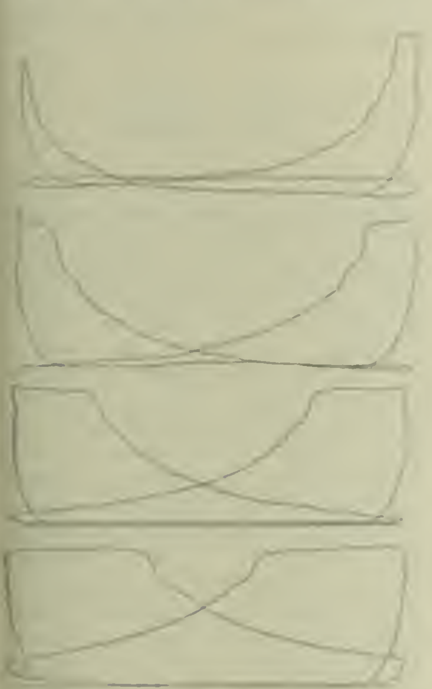

FIG. 1

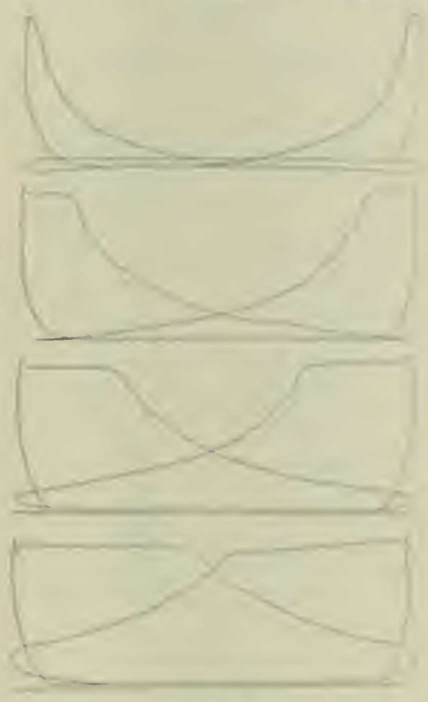

FIG. 2

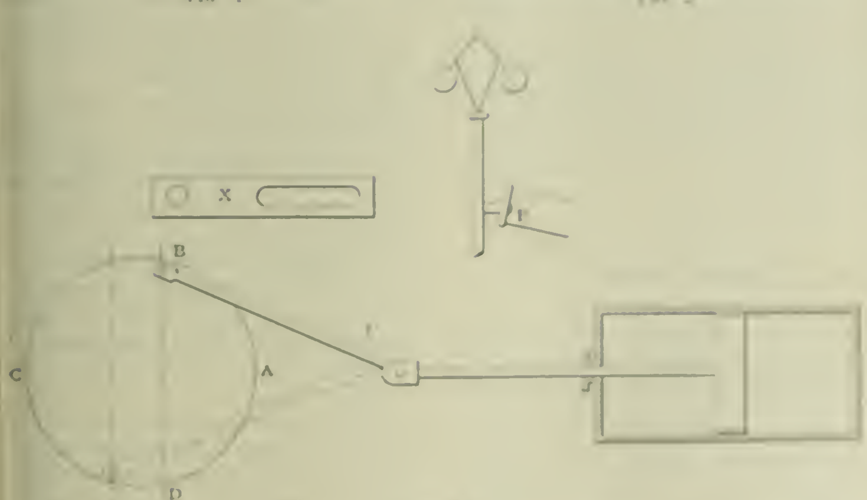

FIG. 3

By referring to Fig. 3, it will be seen that when the piston is at half stroke the pin has traveled from A to B, and the eccentric has moved the same as the pin, not quite 90 degrees, due to the angularity of the connecting rod. On the return stroke the pin travels from the outer center C to D in order to place the piston at half stroke. The eccentric has traveled a greater distance on this return stroke, as when the pin is at E the eccentric has moved the same distance as when on the outstroke from A to B, but the piston would not be at half stroke, as shown by the dotted lines. To overcome this difference in the eccentric travel the crank head valve must be left open longer at full load and close sooner at light load.

In order to do this I lengthened the lower end F of the governor rocker arm operating the cam of the crank-end valve. To determine the length I took a piece of iron, as shown at X, about [illegible] inch thick by [illegible] inch wide and [illegible] inches long, and drilled a hole in one end to bolt to the arm, and a slotted hole in the other in which to attach the reach rod. By taking a diagram with a light load and one with a heavy load, I determined the proper length and then had a new rocker arm cast and fitted to replace the old one. The longer the connecting rod in the engine, the less is the angularity, and the less should the arm be lengthened. In my case the arm was made 1½ inches longer than the original rocker arm.

Municipal Ownership

The editorial entitled "Municipal Electric Light Plants" in the issue of December [illegible] seems to have been written on the assumption that the conditions under which both plants are built and operated are ideal, or can easily be made so.

Those who are most familiar with municipal plants know that so far from this being the case the actual conditions are such as to put the municipal plant at a serious disadvantage in comparison with private plants. This is the case even if graft be left out of consideration.

The business men of a city may discuss municipal ownership as a business proposition, but as soon as it passes from the field of discussion into that of construction it passes at the same moment from the domain of business into that of politics. There lies the weak point in our argument. The affairs of our cities are not conducted in a business-like way, and until they are, all municipal undertakings will be heavily handicapped both by red-tape methods and political considerations. This is admitted freely by everyone who has occupied a municipal office and whenever a business man has had a term of office he has invariably emphasized the unbusiness-like conditions which he has found to prevail in the conduct of municipal affairs. Red-tape methods are responsible for the well known fact that, even where there is no graft, the construction of a municipal plant costs from 25 to [illegible] per cent. more than that of a private plant of the same capacity. This extra cost starts with the purchase of the land, follows through each stage of the construction and equipment, and much more than offsets the slightly lower rate at which cities can borrow money. This is a net result quite to be usually accepted [illegible] "honest graft," but favoritism and influence which are at work leading not always to criminal practices, but always resulting in the municipality paying more than a private party would pay.

Nor does this cost stop when the plant is made. It affects unfavorably the cost of fuel and supplies of all sorts, and thus increases the operating expenses above those of a private plant.

The political considerations are more far-reaching in their injurious results. The acceptance of plans, the making of contracts, and the appointment of labor are in the hands of [illegible], the members of which start with no knowledge of the business and usually remain in office too short a time to acquire more than a superficial knowledge.

The manager, to start with, is apt to owe his appointment to his political activity quite as much as to his technical and executive ability, and this is to be expected; or if this is not the case, he knows that a change of administration may bring his career to a sudden and undeserved end. His salary is always lower than it would be under private ownership, and there is not the opportunity for promotion which exists in private companies. The best class of managers are therefore not permanently attracted to municipal plants, the proof of this statement being that municipal managers are constantly seeking employment in private companies, while there is no tendency the other way. It is not true, therefore, that municipal office attracts technical ability of the highest order; just the contrary is apt to be the case.

Similar considerations affect the minor employees in the same way all along the line with the result that cities rarely get the best class of workmen, and do not get as much or as good work per employee as do private employers. Most of them know that they are not employed solely on their merits, and act accordingly, especially as the power of summary and permanent dismissal is rarely in the hands of the manager, who, by the way, is properly called a superintendent rather than a manager. It is notorious that the productive capacity of a city workman is not usually over one-half of what a private business expects to obtain and does get.

If the employees, from top to bottom, are inferior to those of a private plant of like capacity, and take a less personal interest in their work, it follows that the plant will not be run at its greatest efficiency and economy, nor will the machinery receive the same care as in a private plant. This means that there will be larger bills for repairs, that operating expenses will be heavier, and that depreciation will be greater. And experience has shown that these expected unfavorable results are fully realized in all particulars.

You say that "graft, ignorance and incompetence are not inevitable" in city undertakings of this character. That is true; there are exceptions, but they are rare. But at least two of these three disgraces are prevalent in the great majority of our American cities; and until there is a complete revolution in our methods of city government, they will continue to be the almost universal rule. The cases are so few where municipal electric plants have been operated on business lines for any extended period that the editorial referred to seems likely to be productive of serious misapprehension on the part of such of your readers as are not familiar with the conditions that actually prevail in the great majority of such plants—conditions far removed from the ideal.

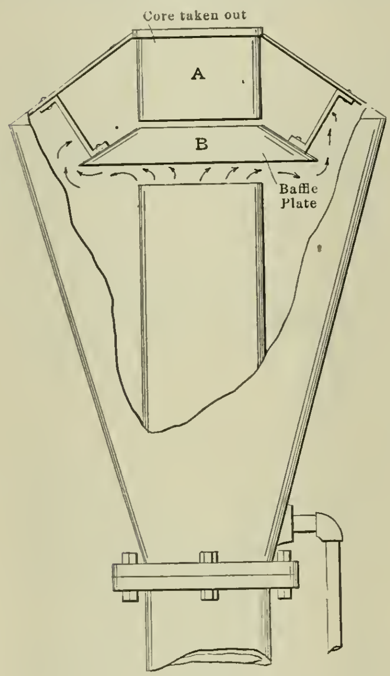
Reduced the Back Pressure

I once had charge of a plant having one engine, the indicator cards of which always showed a back pressure of 4 pounds when the back-pressure valve was up. In my hunt for the cause I examined the exhaust head and found the core *A* extended down to within ¼ inch of the baffle *B* (see illustration).

In this case, the exhaust pipe being 6



SHOWING HOW CORE IN EXHAUST HEAD INCREASED BACK PRESSURE

inches in diameter, the baffle plate should have been at least 1½ inches from the core *A*. I removed the core *A* and thus reduced the back pressure 3 pounds.

Electric Discharges

In regard to George A. Raymant's article in the December 22 issue, page 1045, he will find that if he thoroughly insulates himself from the ground and stands in a cloud of steam issuing from a leak in a high-pressure steam pipe and brings his hand near the ground or pipe, he will invariably obtain sparks. If he will get in a dark place where steam is escaping from a pop safety valve or other large leak directly into the air, he will see a halo of sparks and blue light around the leak. In fact he will see a miniature thunder storm. In his case the calking chisel was the lightning rod and it was struck with miniature lightning bolts. The electricity is generated by the friction of the steam passing through the air.

HOWARD GLUYS.

Richmond, Ind.

Natural Gas for Fuel

I noticed an article in the December 22 number by W. D. Ranney, on natural gas for fuel, wherein he says he obtains a boiler horsepower on 27.95 cubic feet of gas. Now, 27.95 cubic feet of gas is equivalent to only 27,950 B.t.u., and a boiler horsepower is $966 \times 34\frac{1}{2} = 33{,}327$ B.t.u., hence his figures must be wrong. I am assuming Ohio natural gas to contain 1000 B.t.u. per cubic foot.

Steam Piping

Having read the article, "Steam Pipe Connections," by Fred Dubell, on page 1099 of the December 29 number, I am led to call attention to that part of the article under the subhead, "Steam Pipe Should Drop Toward Boiler." This is a statement I challenge. As steam on leaving the boilers begins to condense, the water falls to the bottom of the pipe and is carried along with the steam, and it is impossible for the water to return to the boilers against the flow of steam.

I have in mind an instance of a ¾-inch vertical steam pipe 96 feet high, piped direct from a battery of boilers. This pipe ran horizontally for about 15 feet to an elevator shaft, then up 96 feet to a temporary bathroom. This pipe, contrary to expectation, always stood full of cold water, except when the valves were open at the upper end, although the boilers carried a steam pressure of 100 pounds.

In steam pipes dropping toward the boilers the water accumulates in slugs, and when the flow of steam is sufficiently obstructed it passes on to the engine cylinder, washing out the oil. Valves and valve seats are cut, also the cylinders and packing; piston rings are broken and engines are wrecked.

In twenty-five years' experience, several of which were spent in inspection service, I have never known an engine wrecked from water in steam piping, except when the pipe dropped back toward the boilers.

Steam piping should always drop toward the engine. When erected in this way the condensation is carried along with the steam, and even if allowed to go into the engine, does but very little harm. It is better practice to connect to the engine through a steam separator, or receiver, with a good steam trap to carry off the condensation. It is certainly safer, and better for an engine to operate with even wet steam all the time than to have a cylinder full of water occasionally and saturated steam the remainder of the time.

In practice the steam main dropping from the boilers to the engine in calorimeter tests always shows drier steam at he engine than where the pipe drops toward the boilers.

Combustion Formulas

In the December 15 number Mr. Neely contributed an article of real value. I have checked his charts with a number of analyses of my own, and some from various authors, and find that No. 2 chart gives results as accurately as samples can be taken in a mine.

The classifications attempted by the fuel-testing plant here at St. Louis showed that the hydrogen-carbon ratio was the most satisfactory one, and that fixed carbon alone was not reliable except in true anthracites. We used to have a rule-of-thumb method of estimating heating values for Mississippi valley coals, which was to add the fixed carbon and volatile percentages and multiply by 150. This gives too low results on the best bituminous coals and too high on the poorest.

Mr. Neely's chart is practically exact on coals of the Appalachian range, but varies somewhat in some of the Western coals. Unfortunately, the results as published by the fuel-testing plant give only two each of Colorado and Wyoming coals and these are among the poorest of the two States. For comparison I will quote three with which I have had some practical experience; two are from the past-carboniferous period of the Rocky mountains, and the third is a well recognized bituminous coal of Illinois:

	Rock Springs, Wyo.	Trinidad, Col.	Big Muddy, Ill.
	Per Cent.	Per Cent.	Per Cent.
Moisture	5.65	1.32	7.50
Volatile matter	36.96	38.23	30.70
Fixed carbon	55.70	55.86	55.80
Ash	1.80	3.59	6.00
Total combustible	92.66	94.09	86.50

According to Mr. Neely's table the combustion values would be, respectively, 14,600, 15,000 and 12,600 B.t.u., whereas the values given by the respective analyses are 13,240, 13,680 and 12,420 B.t.u. The explanation for the differences shown is that the volatile matter of the Appalachian coals is usually marsh gas (CH_4), and that of the Western coals is composed of oxygen compounds, which rob the volatile matter of a large part of its hydrogen in combustion. On the other hand, the Western coals make an excellent showing in gas producers, as the oxygen of the volatile matter is readily converted to carbon monoxide and their comparative freedom from ash and sulphur prevents the formation of clinkers. In the Wyoming coals of the southern field the sulphur content averages less than 1 per cent., and is usually present as gypsum instead of pyrite. Another characteristic is their hard structure which enables them to stand transportation and handling without crumbling. This is particularly noticeable in the Trinidad field, some of the coal closely resembling anthracite in appearance and hardness, though usually containing less than 60 per cent. of fixed carbon.

Kent's table, given by Mr. Neely, gives approximate results for most steam coals, but I do not like any estimates based on coal, dry and free from ash. It has been said that one could prove anything by statistics. The situation here in St. Louis is this: A representative coal of Illinois has a formula something like the following:

Moisture, 12 per cent.,
Volatile matter, 33 per cent.,
Fixed carbon, 41 per cent.,
Ash, 14 per cent.

This is not the best nor the worst coal in the State; in fact, its composition is about as fair an average as can be had. The sum of its combustible ingredients is 74 per cent., which makes it fall below Mr. Neely's chart, but its heating value per pound of coal is 10,580 B.t.u., so it falls in line with Mr. Neely's straight line, if it were extended. According to Kent's formula, by interpolation, it would have 13,680 B.t.u. per pound of combustible and 10,123 per pound of coal. The actual results show 10,580 B.t.u. per pound of coal and 14,600 B.t.u. per pound of combustible, a difference of nearly 40 per cent. The moisture and ash contents are 26 per cent., or one-fourth of the whole, or a total of 520 pounds in every ton which has to be transported and handled before it is delivered to the boilers, and again, 280 pounds of ash have to be raked out of the ashpit for each ton consumed, and, in a city, removed at a considerable cost. Yet on comparison of "heat units per pound of coal dry and free from ash," it compares favorably with hand-picked Buck mountain or Pocahontas coal.

The real test of a steam coal, from an economical point of view, is how much steam it will make for one dollar. Many look at the analysis of a coal to see what its fixed carbon content is, and gage its value by that. Theoretically this is a poor way, as a certain amount of volatile matter is an advantage, provided it can be completely burned. With the usual run of furnaces, though, a large amount of volatile matter is allowed to go to waste as chimney gases or soot, hence a classification based on fixed carbon is not so bad after all. The cheapest fuel that we get here in St. Louis is slack or screenings from the nearby mines. It has about one-third each of volatile matter and fixed carbon, and one-third waste in the form of moisture and ash. Its calorific value is about 9000 B.t.u., a little over one-half that of the best coals of the Appalachian range, yet it can be delivered at the boilers for less than one-fourth of the price of any Eastern coal. On the other hand, it requires a larger boiler installation and greater expense for the removal of the ash and clinker formed, and greater depreciation of the plant, so the net gain is not as great as might be supposed at first sight.

It has often been said that analyses of Rocky mountain coals, such as I have quoted, are those of picked samples and do not fairly represent the mine. In three years I took many samples of Wyoming coals and found the following range of contents: Moisture, 4 to 10 per cent.; volatile matter, 30 to 38 per cent., and fixed carbon, 52 to 58 per cent.; ash, less than 5 per cent.; sulphur, less than 1 per cent. One car of coal, or 80,000 pounds, burned under a return-tubular boiler yielded 1800 pounds of coarse ash, or 2.25 per cent.

St. Louis, Mo.

A 500 or 250 Volt System for Motors

The article under this caption, written by A. Chisholm, in the December 15 number, must be very misleading, or else I have misconstrued his meaning. If he has intended his motor connections to be made in a 500-volt three-wire system, well and good; but if intended, as I imply, to be a common 500-volt system I cannot see that it is at all practical.

I would call his attention by way of friendly criticism to the all too common error of expression of electrical terms which appears in the second paragraph: "C and D are two ordinary starting boxes such as would be used for motors running at any voltage." Now there is no such thing as an ordinary starting box for any voltage. If you think so just put a 5-horsepower 250-volt starting box on a 5-horsepower motor using 500 volts and see how it works.

Ensley, Ala.

The Modern Surface Condenser

Referring to C. A. Orrok's reply in the issue of December 29, page 1054, to Mr. Mueller's remarks on Mr. Orrok's surface-condenser article, Mr. Orrok states that he fails to understand how surface efficiency can be obtained by excessively large air pumps in the [illegible] installation. To the writer this seems to require no explanation whatever, inasmuch as the surface efficiency depends to an enormous extent on the amount of air in contact with the tubes.

It is not so much a matter of how much the air pumps remove, but of the quantity they leave behind in the condenser, blanketing the tubes. The amount of air removed by the air pump while at work depends on its volumetric capacity and efficiency. As regards the various [illegible] cient as an air remover than an ordinary air pump, but the amount of power required is at present, I believe, an open question, and not to be recommended, except a high vacuum is required, as in turbine work.

W. VINCENT TREEBY.

Stratford, England.

Wrenches

On page 15 of the January 5 number, Mr. Collins gave some sensible advice in regard to the use of wrenches. With an extended experience in charge of men and tools, I have had all the trouble enumerated by the author in the misuse of wrenches.

There is one statement, however, that is not absolutely correct, and that is where he says a pipe wrench should always be used close to the fitting the pipe is being screwed into. On extra-heavy pipe and generally on butt-welded iron pipe this will do, but on standard pipe the wrench should be at least one and a half times the diameter of the pipe from the fitting; if it is a close nipple, a nipple driver should be used. The reason is that the wrench distorts the pipe and the oblong frets bind in the fitting. This is especially so where it is necessary to remove a light nipple from a fitting, when it will be found that it will start more easily if the wrench is a proper distance away. There is a strap wrench made that will not crush even the lightest brass pipe, or injure the surface of studs or pipe, that Mr. Collins did not get into his very complete list of wrenches.

PETER H. BULLOCK.

Concorn Junction, Mass.

Turning a Worn Turbine Shaft

While putting a new guide bearing in one of our 5000-kilowatt Curtis turbines we found the shaft worn badly on one side. We proceeded to put the guide bearing in, but before putting up the dies, we took measurements in order to make a turning tool with which to turn the shaft down. The accompanying sketches show how we did the job.

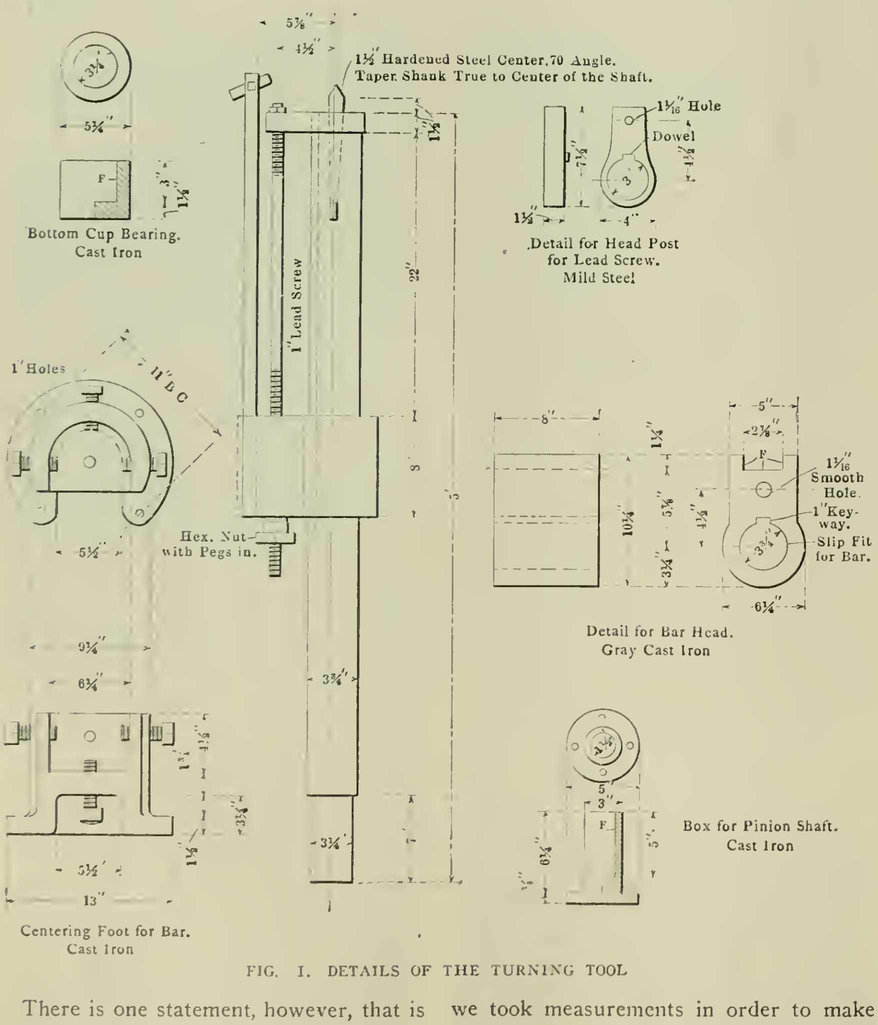

FIG. 1. DETAILS OF THE TURNING TOOL

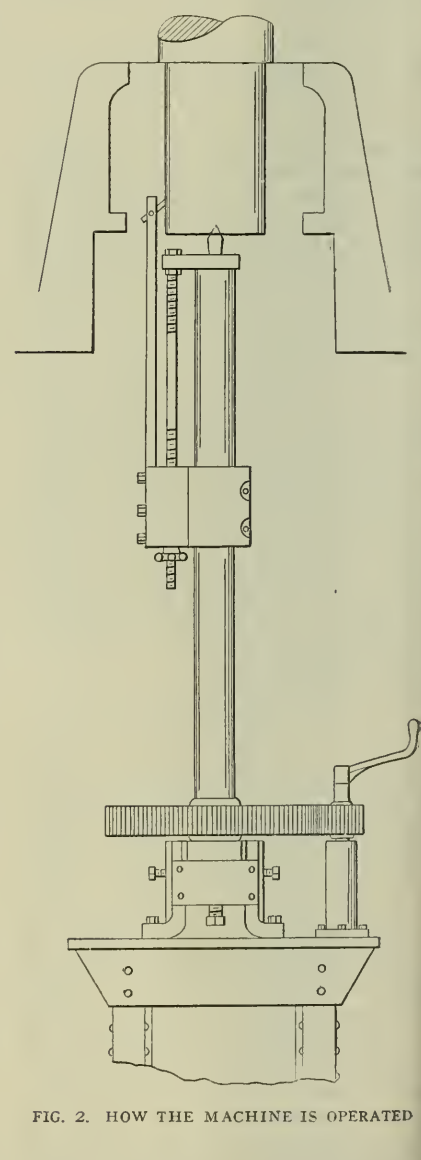

FIG. 2. HOW THE MACHINE IS OPERATED

In Fig. 1 are shown the details of the turning tool. Fig. 2 shows the machine in operation. I would suggest, however, to anyone desirous of using this machine, to substitute a worm gear for the gearing shown, use a small motor for a drive and mount it where the crank is shown.

As we were pushed for time we took the crank from a drill press and turned the turning tool by hand. It took only three days to remove 0.09 inch from the diameter of the shaft, the shaft being 11 inches in diameter and the cut 17 inches long.

In order to center the bar we used the center in the end of the turbine shaft. About 16 inches from this end we found a place where there was an oilway in the box, hence the shaft was not worn at this point. We could not get a very smooth finish with the long toolholder we had, but we got the finishing touches on by placing a piece of ⅜x1½-inch band iron in the place of the toolholder, with an emery brick fastened to the end. By putting a set screw in the lower end of this strap-iron, we could work that end away from the head and thus increase the tension on the brick. We used water on the brick.

As the space betwen the shaft and bearing case was too close to get an ordinary incandescent lamp in we mounted one of the oil-switch pilot lamps on a broomstick and used it for a lamp.

Development of the Surface Condenser

Descriptions of the Various Types of Surface Condenser, Beginning with Watt's and Including the Most Modern Apparatus on the Market

BY WARREN O. ROGERS

To James Watt belongs the distinction of designing the first surface condenser, although it is true that Savary condensed steam in the cylinder of his engine, if engine it may be called, by pouring cold water over it to produce a more rapid vacuum.

In Newcomen's engine, which was the first reciprocating engine put to practical use, the steam was condensed from the bottom end of the cylinder. The piston was kept tight by a small amount of water on its upper surface. When the piston

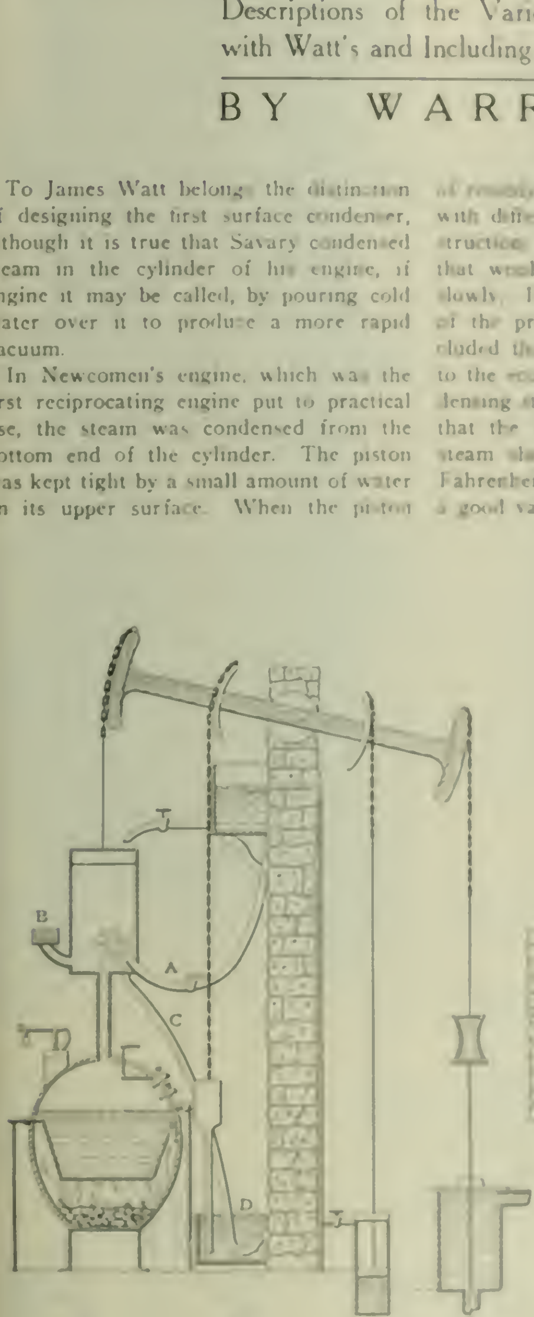

FIG. 1

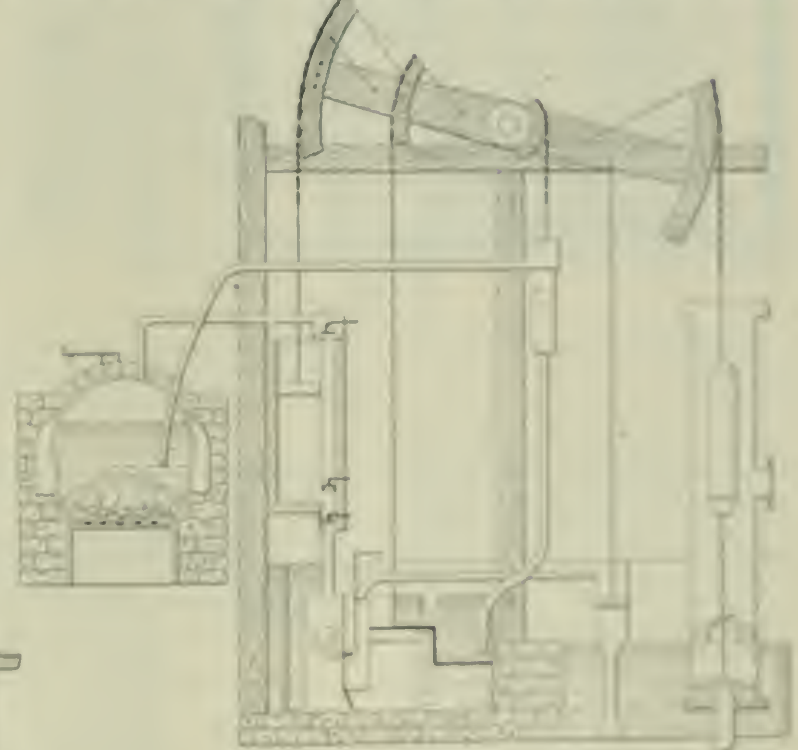

FIG. 2

reached its highest point of travel, the injection valve A was opened and water admitted to the cylinder, as shown in Fig. 1. This supply of water condensed the steam, the air escaping through the vent B, while the condensed steam and injection water passed out through the pipe C to the hotwell D. From this it is evident that the first condenser was of the jet type, which was also the type first designed by Watt, although it must not be assumed that the idea was the growth of a moment. When Watt observed the wastefulness of Newcomen's method of condensing steam he tried various means of remedying the defect by experimenting with different materials for cylinder construction, in order to find a substance that would take in and give out heat slowly. It was only after an examination of the properties of steam that he concluded that two conditions were essential to the economical use of steam in a condensing steam engine, one condition being that the temperature of the condensed steam should be as low as 100 degrees Fahrenheit, or lower, in order to maintain a good vacuum, the other, that the cylinder should be as hot as the steam entering it.

In 1765 Watt conceived the notion that by condensing the steam in a separate vessel these two conditions could be maintained and the idea was put into practice. Fig. 2 shows the design of this condenser. It consisted of a small cistern [illegible] the engine into which the exhaust steam from the cylinder was allowed to flow through the opening in the top. The steam was condensed by cold water surrounding the outside and also by a jet of water on the inside. An air pump removed the condensed water as well as the air in the condensing chamber. The inlet between the condenser and the air pump was fitted with a swing foot valve, and as the plunger was fitted with valves the water was forced up through them to the top of the plunger on its downward stroke, and expelled through the discharge pipe on its upward stroke. This condenser embodies the principles of both the jet and surface condenser in a crude form. This invention was not patented until four years later, and it was three years more before steam pressure and vacuum were applied to both sides of the piston. Even with the vacuum acting on but one side of the piston the gain over the old method of condensing the steam in the cylinder is said to have been 50 per cent.

The specifications of the patent granted to James Watt, January 5, 1769, read in part as follows:

"In those engines that are to be worked wholly or partially by condensed steam, the steam is to be condensed in vessels distinct from the cylinder, though occasionally communicating with them. These vessels I call condensers, and while the engines are working, [illegible]

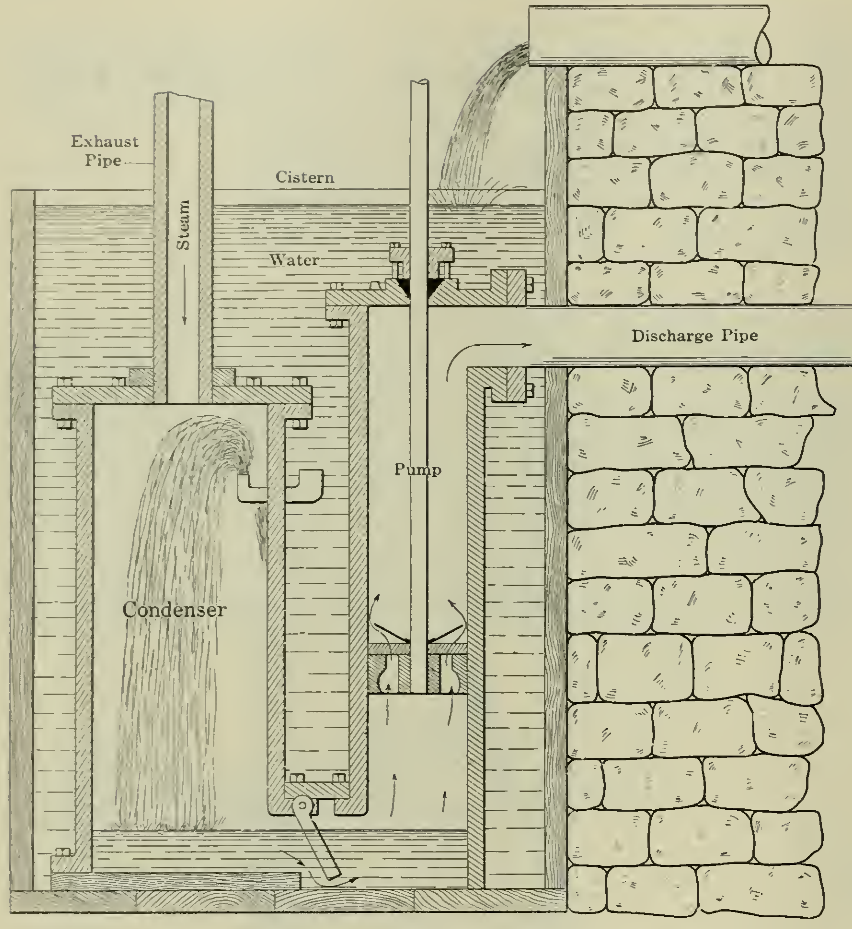

FIG. 3

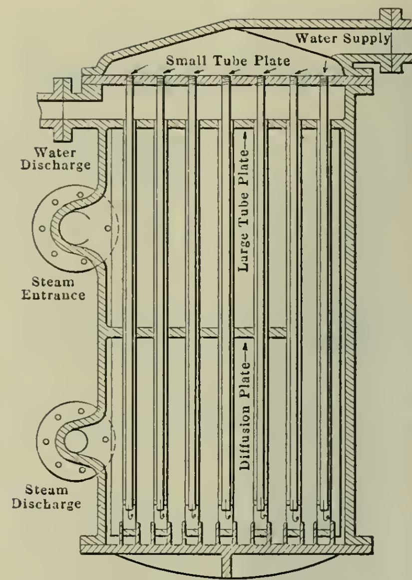

FIG. 6

as cool as the air in the neighborhood by the application of water or other cold bodies."

There were no drawings attached to the specification papers, but from fragments of Watt's experimental apparatus it is evident that the design shown in Figs. 2 and 3 is approximately the arrangement of the first separate condenser, from which grew the surface condenser, although the jet type was employed by Watt in connection with his subsequent engines, and became almost universally used during the years preceding 1831. Fig. 2 shows Watt's engine and condenser of 1769.

In 1831 Samuel Hall invented a commercial surface condenser. In the specifications of Hall's patent the following may be found:

The condenser "consists of an improved mode of using a system of metallic surfaces, which may be composed of vessels, channels, passages, or pipes, of any convenient form and arrangement for condensing the steam and cooling the water resulting therefrom on its passage from the condenser to the air pump."

Two years later Hall obtained a second patent in which the circulation of the condensing water is described as passing through a cistern containing the tubes, the cold water entering the cistern at the top at the end of the cistern nearest to the air pump, and escaping at the bottom of the other end next to the working cylinder. In the Hall condenser the *steam* flowed *through* the tubes, the cooling water flowing about them on the outside. With this exception this condenser of seventy-six years ago was practically the same, as far as construction goes, as many of the surface condensers of today.

A type of this condenser is shown in Fig. 4, in which the general arrangement of the condenser and air pump is illustrated. It is seen that the steam passes downward through the tubes to the air-pump suction. The circulating water was circulated upward by a centrifugal pump. Strange as it may seem, the design of surface condensers remained almost the same as it was in 1831, up to within a few years. The most important change made

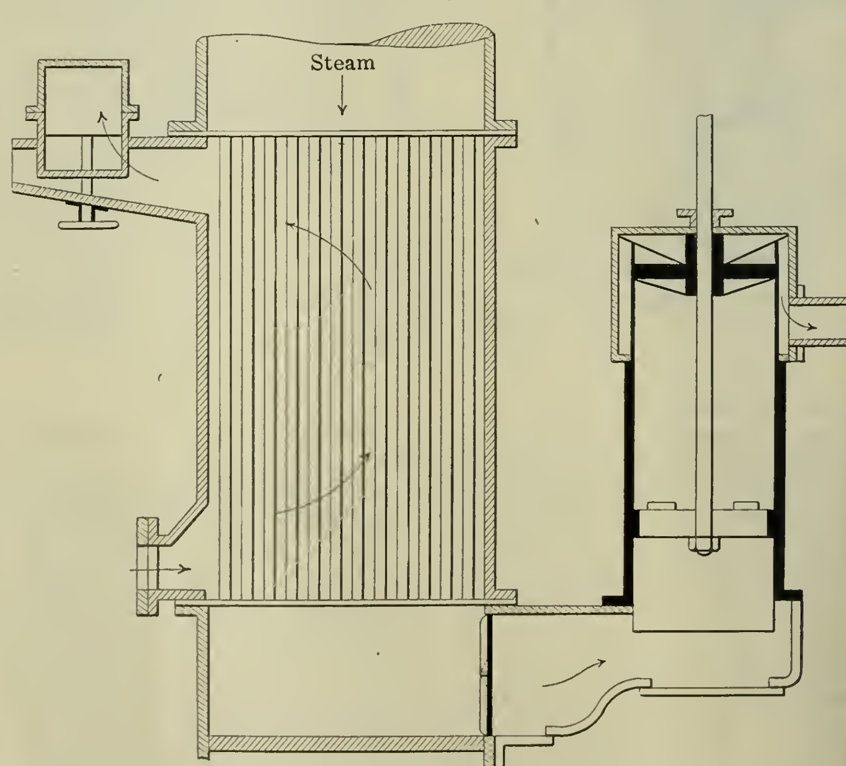

FIG. 4

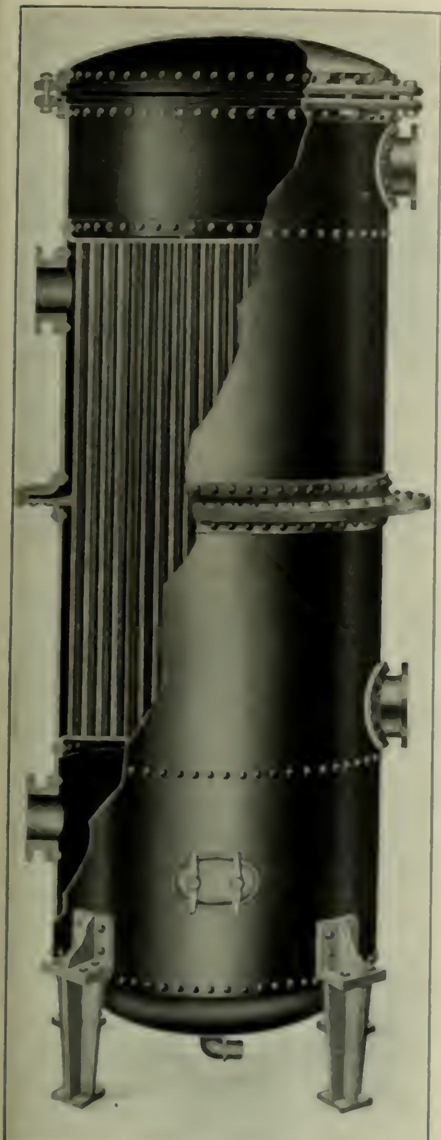

FIG. 13

has been that of circulating the cooling water through the condenser tubes instead of the steam; this change is preferable, and is now invariably adopted. Probably J. F. Spencer took as active a part as anyone in introducing this latter method of circulating the cooling water.

In Fig. 5 is shown a condenser designed and built for commercial use more than thirty years ago. It will be seen that the condensing surface consists of two nests of tubes with a baffle plate central in the inlet-water chamber. The cooling water coming in at the bottom and passing to the left through the lower bank of tubes enters the chamber at that end and, reversing its direction of flow, passes through the upper bank of tubes to the outlet. The steam from the engine cylinder enters at the top inlet and passing down over and surrounding the tubes is condensed, the water of condensation passing to the air pump through the bottom outlet.

The first double-tube surface condenser was designed by an American named Miller in 1862. In this design, Fig. 6, small tubes were placed inside of large ones. The condensing water entered the water chamber through the bottom inlet, from whence it passed through the small inner tubes, returned through the large outer tubes, and then discharged into the air pump. This is practically what is found in the modern type of surface condenser, with the exception that they are generally made to be placed in a horizontal position, the steam entering at the

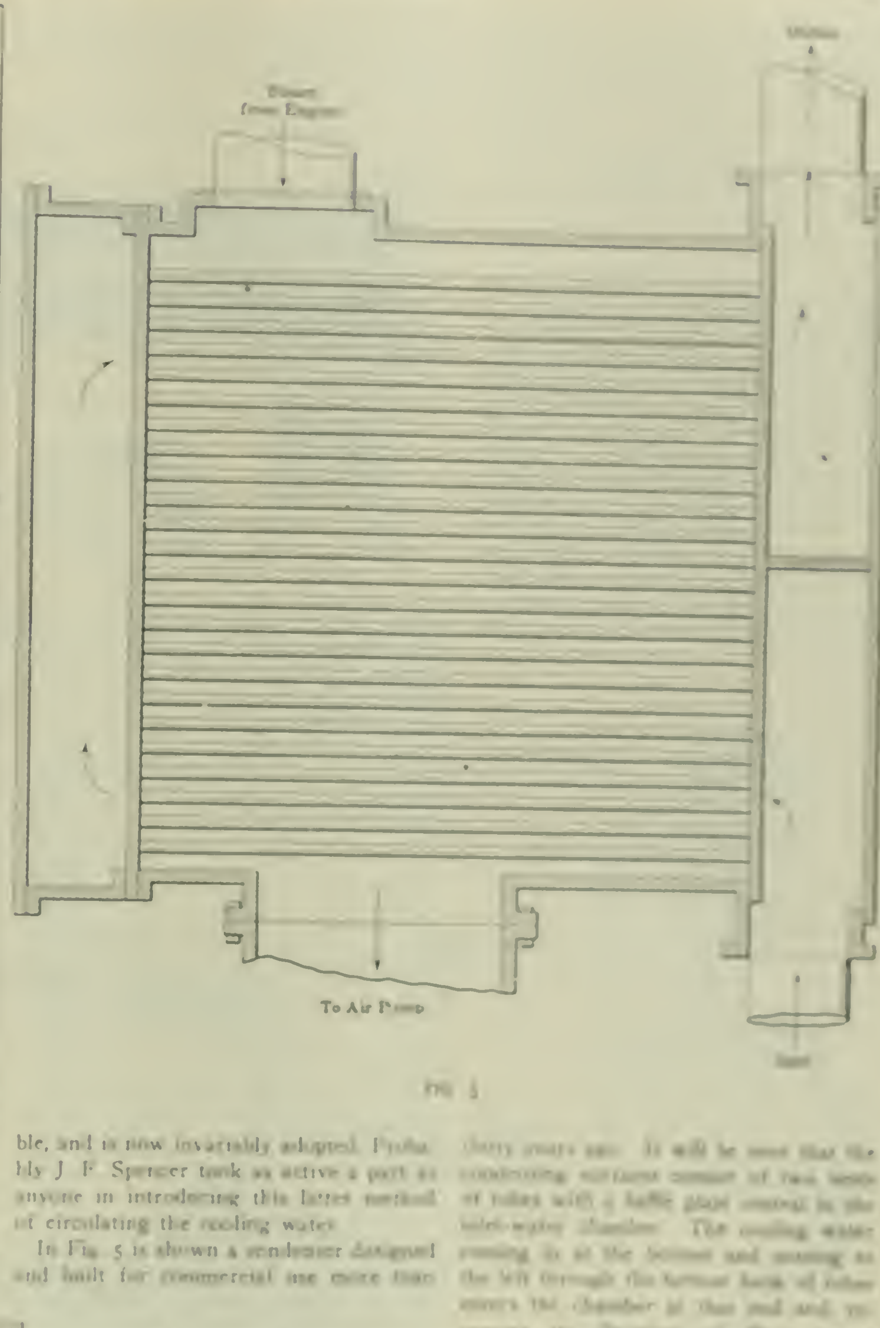

FIG. 5

FIG. 7

top and the condensed steam discharging at the bottom.

In Fig. 7 is shown the modern type of double-tube condenser. A comparison with Fig. 6 shows but a slight difference in construction. No ferrules, washers, or packing of any kind are used, the tubes screwing firmly into the tube heads at one end, as shown, thus taking care of the expansion. The arrows designate the path of the cooling water, also that of the steam and products of condensation.

Fig. 8 shows a type of single-tube condenser familiar to all. The design allows of a good distribution of steam, and each tube is supposed to do its share of work. The arrangement of the air and circulating pumps is also shown. In the condensers shown in Figs. 7 and 8 the weight of the condenser rests on the air and circulating pumps. While this does not interfere with the attendant getting at the valves of each, it does necessitate an extra amount of work when it becomes

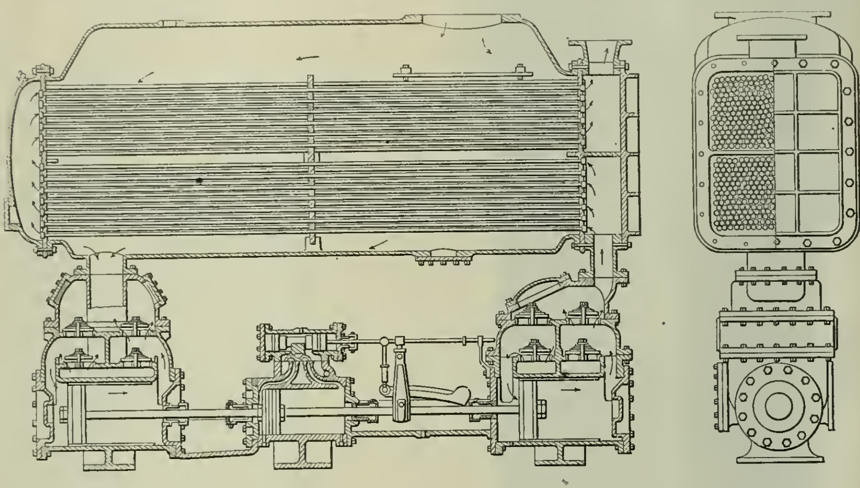

FIG. 8

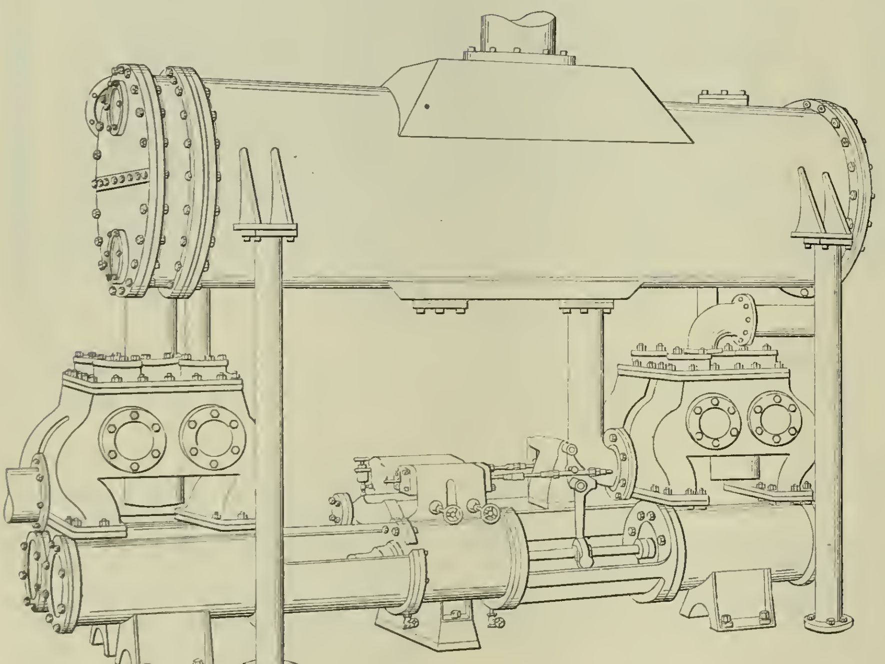

FIG. 9

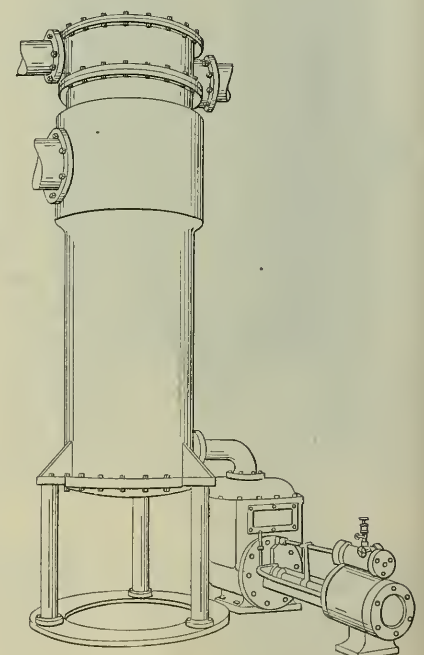

FIG. 14

necessary to remove the air or circulating pumps. To obviate this, some builders of surface condensers manufacture a design which is supported independently upon four or more supporting columns.

In Fig. 9 such a type is shown. It is manufactured by the Epping-Carpenter Company. By breaking the connection between the condenser shell and the pipe connection to the pumps, either the condenser or duplex pump may be removed without disturbing the other. The interior construction of the condenser is shown in Fig. 10. The tubes are held in place by means of screwed glands on one end and so made that expansion and contraction are taken care of. Fig. 11 shows the construction of the tube packing and glands. The arrows indicate the path of the circulating water; in this case two passes of the water are provided for, but as many as desired may be provided.

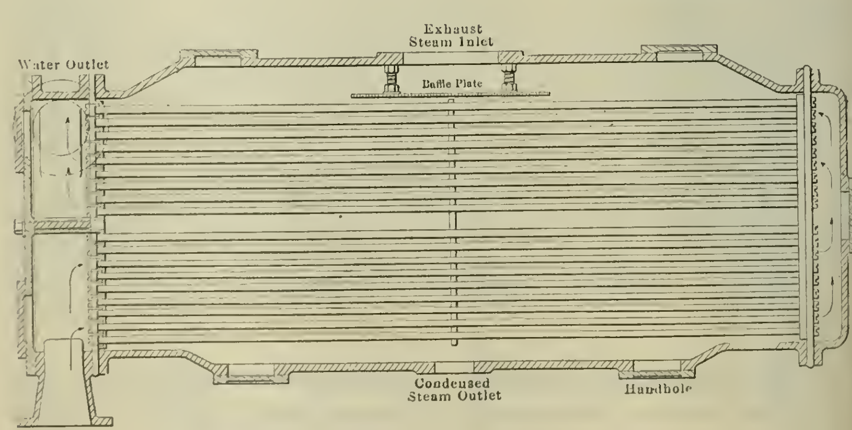

FIG. 10

The application of the surface condenser is varied. That they may be attached to the individual auxiliary is shown in Fig. 12. This represents one type of surface condenser manufactured by the Union Steam Pump Company. It is a most convenient arrangement under certain conditions. An independent air pump is used to remove the water of condensation and maintain a vacuum. The water handled by the pump is forced through the condenser tubes and, as the amount of water passing through them is

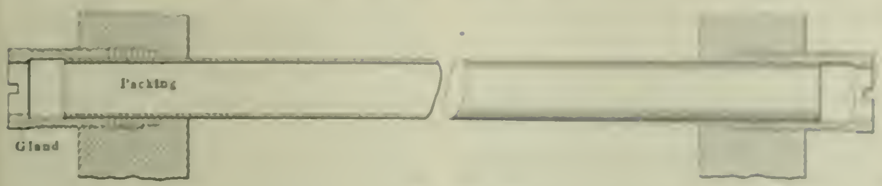

FIG. 13

FIG. 14

many times greater than that necessary to condense the steam, it is evident that the condenser is very efficient. The water passages are made large, and the resistance to the passage of the water is slight.

A condenser of entirely different construction as regards expansion and contraction, is shown in Fig. 13. The tubes of this condenser, which is manufactured by William [illegible] & Son, are expanded solidly into the tube sheets, the expansion being provided for by the [illegible] [illegible] in the shell as shown. This condenser is of the vertical type, although it is also made in the horizontal form. In the vertical type the top head is removable and, as the lower end contains a chamber which is fitted with a manhole, the tubes are accessible at both ends for cleaning. The upright position of the tubes, which are made with a large area, insures a natural circulation. In [illegible] area is restricted, this type of condenser has its special advantages.

In Fig. 14 is shown another type of vertical surface condenser. It is manufactured by the C. H. Wheeler Manufacturing Company. The cooling water enters at the top and, passing down through one bank of tubes to the bottom of the condenser, reverses its direction of travel and passes up through the second bank of tubes and out at the opposite side of the shell. The exhaust steam enters the [illegible] large opening at the top of the shell and the water of condensation is removed by the air pump [illegible] of the condenser.

Cooling Towers

By H. F. [illegible]

Cooling towers and cooling ponds [illegible] represent a comparatively recent development in engineering practice. While their adoption has been rapid, the question of design and efficiency is in a somewhat chaotic state. Comparatively little is known by the average engineer in regard to the relative efficiencies of the different types and their respective advantages for special installations.

Cooling towers today serve simply one purpose, in a variety of applications: To cool water in industrial operations where large quantities of water are required for any purpose whatever and the necessity of the water being cool is a prime requisite. Thus in all steam-power plants of any type whatever, cooling towers are used in conjunction with the condenser for furnishing a continuous supply of cold water to it. In all refrigerating installations and ice-manufacturing plants they serve the same purpose and supply cold water for the operation of the ammonia condensers, in which a large amount of cold water is used. In any of these installations the cooling tower is necessary wherever the water supply is restricted, limited in amount or too impure for use. They take the water from the various condensers after it has become hot through the condensation of steam, and cool it economically so that it can be used over again for the same purpose. They serve essentially the same purpose in any plant where the water is used to absorb heat and hence loses its ability to do so when it becomes hot.

Classification of Cooling Towers

Cooling towers may be divided into two classes, the natural and forced draft. Both of these operate on the principle of air, which is obliged to absorb water vapor under certain conditions to produce cooling. Water vapor exists in the air in amounts depending largely upon the temperature and the [illegible] [illegible]

[illegible]

readily by mechanical means, since the pressure of the latter under ordinary conditions is quite small. The ordinary water vapor in the air is in an unsaturated condition, due in a great measure to the fact that the air or water vapor has become heated some time after its contact with a water surface. When brought in contact with this, however, it absorbs additional water in the form of vapor until it becomes saturated. Air in reality generally possesses the remarkable property of absorbing large quantities of water vapor from a water surface with which it is brought in contact. It can only do this, however, when the water vapor present is in an unsaturated condition.

Very seldom in actual practice, except during periods of rain or great humidity, does the air or the water vapor approach the saturation point. Under these latter conditions, however, the air does not absorb water vapor, and therefore possesses very little cooling effect on the water. This cooling effect under ordinary circumstances is very large, since every pound of water evaporated by this means is accompanied by the absorption of heat from the remaining water, equivalent to the latent heat of vaporization of the water changed into the vapor. Cooling towers are quite variable in their action as dependent upon the condition of the atmosphere in regard to humidity, since the actual loss of heat by conduction from the water to the air is quite small under all circumstances.

This variability of cooling towers with atmospheric conditions has led to the development of the two types. The amount of cooling produced depends primarily upon the condition with respect to humidity of the air and, secondly, upon its temperature. The capacity of the tower depends upon these factors and upon the amount of air brought in contact with the water per unit of time. This latter feature is the main determining factor in the development of the two types. These are known respectively as the closed and open types of tower.

The Open-type Tower

The open type consists of an openwork iron structure, with a standpipe for the conveyance of the supply water to the top, and possesses a spraying device at this point and various devices installed throughout the tower for the separation of the water into small particles with large surfaces for evaporation and its retardation throughout the descent. This mechanism furnishes a very large water surface for contact with the air, and assures complete saturation of the air in the tower.

By great retardation of the descending water very large quantities of air can be brought in contact with a given water surface, therefore the amount of water abstracted from it in the form of vapor can be made comparatively large and the cooling produced by this means considerable. Such a tower is open at the sides and depends for air circulation upon the natural air circulation in the atmosphere. Its efficiency varies with the velocity of the wind, its humidity and temperature, and also upon the design of the tower for separation and retardation. Various interesting problems in constructive details have arisen, and the deterioration factor in this type is quite large, since the destructive effect of air and water under these conditions is most pronounced.

The Closed Type

The closed type of tower is practically identical with the open type in construction, with one important modification. The walls of the tower are inclosed and air is supplied at the bottom and forced upward throughout the tower by means of a fan. The air supply under these circumstances can be varied by mechanical means and the resulting cooling effect made practically independent of temperature and humidity variations of the outside atmosphere. The operation of the tower is further independent of the existence of winds for its efficient operation. Such a tower, however, costs considerably more in regard to installation and its operating factor is much greater, since expense of operating the fan must be added to that of water circulation.

However, as an engineering unit, it is considerably more reliable and, as has been said, can be made in its operation absolutely independent of external conditions. It further eliminates another serious difficulty which has arisen in the open type: When high winds exist during the operation of the latter, the water cannot be restrained within the confines of the cooling tower, and a fine spray covers all the surrounding objects. This has often proved a considerable annoyance from lawsuits in regard to the nuisance produced by this means. Farther, the deteriorating effect on the other units in the installation cannot be overlooked.

These two types of tower represent practically the sole developments in this field. They exist in a wide variety of designs, however. The chief open types on the market consist practically of drip pans installed at regular intervals, allowing free access of the air between them, and possessing holes in these at regular intervals for the equal distribution of the water. Shavings, boards, mineral wool, tile and even slate have been used with greater or less success in this type and in the closed type as well. The question is largely one of expense of installation and the consideration of the deterioration factor. Almost any device for satisfactory distribution and separation of the water with adequate retardation is thoroughly sufficient for the purpose.

Where Each Type is Used

The result in the development of these various types of tower is that there has been a distinct specialization of the various designs. Thus, in installations where reliability is a matter of prime importance and cost of installation a matter of minor significance, the closed type is invariably installed. The majority of large power plants use the closed type. In some developments these towers are used as an integral part of some other device, such as a condenser, and are operated along with it.

On the other hand, in plants where the cost was a matter of the greatest importance, and the possible isolation of the tower a simple problem, the open type has been developed. In the majority of small refrigerating and ice-manufacturing plants where the question of cost is a matter of prime consideration, the open type is almost invariably installed. Similar conditions hold in regard to the small steam unit and this subdivision of the two types and their developments as dependent on related conditions is a general one.

A wide variety of different types from a constructive point of view have been in existence, but a more and more complete standard of constructive details is steadily developing. Much more is known today in regard to capacity and efficiency of such towers. Cooling towers under average conditions are more thoroughly known, and the size and cost of the installation depends primarily upon the locality and amount of water to be cooled and the range of temperature required. Very seldom in summer can the water be cooled much below 75 degrees Fahrenheit. The higher the temperature of the initial water, however, the more efficient is the tower in its operation.

Condenser water from steam condensers is furnished at a temperature ranging from 110 to 165 degrees Fahrenheit down to 80 degrees Fahrenheit, and their operation under these circumstances is very efficient. Refrigerating plants have a range of temperature depending simply upon the pressure maintained in the condenser and seldom rises above 120 degrees Fahrenheit for initial temperature in the cooling tower. The evaporation of the water in the cooling tower must, of course, be re-supplied, and this represents a certain loss. In steam-condenser work, if the condenser is of the jet type, the water is more than re-supplied from the condensed steam and a constant overflow must exist. In refrigerating plants the loss of the water is from 5 to 15 per cent. for each circulation, and this loss must be re-supplied.

The efficiency of a cooling tower, of course, depends primarily upon the cost and availability and character of the water supply. It must not be pumped too great a distance, or too great a hight. Practically every individual plant presents special conditions for consideration in regard to its availability, and the efficiency of the type is practically dependent upon these special conditions.

Some Useful Lessons of Limewater

Hard Water and Boiler Scale; How to Make Carbonic Acid Gas Water; the Action of Limewater Upon Litmus Paper; Acids, Alkalies

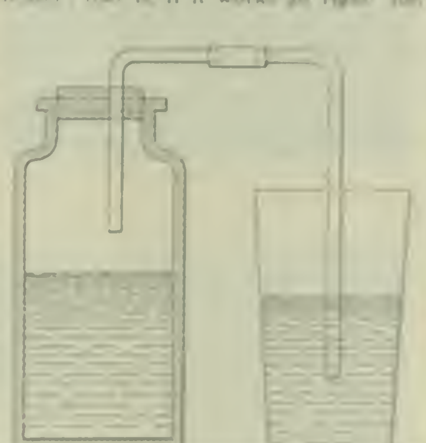
BY CHARLES S. PALMER

In the first shift, Mr. Furnaceman, you got the idea that lime will dissolve somewhat in water; that the lime can be thrown out of solution as plain carbonate (which is not soluble in water) by the carbonic acid of the breath, and by the same thing from the burning of common coal; it was also noted that by adding more of this carbonic acid from the breath, or from the gases of the burning coal, to the water with the insoluble plain carbonate of lime, you got the fairly soluble extra or bicarbonate of lime. You saw that this solution of somewhat soluble extra or bicarbonate of lime, after filtering, is the same thing as artificial temporary-hardness water; for, on filtering it to get it clear, and then on heating it, the extra carbonic-acid gas goes off, and down comes again the insoluble plain carbonate. You saw quite a little of this insoluble plain carbonate, both as a sediment in the bottom of the glass, and also as a scum or thin flaky crust floating on the surface of the water. If you shake this and let it settle, you will get enough to show that this plain carbonate of lime would make trouble if it were in any great quantity. This plain insoluble carbonate of lime is what makes the soft scale of temporary-hardness water; in contrast to the hard sulphate of lime scale, which makes the scale of permanent hardness water, which will be studied later. There are also compounds of the metal, magnesium, in many hard waters, and they will be taken up later on, also, after the lime compounds are disposed of.

Now, the thing to get clearly in mind is this: That even a *little* scale is a bad thing to have on the boiler tubes. It may not take a layer as thick as your hand to make both danger and extra cost in firing the boiler. And it is costly, not only for the management that pays for the coal, but also for you, the man who must handle it all.

Of course, we may shrug our shoulders when the books try to tell us just how much heat is lost by scale of such and such thickness; for if one is not rushing the fire, and if there is more than enough heating surface in the boiler and tubes to absorb the heat of the furnace, the scale, especially if it is not very thick, may not do much damage. But if your boiler has none too much heating surface, and if you are forcing the fire, that may be an entirely different matter, as you may know from actual experience. So we will not tie ourselves down to any special figures on the heat loss from scale of any particular thickness, but we must all agree that any scale is liable to cause both waste of coal and waste of the fireman's own good strength, not to mention some danger. That is why we are trying to get together on this eternal riddle of hard water.

To get back to the first solution of filtered limewater, the stuff that tastes slightly bitter-sweet, that throws down plain insoluble carbonate of lime, both from the breath and from the gases from the burning coal. This sediment was fairly soluble in extra carbonic acid, making the double or bicarbonate, which is somewhat soluble, and this is thrown down by heating, just as the temporary-hardness water is cleared up by your heater; that is, if it works all right. But



FOR MAKING CARBONIC-ACID WATER

it takes time to throw out the lime from the hard water in the heater, and it takes time for it to settle, and that will set you to thinking of some way to handle the heater, so that it will always do its work in softening the water, as it may not always do.

Make Some Carbonic-acid Gas

We have found out, in the foregoing, four things about the lime: the solubility, the insolubility, the resolubility and the reinsolubility. But you want to know more about this carbonic-acid gas which picks up the lime from the insoluble limestone bed and carries the extra, or double or bicarbonate of lime, down to your boiler room. You can see that if this carbonic-acid gas should get into the water which seeps through the limestone bed, it will naturally take some of the plain carbonate from the bed and carry it along. For there is some carbonic-acid gas in the air; and so, of course, this gets into all natural water, more or less.

If you pour some of the filtered solution of limewater out into any open dish, as a glass tumbler, in a few minutes you will see a thin scum form over the solution. This scum will form a thin skin over the surface of the limewater, and this white skin is the same plain insoluble carbonate of lime that you got by putting the gas from the burning coal and from breathing through limewater. As you look at your bottle of filtered limewater, you will note that with all your cleaning, the cork and neck of the bottle are smeared with the same white, plain carbonate of lime; indeed, some of it has got into the bottle of filtered limewater, especially if you have allowed the water to get low in the bottle so that there is quite a little air in the bottle above the filtered solution. This means that you will have to filter the limewater again from time to time, for the air about us is always at hand and it is always getting in its work on the filtered limewater. There is not much carbonic-acid gas in the air, only about one part in thirty-five hundred, but this is quite enough to show with so sensitive a chemical as limewater and with the insoluble carbonate so ready to form.

You are probably quite well acquainted with this carbonic-acid gas; you may know it very well as "soda water," or as the "fizz" which is used to mix with other things. It is kept in that strong "siphon" bottle, and the thick walls of the siphon bottle, the readiness with which it squirts out as you press the lever on the top, together with the strong foaming in the drinking glass, all show that the carbonic-acid gas in the siphon bottle is under strong pressure; indeed, the water in the siphon bottle is quite a strong solution of this carbonic-acid gas.

If you should take some of this water from the siphon bottle and pour it into some limewater (very little of it, for this is a strong solution of the carbonic-acid gas), you would get the same white insoluble plain carbonate of lime. And if you should again add to this plain white, pour a little more of the water from the siphon bottle, you would make the same fairly soluble extra or double or bicarbonate of lime as before, with the [illegible] coal. In this way, you would make the temporary-hardness water; and, after filtering it, because the bicarbonate of lime is not quite soluble enough in water to dissolve entirely, you would have a clear solution. which would throw down the plain carbonate, as before, by heating.

How to Make Carbonic-acid-gas Water

It may not be handy to get a siphon bottle of carbonic-acid-gas water, but all the same you want some of it. So you will make it yourself. Just rig up an apparatus consisting of a bottle, a tumbler and tubes, as shown in the accompanying sketch. Take a wide-mouthed bottle, say a common horse-radish bottle, and a common tumbler. The bottle is closed with a flat cork, pierced by one hole for the tube to carry the carbonic-acid gas to the tumbler. The tube is made of two pieces of glass tubing, joined with a bit of rubber tubing (which you can get with the outfit mentioned in the first lesson). In the bottle are placed some lumps of common white marble, which is nothing more than plain carbonate of lime (or calcium). Pour over the marble about two or three inches of water, and then about one-fifth as much hydrochloric (muriatic) acid. If you do not have the acid, you may use vinegar; but in that case, do not add any water, and have the vinegar warm. Hydrochloric acid is more active than vinegar and cuts the marble quicker than the vinegar does. You will see quite a foaming; clap on the flat cork and lead the carbonic-acid gas which comes off through the tube, passing through the flat cork, into the tumbler, which contains some of the original filtered limewater. As the carbonic-acid gas comes over and passes through the limewater, you will get the same white insoluble plain carbonate of lime (or calcium), and if you keep the current of gas going, pretty soon you will see the same change in the precipitated limewater which you got from blowing your breath through limewater, and from sucking the gas from glowing coal through limewater. Thus you see that you can get this carbonic-acid gas from the breath, or from burning coal, or from limestone. The carbonic-acid gas is locked up, "fixed" the old chemists used to say, in the limestone, which is carbonate of lime; and when you add some strong acid to limestone, this acid displaces the carbonic acid, forces it out and, as carbonic acid happens to be a gas, you can grasp the explanation of the action of this apparatus.

If you use vinegar, take about a cupful, for vinegar is only a diluted, or thin, solution of acetic acid in water. You might use nitric acid, also, but that usually costs more than muriatic (or hydrochloric) acid; but you will not use sulphuric acid, because this acid in acting on limestone makes sulphate of lime (or calcium), and this is so insoluble that it coats over each lump of limestone and shuts off the action. But to go back to the experiment:

You were driving the carbonic-acid gas over into the limewater; you had got the same plain insoluble white carbonate-of-lime precipitate (a "precipitate" is anything thrown out of solution when two clear liquids are mixed, and one liquid is said to "precipitate" the other; also, the thing thrown out of solution is said to be "precipitated") as with the breath and limewater, or with the gas from glowing coal and limewater. And, as in those cases, with more carbonic-acid gas led into the precipitated insoluble lime carbonate, you get the same extra, or double, or bicarbonate of lime. Keep the liquid in the tumbler shaken up, as the gas bubbles through, so the carbonic-acid gas can act on the insoluble carbonate of lime in changing it into the extra carbonate of lime. When it shows the change of beginning to be more soluble, as though you could almost see through it, take the tumbler and filter the contents, and you will have the same solution of extra, or double, or bicarbonate of lime (or calcium) that you had before; in fact, some of the temporary-hardness water.

If this is warmed, down comes the same insoluble plain carbonate which makes the scale. If you don't happen to have any pieces of marble, you may take instead a handful of common cooking soda from the kitchen at home; only in this case, you will have to add it a little at a time, because the acid will act on it almost as soon as it is thrown into the wide-mouthed bottle, which has strong acid in the water. If you keep right at these homemade experiments you will begin to see how easy it is to follow one thing up after another, and these tests that you are making are just the sort of thing that the thinking man has to use and study everywhere.

The Action of Limewater on Litmus Paper

But there is one fact about limewater that you ought to know by this time. That is its action on litmus. You have a sheet of this litmus paper or a little package of it cut into strips, with your outfit. If it came in one sheet, cut some of it into little strips about a ¼ of an inch wide and 2 or 3 inches long, and put them in any clean, wide-mouthed bottle, which you will keep corked and handy for use.

This litmus paper, so say the books, and they are useful occasionally, is turned red by acids and blue by alkalies. As Long Jack said to Harvey Cheyne (in Mr. Kipling's "Captains Courageous") about shiptackle, this is one of the things that "ivry man must know, blind, dhrunk, or asleep." This must be learned once and for all. Litmus, *acids red, alkalies blue*.

All right, but what about limewater? Just try it. If you have red litmus to start with, it turns *blue* in the limewater, and if you have *blue* litmus paper, it *stays blue* in the limewater. So, then, our limewater is an alkali. This is a big piece of chemistry, and it is a leading fact by which to find out thousands of other facts which are worth dollars to the man who will have the sense to use them. *Limewater is an alkali!*

Acids and Alkalies

Let us take a little excursion among the common things over on the boiler-room shelf, or in that interesting old pantry, and you will find it just bursting with information which it is a thousand times better for you to find out in this practical way than merely to read about in the books. There are salt, pepper, spices, sugar, soap, soda, vinegar, ammonia water, and perhaps a lemon, a sour orange, or an apple. Now some of these are active chemicals, and some of them, while having plenty of *taste*, are indifferent to litmus or useless for our purpose. But you will soon find that the soap, the soda, and the ammonia will each turn the litmus paper *blue* like the limewater, so they are all alkalies, or have some alkali in them, while the vinegar, the sour lemon and orange, and even the apple, will all turn the litmus *red*, and hence contain acids.

This division between *acids* and *alkalies* is as old as Mother Nature, though chemists did not begin to get onto this important fact until two or three centuries ago; but it is just as Long Jack said about his shiptackle, it must be riveted into the mind of attention and into the finger of testing. You cannot afford ever to forget it, or to think that it does not matter particularly whether or not you make the test, even if you think you know about what it is without testing. Make the test; do it; and then you can explain why it was that something happened that you were not expecting, as it always does in the long run. That waste water over there in the corner may be chewing out your pipes; litmus may tell something; but that story comes later.

But you must stop awhile with the soap, the soda, the ammonia, and the limewater on the one hand, and with the vinegar, the sour fruits and the like, on the other. As you go on you will find that there are several other acids: sulphuric, nitric and hydrochloric (or muriatic, as it is still popularly called). You will also find several other bases or alkalies, such as caustic soda or sodium hydroxide (or hydrate), caustic potash or potassium hydroxide (or hydrate, chemists are generous with names), sodium carbonate, and so forth.

Suppose we experiment awhile with our litmus, and the acids and bases; it is well worth the while. You note that *any* strong acid will turn the litmus *red*, and *any* strong alkali will turn the litmus *blue*; though it may take more of it and more time in some cases than in others. Then you take a little of some acid, vinegar for instance, in a tumbler. Slip a strip of litmus down the side, and pour in limewater. Soon the one will "kill" the other, and you can get both dead (or "neutralized" as the wise folk say) by mixing just enough of acid and alkali together, though at first you may pour in too much limewater to the vinegar, or not enough, and you will have to coax and tease the solutions back and forth until you get them so that perhaps a drop or two will do the trick, and the litmus is neither red nor blue, but a sort of purple. That is the *neutral* point. Now if you taste these neutralized solutions, you will get neither the sharp taste of acids, nor the flat but peculiar taste of alkalies, as a rule, you will get a taste something like common salt, as tastes run; in fact, the things made by mixing acids and alkalies (or bases, for alkalies are only the more soluble and stronger bases) are "salts," and common salt is only the commonest salt.

This common salt can be made by mixing some soda with hydrochloric acid, until the exact point of neutrality is obtained, and, of course, it is a simple thing to evaporate some of the mixed and neutralized acid and alkali down to dryness, and thus collect some of it. Now there are millions of possible salts, and some thousands of these are known, and some hundreds of thousands remain to be found and to be used; but we will not bother about more than a few of them. We have too much to do with that bad boiler water to fool time away on what does not concern us. What we want to get at is that hardness, and to find out whether it is of the temporary kind or of the permanent kind, and whether we can help the "boss" get rid of it in some cheap and practical way. For you will find out that there are two or three principal kinds of salt that bother the poor [illegible] almost to death, and they are mostly salts of this alkaline base, lime, that you have started to study.

Ingenious Automatic Cutoff for Rope Drive

The W. F. & John Barnes Company, of Rockford, Ill., having a limited space [illegible] was forced to put a rope drive between the engine and the blower (as shown in Fig. 1).

In order to take up the slack in the rope caused by its natural stretch or the changes in atmospheric conditions, one strand of the rope was carried over a sheave wheel on the carriage *A*, which is mounted on a track above the engine. The weights *B* were hung on a rope that was passed through the pulley *C* and attached to the carriage *A*. This keeps the proper tension on the rope drive.

As the engine was not watched very closely, but was left to run itself, there was danger of the rope breaking, which would cause the engine to run away when relieved of its load. To overcome this an ingenious arrangement of sprockets *D*, *E*, *F* and *G*, with their chains and rods, was rigged up. If the rope in the drive broke, the carriage *A* would be run back to the fork *H* by the weights *B*. The carriage striking the fork *H* would move the rod levers *I* and *J* and these in turn would release the sprocket wheel *D* and its shaft, which would allow the weight *K*, that is fastened to the chain, to drop to the bottom of the sprocket wheel *F*. When the weight *K* drops it carries the chain with it and transmits this motion back to the throttle at *G*, Fig. 2, thus closing the throttle and cutting off the steam, which will cause the engine to stop.

This is a simple and cheap rigging that can be easily installed, but it does its work perfectly and might be useful to others if placed in a similar position through lack of space.

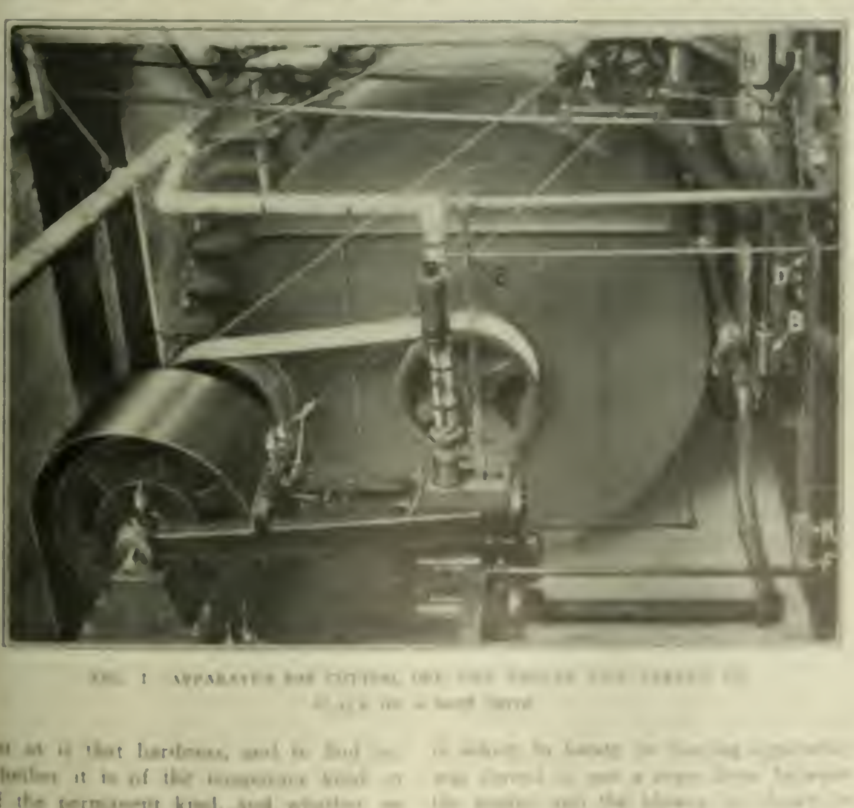

FIG. 1. APPARATUS FOR CUTTING OFF THE ENGINE [illegible]
[illegible]

Power Costs in a 5000-Kilowatt Central Station

By H. S. Knowlton [illegible]

The study of power costs in a modern central station throughout a period of years usually affords opportunity to determine the factors of chief importance under the prevailing conditions, in their bearing upon the efficiency of current production. An example of this is afforded by the following record of four years' cost of power in a New England central station of about 5000 kilowatts rated capacity. The figures cover consecutive years from [illegible] to [illegible], inclusive. During this period the equipment of the plant remained substantially unchanged until [illegible], when a new station was begun by the company on a site adjoining the older installation. Part of the output for the [illegible] was generated by the new plant, which will ultimately supersede the older station.

The equipment of the plant in [illegible] consisted of [illegible] boiler installations of [illegible] horsepower, and an engine equipment of [illegible] horsepower. There were [illegible] Babcock & Wilcox boilers, with [illegible] setting, each having [illegible] and [illegible] inches in diameter [illegible], and operated at an average steam pressure of

120 pounds per square inch. The engine equipment was as follows: One Harris, 22 and 22 by 48-inch, 78 revolutions per minute, 750 horsepower; one Harris, 18 and 30 by 42-inch, 84 revolutions per minute, 500 horsepower; one Harris, 18 and 30 by 36-inch, 96 revolutions per minute, 450 horsepower; one International Power Company, 19 and 44 by 48-inch, 100 revolutions per minute, 750 horsepower; three Brown, 22 and 40 by 48-inch, 100 revolutions per minute, 750 horsepower. The electric-generating equipment of the plant consisted of 10 generators ranging in size from 135 to 675 kilowatts.

The total energy generated in the plant during 1905 was 5,354,000 kilowatt-hours. The company sold 1,409,000 kilowatt-hours for power purposes, which was an important factor in economical generation through its effect on the station-load factor as a whole. The company burned 7857 tons of New river coal, costing on the average $4.28, the fuel consumption per kilowatt-hour being 3.29 pounds. The operating force of the station consisted of three engineers, four oilers and cleaners, three firemen, two coal passers, three dynamo and switchboard men, two repairmen and one station clerk. The operating cost was as follows, omitting cents in total figures:

Coal or other fuel	$33,622
Rentals, station real estate	120
Oil and waste	561
Water	1,056
Wages at station	17,020
Station repairs	5,594
Steam-plant repairs	9,655
Electric-plant repairs	621
Station tools and appliances	1,562
Total	$69,814

Per kilowatt-hour the principal costs are fuel, 0.63 cent, and wages at station, 0.318 cent.

The equipment of the station was the same during the next year as in 1905. The cost of coal per ton increased to $4.42, and the plant consumed 8328 tons. The output was 6,038,000 kilowatt-hours, and the power sales 1,772,000 kilowatt-hours. The company's efforts to increase its power business enabled the machinery to be run at better loads during the daylight hours, when the demand upon the plant for lighting current was the least. The station force was practically the same, with the addition of one man, as in 1905. There was a saving in fuel consumption of about 0.2 pound of coal per kilowatt-hour. The total fuel cost was $36,820, or 0.61 cent per kilowatt-hour. The wages cost was $17,296, or 0.286 cent per kilowatt-hour, and the total cost of manufacture was $71,021, or 1.18 cents per kilowatt-hour. There was a saving of about $5000 in station repairs compared with the previous year.

In 1907 the equipment of the plant was practically the same as in the preceding two years. The output increased to 2,196,000 kilowatt-hours. The station was operated by seventeen men and the cost of coal rose to $4.55 per ton. The total fuel consumption was 9869 tons. The total fuel bill came to about $45,000, or 0.635 cent per kilowatt-hour. The labor cost was about $17,450, or 0.247 cent per kilowatt-hour, and the total cost of manufacture was $69,000, or 0.975 cent per unit produced. There was a reduction this year of about $9000 in steam-plant repairs. Other items showed less variation. The total repairs of station, steam and electric plants came to about $3400.

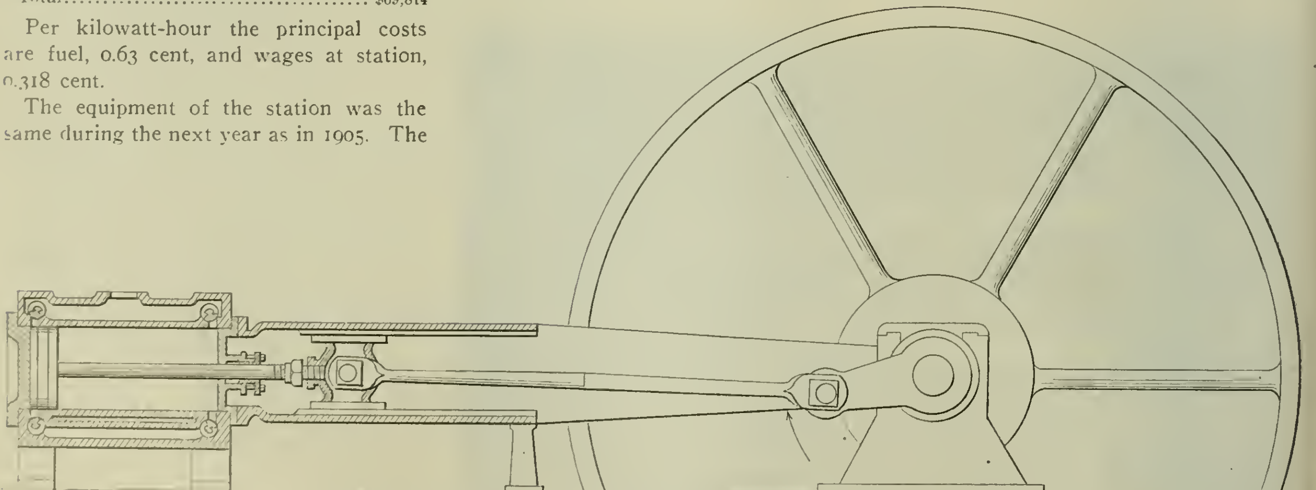
For the last year of the station record, 1908, the cost of fuel per ton increased to $4.75. In this year the initial installation of the new plant was opened for service, and this consisted of a 2000-kilowatt Curtis steam turbine, with three Stirling boilers having each three hundred and ten 3¼-inch tubes, operated at 180 pounds and rated at 526 horsepower. The total boiler capacity was thus increased to 3229 horsepower, and the total engine and turbine horsepower to 7200. The coal consumption was 14,101 tons, and the station force was five engineers, four firemen, six station electricians, ten boiler-room men and two repairmen. The fuel cost in toto was $67,000, and the advance in price per ton tended to increase the cost per kilowatt-hour to 0.71 cent. Station wages came to $24,700, or 0.262 cent. per kilowatt-hour, and the total manufacturing cost per kilowatt-hour was 1.06 cents, the amount expended for power production being $100,000. The energy generated by the station was 9,426,000 kilowatt-hours. The other items of production cost were not altered to any considerable extent compared with those of the previous year.

Summing up the history of the station during the period considered, there has been a progressive increase in the cost of coal, which is a serious obstacle to the economical production of power with a fairly stationary equipment. This has been offset to a considerable degree in the plant by careful operation, and particularly by the increasing of the power load each year. At the end of the four years this had increased to 3,760,000 kilowatt-hours, or 2.7 times the power sales of 1905. The steadying effect of such an output is inevitably a great help toward the operation of station apparatus at points nearer their most efficient output. That the cost per kilowatt-hour should have been reduced from 1.3 cents to about 1 cent in this period indicates that the plant has been operated with skill, in the face of high fuel costs and not the most modern equipment.

Two Loose Nuts

By W. H. Wakeman

The engineer of a certain plant reported that his engine pounded badly for a portion of the time, then would run quietly until for some reason the pound returned, and this disagreeable condition of affairs annoyed him for several days. If the pound had been continuous the cause would undoubtedly have been found with little delay and trouble, but the intermittent action constituted a puzzle that baffled his efforts. Another engineer was called in for advice, and he proceeded to give the machine a thorough examination. He found the piston rod screwed into the crosshead in the usual way, but the check nut was loose, and this allowed the rod to



LOOSE CHECKNUT AND PISTON PARTLY UNSCREWED FROM THE CROSSHEAD turn in the crosshead. It would unscrew until the piston struck the cylinder head at every revolution, causing a heavy pound, but for some unaccountable reason nothing was bent or broken.

The rod would then screw into the crosshead until the usual clearance on the head end was restored, consequently the pound disappeared. As the nut was frequently in contact with the crosshead when the engine was shut down, the defect was not discovered by the regular engineer.

In another case the same defect caused trouble, but in this instance much heavier blows were struck on the cylinder head when the crank was about to pass the inside center, as shown in the illustration. The engine was promptly shut down, the defect discovered, and both rod and nut were returned to their proper places, with but little delay in the operation of the machinery.

Shims had been placed between the end of the connecting rod and the corresponding half of the wristpin box, and these were forced together until a more perfect fit was secured for the surfaces in contact, by the great stress brought to bear on them by the toggle-joint action of the crank while in the position illustrated, in connection with the leverage of the flywheel. When the engine was started again there was a slight pound at the wristpin, although this box gave no evidence of lost motion before the accident. It was necessary to readjust the wedge at this point in order to restore normal conditions.

The joint made by joining the frame to the cylinder began to leak steam soon afterward, and when at attempt was made to tighten the nuts at this point, three studs were found broken in two, or pulled apart by the great strain that had been brought to bear on them. Fortunately the remainder proved sufficient to carry the load, thus preventing more serious trouble, but it was a very narrow escape.

This method of fastening a piston rod is preferred by many engineers because it admits of easy and accurate adjustment at all times, and allows the piston to be removed from the cylinder with little trouble. Do not use a pipe wrench on the piston rod to turn it out of the crosshead, as a certain engineer did, but turn the check nut back as far as it will go on the threads, then apply the solid wrench which is supplied by the engine builders for this purpose.

Great care should be taken to fasten the nut securely when the rod is returned to its proper place. It is not sufficient to put a wrench on it, then allow the fireman to sit on its short handle, but several smart blows with a hammer of suitable weight ought to be struck near the end of it, as the shock so produced is equal to, or better than, the operation of a long lever under steady weight or pressure.

Production of Electricity by Peat

By E. [illegible]

Peat exists in large quantities in Europe and America. In some sections of the United States, as in Michigan, for instance, the peat deposits are covered by woods, shrubbery or swamp, and are sometimes 40 feet in depth, rarely more. Wet peat contains from 80 to 90 per cent. of water and is dark brown, nearly black.

In order to prepare peat for fuel it has to be dug, formed into rectangular strips or blocks, of cross-section about the size of a tile, and dried in the open air. These operations may be wholly done by hand or partly by machinery. In the latter case the peat is dug by hand, carried by a conveyer to the press or mixing machine, where its fibrous structure is separated and expelled in the form of strips about 5x5x15 inches in size. These are piled on the ground for some weeks to dry. They are laid crosswise in a pile about 2 feet high, which permits the air to circulate around them, and in this way they become thoroughly dried, when they are ready for use.

Dry peat is dense and hard, like tile, is very inflammable and produces little smoke and ash. Its thermal value is about from 6900 to 7200 B.t.u. (if containing from 15 to 20 per cent. moisture), or practically one-half the thermal value of high-grade coal. The material when free of water is composed of 60 per cent. C, 5 per cent. H and 35 per cent. O.

The use of peat produced in the manner outlined has two marked disadvantages: (1) The drying process is dependent upon the weather. In Europe, for instance, the production period usually only extends over 100 days a year, and the capacity of the plants is very small. In fact, 10,000 tons a year is considered a very high output. (2) Transportation costs are in proportion to the weight, not the thermal value, and this means paying twice as much freight, compared with coal, for the same amount of heat. Therefore, peat is in general more expensive than coal.

Careful investigations have led to the following conclusions: It is better to bring the factory to the peat than the peat to the factory, and save the cost of transportation. Also, it is more profitable to use wet peat for fuel, as this permits the plant to be operated the year round without regard to the weather.

Producing Electricity from Peat

In certain parts of Europe, in producing electricity from peat, either of the following methods is used:

(a) Gas is made in a producer and burned in a gas engine. For the most part dry peat is used, but it is possible to use wet peat, or from 40 to 50 per cent. moisture. The producers and gas engines used with peat [illegible] usually the patents of firms which have been engaged in this line for years. The gas producers are built by Lutter in Braunschweig (Germany), Reed in Mannheim and Körting in Hannover. The thermal value of the gas is from 990 to 1100 B.t.u.

(b) Wet peat is placed in a boiler, where the moisture (80 to 90 per cent.) is evaporated and superheated and employed in driving a steam engine or turbine. The residue is dry peat, which is automatically ejected and burned under the boiler. Thus, while some dry peat is used it only requires about one-eighth as much as though dry peat were used altogether. A wet-peat plant of great horsepower is in course of construction to supply light and power to the towns of [illegible] and [illegible] and fifty other places within a radius of thirty miles. The engine and boiler are to be furnished by the Maschinenbau Gesellschaft, Nürnberg.

These two methods are comparatively new. The difficulty with the first is to produce a gas free of tar. This would not be difficult ordinarily with dry peat (of 20 per cent. moisture), but in the case under discussion the process is expensive and the peat exists in small quantity. The objectionable feature of the second method is the complicated boiler.

Peat Problem in the United States

Under present conditions in the United States the peat problem is not very important. Coal is cheaper and wages higher. When the United States becomes more densely populated the problem will be ripe for discussion and solution. Americans have to get the experience of the old country, as yet, and it would be a waste of time to try new methods. The only chance for improvement is to substitute machinery for hand labor, and perfect the machinery.

The peat problem seems very simple but, in truth, it is quite the reverse. Millions upon millions of dollars have been lost, but it is also a fact that experienced producers made big profits with small investments.

In the inquiry on "Path of Point on Connecting Rod," published in the December 29 number, page 1104, formula (1) and the last formula used in the answer were not printed according to copy. Formula (1) should read

[illegible]

and the substitution of figures made in the formula should read

[illegible]

The answer was given correctly but it would, undoubtedly, be a matter of question how such a result was obtained from the expression as printed.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 we printed and circulated 1,836,000 copies of POWER.

Our circulation for January, 1909, was (weekly and monthly) 160,000.

February 2............ 40,000
February 9............ 37,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

Contents

Municipal Ownership

We give place to a letter on "Municipal Ownership," by Arthur Williams, in our correspondence columns, despite the fact that we are not interested in the question, which is a sociological rather than an engineering one. POWER'S subject is engineering and not political economy.

The clipping from the Wisconsin paper, to which the editorial which called out Mr. Williams' letter refers, says that "a city cannot run a lighting plant as cheaply as private companies can supply the light." The subscriber who sent it asked for our opinion upon this question, which, divested of politics, is an engineering one; and after a careful consideration of Mr. Williams' contention we should still answer it as we did before. The boilers, engines and generators do not know nor care who owns them. Put them into the hands of an equally good man, give him a free swing and hold him responsible for results and they will produce current for the people as cheaply as for a corporation. The additional dividends which it is necessary to pay upon watered stock, franchise valuation, corruption funds, etc., may be put against the increased costs due to political graft, etc., of which Mr. Willams protests—but this is getting out of the engineering side of the case.

The business of producing electricity is getting systematized. The cost of plant per kilowatt, the cost of putting current upon the switchboard, the cost of distribution are becoming known and a free exchange of data among such plants and the publication of uniform reports, as is done by water-works engineers, would make a particularly extravagant station stick out like a sore thumb, whether it belonged to the public or to an individual.

Please remember that a continuation of this discussion must be along engineering and not socialistic nor political-economical lines.

The Gas Engine Engineer

Repeatedly the assertion has been made that the average stationary engineer does not develop into as efficient a gas engineer as the ordinary machinist, although why such a view of the matter should be taken is not always definitely stated. The average machinist has the advantage of knowing how to repair or even make a part of a machine in case of breakdown. He has a better knowledge of the use of tools, if he is a man of experience, but it is difficult to see how these accomplishments are such strong points in his favor as to put the steam engineer out of the race. The machinist's one real advantage over the steam engineer is that he does not know how to run a steam engine; this can be considered advantageous because, not knowing anything about the operation of any type of engine, he is more likely to feel receptive toward advice and instruction.

The steam engineer is familiar with the operation of both steam and gas engines, as far as the reciprocating parts are concerned, but in the matter of the action of the power medium he is familiar only with steam. Of the action of gas in an engine cylinder he has much to learn—as much as, if not more than, the machinist, because there is liability of his confusing the manner of regulating the effect of exploding gases with that of steam expansion. In the matter of adjustments the engineer should be at home; in the care of bearings, the same vigilance is required as with steam engines, and no more.

With all the good things that may be said in favor of the steam engineer as a candidate for gas-engine honors, however, he is handicapped in one particular. He is familiar with steam-engine operation and expects to obtain the same results from a gas engine. This is something that cannot be done. It is no uncommon thing to see a steam engineer fret and worry because his engine has developed a pound or some little thing out of the ordinary; such an engineer will not rest contented until that fault is found and remedied. His greatest ambition is so to adjust his engine that it will operate practically without noise, and in some cases this is carried so far as to become almost a mania. There is a good deal of satisfaction in having a smooth-running engine, and the engineer is excusable if he is a trifle "finicky" on this subject. When it comes to running a gas engine, noiseless operation is a snare and a delusion to an operator who has fond dreams that its operation is to be a round of pleasure. He expects almost noiseless operation, and gets rattling and sometimes clanging. He listens for a modest click by the valve gear and hears the whacking of the cams and the muffled thump of the valves as they seat. The smooth-running engine which was expected is not in evidence, and then the steam engineer makes his mistake; he attempts, by adjustments here and there, to make the gas engine operate as quietly as a steam engine. As the functions of the different devices on the gas engine are not at first fully understood, it does not take long for him to get the adjustments so out of place that the engine refuses to work properly, and serious trouble ensues.

Here, then, is the chief difference between the two candidates. The machinist, not expecting any particular sounds from the engine, accepts the noises of operation as he finds them, and consequently does not meddle with the adjustments until he has so familiarized himself with the working of the engine that he knows what he is about. If a steam engineer will not demand of the gas engine that which it cannot give, and will leave all adjustments alone until he understands what the effects of making them will be, he will be able to hold his own against all comers.

Compression

Some months ago there were received from a small town in Oklahoma two sets of indicator diagrams. One set was of the conventional type of Corliss-engine diagram, with the compression curve rising to about two-thirds the initial pressure and with plumb-line induction, showing ample lead of steam valves and full pressure on the piston while the crank was still on the center. The other set from the same engine showed only a little rounded heel of a compression curve and the admission line inclined toward the middle of the diagram, showing plainly that the piston had actually moved a measurable distance before full steam pressure was realized in the cylinder.

These second diagrams were not good-looking, as handsome diagrams are usually considered, and computation showed that the indicated horsepower was considerably less in the case of late steam-valve opening and lack of compression than it was where ample steam lead had obtained and all of the lost motion in pins and journal was taken up by plenty of compression. But the engineer said that the actual load, that is, the useful work that the engine was doing, was the same in both cases, and asked why less steam was used to do the work with the one style of valve setting than with the other. The answer that was given him said in substance that the reduction of pressure on pins and main journal reduced the friction of the engine and thus decreased the load to be carried and consequently reduced the quantity of steam used per brake horsepower per hour.

Attempts were made to get one or two mechanical-engineering professors interested in the matter, to the extent of experimenting on an engine with a fixed load with different valve settings, with rather discouraging results. It was said the steam in expanding gives up to the piston all of the energy expended in the compression and it makes little or no difference as far as economy is concerned whether an engine is operated with or without compression.

These ex-cathedra statements have a tendency to create a feeling of antagonism in the mind of the average operating engineer toward all technically educated men. Some engineers know from experience that there is a slight loss if compression is carried above the terminal pressure, while others feel that there is really a gain made by carrying the compression line to about one-half or two-thirds of the boiler pressure.

Most of the mechanical-engineering laboratories of the universities of the country are equipped with engines fitted to decide this question by scientific investigation. It could be shown whether an engine with a constant brake load, such as could be readily measured, would use more or less steam with one form of valve adjustment than with another. Pounds of steam per indicated horsepower-hour, pounds of steam per brake horsepower-hour and the indicated horsepower necessary under different valve setting to carry a certain brake horsepower are questions that are of vital interest to the designing as well as to the operating engineer. And only in the laboratories of the technical colleges of the country is the apparatus suitable for making an exhaustive test to be found. Can the men at the heads of these experiment stations determine these things?

Some years ago some experiments along this line were made in Belgium and although they were incomplete, owing to the fact that the engine used "did not lend itself readily to compression," the conclusion reached was that compression of exhaust steam in the clearance space resulted in a direct loss.

At many of the universities are engines which will readily lend themselves to compression. Can one or more of these engines be pressed into the service of settling for the operating engineer, who has no opportunities for satisfactory experiment, the question of whether compression leads toward economy or away from it?

The Engineer and the Central Power Station

Successful steam-engine operation means a great deal beyond the running of a steam plant at its highest efficiency. Not alone should the engineer seek to keep his plant in the best of operating condition, but he should also see to it that nothing that may be of advantage to himself or the plant escapes his attention.

In its search for business the central power station is competing with the isolated plant and through its solicitors attempting to show the small-plant owner that business wisdom indicates that it is better and cheaper to buy power than to attempt to make it. Whether this is true can be better determined by the engineer of the small plant than by anyone else in the world.

In a manufacturing town a new engineer of a large building found several of the tenants buying both power and light from the central station and the proposal was good for some business for the central plant. After thoroughly familiarizing himself with all of the facts of the situation he went to the proprietor and said:

"You have an engine furnishing power and lights to some of your tenants. The proper thing to do is to furnish all the power and all the light to all of your tenants. You have an engine running at sixty revolutions a minute and it is lightly loaded. The speed should be increased to one hundred revolutions, and it can be with perfect safety. This will give you an increase of forty per cent. in power, which will enable you to take over all of the load that is being carried by motors with current from the central company. I know how many lamps are being used and the size of dynamo needed to light them. Buy and install this and change the speed of the engine, then I will say to your tenants: 'You are paying thirteen cents per kilowatt-hour for current to light your rooms. I am prepared to furnish this light to you for eight cents.'

"Since I will have a full load for the engine without costing you any [illegible] for extra coal. For seven months of the year you have to heat the buildings, so it will cost you practically nothing to run the engine and the revenue from the lighting will pay a big rate of interest on the outlay."

The proprietor was skeptical, but finally consented to the change. At the beginning of each month the engineer laid his reports before the owner. As time went on the revenue from the lights, which had been applied directly to the liquidation of the coal bill, began to show a surplus. One day when the reports were being examined the engineer said:

"You see that the coal bill last month was six hundred and some odd dollars, while the amount collected for lighting amounted to more than seven hundred dollars. From these figures you can readily see that you do not need to worry any over my salary. The Central Lighting and Power Company is paying that [illegible]."

And being asked to explain, he said:

"Before I took this place you were burning very nearly as much coal as you are today. You were heating the different buildings with [illegible] through the engine, lots of steam direct from the boilers was used.

"The engine has been speeded up and more load put on and the exhaust used for heating. The extra load came from the lights and power that were taken from the Central Company. The money that your tenants paid that company is now paid to you and it is all profit, a small interest and depreciation [illegible]. [illegible] formerly went to the Central, it costs you practically nothing. [illegible] for you. I have shown you that I am a source of revenue to you. I want a part of it because I am worth it, and because I [illegible] Central Company."

The Weighton Air Gage

In steam-engine practice the losses resulting from air leakage in the condenser system have been guessed rather than calculated. In order that the engineer may determine at a glance the amount of air being discharged an air pump may be

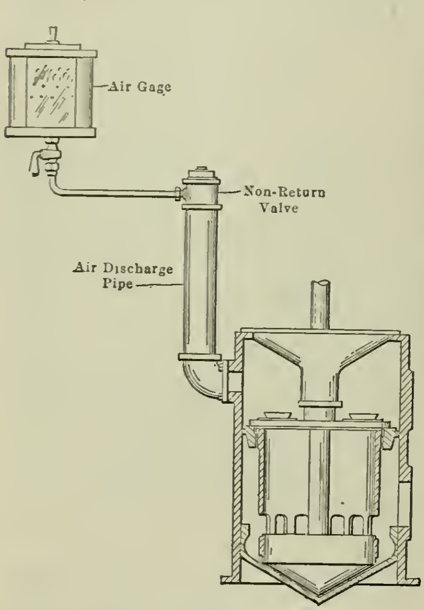


FIG. 1

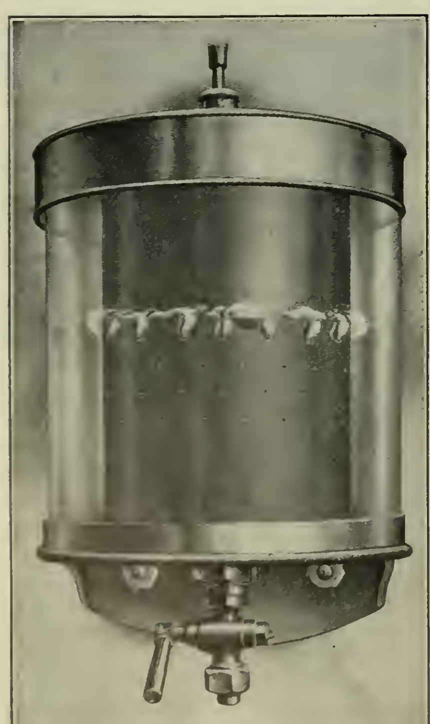

FIG. 2

fitted with a Weighton air gage. It is a glass cylinder, closed at the bottom and containing a stationary bell, the interior of which is in communication with the air-discharge pipe of the air pump. See Fig. 1. Around the surface of the bell are several rows of holes, as shown in

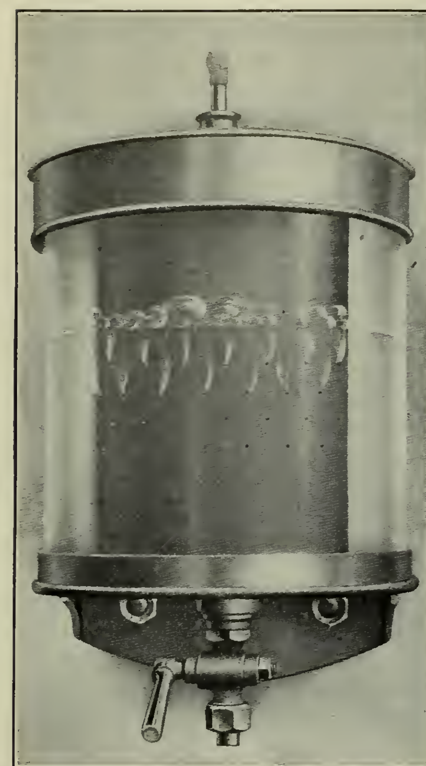

FIG. 3

Fig. 2. The outer cylinder is filled with water to a point where it will just cover the highest row of holes. When air is admitted, even under very slight pressure, the water level is depressed below the top row of holes and air escapes through them. As more air is admitted to the bell the water is correspondingly depressed and additional holes are exposed. As original calibrations have been made, the number of cubic feet of air being discharged under any given condition is easily ascertained, while the relative amount of air being handled by the air pump is shown by the condition of the air gage (Figs. 3 and 4). The device is the invention of R. L. Weighton, professor of electrical engineering at Durham College of Science, Newcastle-upon-Tyne, England. It will be introduced in this country by the Elwold Company, North American building, Philadelphia, Penn., which also represents the Contraflo Condenser Company, Ltd., of London.

FIG. 4

Museum of Safety and Sanitation

Announcement has just been made of the acceptance of the treasurership of the Museum of Safety and Sanitation by Frank A. Vanderlip. An executive office for the administrative and promotive work of the museum has been opened at the United Engineering Societies' building, 29 West Thirty-ninth street. New York City.

A committee on plan and scope includes Prof. F. R. Hutton, chairman; Dr. Thomas Darlington, commissioner of the health department of the City of New York; P. T. Dodge, president of the Engineers' Club; William J. Moran, attorney-at-law and Henry D. Whitfield, architect.

Plans are being pushed forward along practicable lines to prevent the enormous loss of life and limb to American life and labor, through the Museum of Safety and Sanitation, where safety devices for dangerous machines and preventable methods of combating dread diseases may be demonstrated. Charles Kirchhoff, editor of *The Iron Age*, is the chairman of the committees of direction; T. C. Martin, editor of *The Electrical World*, vice-chairman, and Dr. William H. Tolman, director.

Street and Electric Railway Power Plants

In a preliminary report on street and electric railways in the United States, exclusive of Alaska, Hawaii, Philippine islands and Porto Rico, the Department of Commerce and Labor shows that for the year ending December 31, 1907, there were 827 power houses, 2,384,518 horsepower of steam and gas engines, including turbines, or 2552 units in all, and 228 water wheels, aggregating 91,961 horsepower, employed in the street-railway business. These figures represent 2.7, 83.4, 8.5 and 42.5 per cent. of increase, respectively, over the year ending June 30, 1902.

GROUP OF OFFICERS AT NATIONAL MARINE ENGINEERS' BENEFICIAL ASSOCIATION CONVENTION AT WASHINGTON, D. C., JANUARY, 1909

DELEGATES AT NATIONAL MARINE ENGINEERS' BENEFICIAL ASSOCIATION CONVENTION AT WASHINGTON, D. C., JANUARY, 1909

NEW YORK DELEGATION TO NATIONAL MARINE ENGINEERS' BENEFICIAL ASSOCIATION CONVENTION AT WASHINGTON, D. C., JANUARY, 1909

Bulletin No. 26, "High Steam Pressures in Locomotive Service," has just been issued by the University of Illinois Engineering Experiment Station. It summarizes the results of one hundred locomotive tests conducted by Dr. W. F. M. Goss under the patronage of the Carnegie Institution in coöperation with the authorities of Purdue University. The general question is discussed as to whether a possible increase in the weight of a boiler should be utilized by making the boiler stronger that it may carry a heavier pressure, or by making it bigger that it may have more heating surface. The conclusion is to the effect that single-expansion locomotives using saturated steam are most efficient when operated under a boiler pressure of 180 pounds; that when this limit of pressure has been reached, any farther increase in weight which may be possible should be utilized in securing increased boiler capacity rather than higher boiler pressures. Copies of this bulletin may be obtained gratis upon application to the director of the Engineering Experiment Station, Urbana, Ill.

The American Anti-Accident Association, with headquarters at Sharpsville, Penn., will hold open meetings, afternoon and evening of Thursday, February 11, in the Y. M. C. A. hall, 215 West Twenty-third street, New York City, for the delivery of addresses and considering of ways and means to prevent accidents. In order that all classes may have a hearing the society extends a general invitation to Government and municipal officials, professional men and women, commercial travelers, manufacturers, managers and superintendents, merchants, labor leaders, mechanics, etc., factory inspectors, fire and life insurance officers, teachers and all other citizens who may be interested in this work, to attend both sessions of these public meetings.

NATIONAL MARINE ENGINEERS SUPPLYMEN'S ASSOCIATION AT THE CONVENTION AT WASHINGTON, D. C., JANUARY, 1909

Inquiries

Questions are not answered unless they are of general interest and are accompanied by the name and address of the inquirer

---

Using a Motor as a Dynamo

Can I use a 500-volt direct-current motor as a 110-volt dynamo? If so, what changes are necessary?

R. M.

No; not without completely rewinding the field magnet and armature. You can use the machine as a 500-volt dynamo by discarding the starting box, putting a rheostat in the field-winding circuit and driving the armature at a speed about 10 per cent. higher than that at which it runs as a motor.

Reversing a Compound-wound Dynamo

What changes are necessary in order to permit driving a compound-wound direct-current dynamo in the reverse direction of rotation?

G. W. McF.

Transpose the cables leading from the brush holders to the terminal block, making the change at the brush-holder ends in order to avoid accidental disturbance of some other connection. Then reverse the brush holders so that they extend from the studs in the opposite direction from the original one. That is, if they now "trail" with respect to the travel of the commutator, they should be turned around so that they will "trail" when the rotation is reversed. Carefully avoid making any changes in the connections of the field-magnet windings.

Power Value of Different Gases

What is the effect of the kind of gas used in an engine upon the power of the engine? That is, will rich gas give more power than poor gas?

J. T. M.

The maximum ability of an engine of given piston displacement is somewhat higher with rich gas than with poor, but not in proportion to the heat value. It is the heat value of the mixture that really determines the performance, and rich gases require so much more air than poor gases that the mixture is not as much richer as you would think. A good mixture of natural gas and air has only about 50 per cent. more heat value than a good mixture of producer gas and air, although natural gas has about seven or eight times the heat value of producer gas.

Ratio of Expansion

Will you please tell me what is ratio of expansion and how is it found?

M. H.

Ratio of expansion is the proportion the total volume of the steam in the cylinder at the end of the stroke bears to the volume at cutoff. To find the ratio of expansion divide the stroke in inches by the number of inches of the stroke completed when cutoff takes place. To be exact in calculating the ratio of expansion the clearance must be known and taken into consideration. If, for instance, the effect of the clearance is such that it adds 1 inch in length to the volume of the cylinder at each end, then this must be added to the stroke of the piston and to the distance the piston moves before cutoff. Suppose the stroke of the engine to be 30 inches and the cutoff to take place after the piston has traveled 6 inches; nominally the cutoff would be at 1/5 stroke and the ratio of expansion would be 5, but actually the cutoff would be 7/31 of the stroke and the ratio of expansion would be 4.428.

Effect on Cutoff, etc., of Shifting the Eccentric Center

What is the effect, on the cutoff, compression and lead, of shifting the eccentric center toward the shaft center when the point of suspension of the eccentric is located on the center line of the crank and the shaft on the same side of the shaft as the crank pin?

M. C. B.

Lead being understood as the distance which the valve has opened when the crank reaches the dead center, it would be affected by shifting the eccentric center toward the shaft center as follows: First, with the eccentric pin preceding the crank in the direction of rotation, the lead would be increased if the movement of the eccentric rod was reversed through a rocker arm, as is the case with some engines, and had an inside steam valve, that is, a valve which admits steam by the inner edge. Second, under the same conditions the lead would also be increased if the motion of the eccentric rod was transmitted direct to the valve through the ordinary carrier arm, and an outside valve was used, that is, one taking steam by the outer edge like an ordinary slide valve. Third, if the eccentric followed the crank in the direction of rotation, the lead would be decreased if the motion of the eccentric rod was reversed through a rocker arm and an outside steam valve was used. Fourth, with the eccentric following the crank the lead would be again decreased if the eccentric motion was transmitted direct through a carrier arm and an inside steam valve was used. The cutoff and compression would take place earlier under each and all of the above arrangements.

Amount of Injection Water Required to Condense Steam

Will you give me a rule or formula that will enable me to determine the amount of injection water needed to condense the steam from an engine?

T. W. L.

The quantity of water necessary to condense the steam from an engine depends upon the volume and total heat of the steam and the temperature of the condensing water. Let

H = Total heat in 1 pound of steam at terminal pressure.

h = Heat in a pound of water at the temperature of the condensed steam.

t = Temperature of condensing water entering the condenser,

T = Temperature of water leaving the condenser.

Then, the amount of water needed would be determined by the equation

$$\text{Quantity of water} = \frac{H - h}{T - t},$$

because the number of heat units absorbed by each pound of water will be represented by $T - t$ and the number of heat units taken out of each pound of steam will be represented by $H - h$.

From the formula the rule is deduced:

RULE—*From the total heat of 1 pound of steam at the given pressure, subtract the heat in 1 pound of water at the temperature it leaves the condenser. Divide this remainder by the rise in the temperature of the condensing water. The quotient will be the pounds of water needed to condense 1 pound of steam. That multiplied by the number of pounds of steam used by the engine will give the total condensing water required.*

In a general way, it may be stated that with condensing water at or near 70 degrees temperature and with a 26-inch vacuum, from twenty to thirty times the weight of water fed to the boilers will be required to condense the steam.

Changing Generator Frequency

I have an old-style Thomson-Houston 1100-volt 125-cycle generator and I should like to know if this or any other 125-cycle generator may be changed to 60-cycle by reducing the speed one-half. I take it that the capacity would also be reduced one-half, but by keeping the voltage of the former amount would not the machine do as good work at a lower frequency but with the same voltage? Of course, there are other things to be considered.

D. A. S.

The frequency can be changed to 60 cycles by reducing the speed to 48 per cent. of the rated speed. This, however, will reduce the voltage to 48 per cent. of the normal, or 528 volts. In order to avoid this the armature would need to be rewound with wire coils containing 2.08 times the present number of turns of wire. This wire would be less than half the size of the present wire and the full-load current would be correspondingly reduced.

La Technique Moderne is the name of a new monthly journal of applied science and published by Messrs. Dunod & Pinat, at Paris. Editorial direction is under M. Boutroux, inspector of technical instruction in the Ministry of Commerce and Industry. The committee of advice comprises some well known professional and university specialists, and the first number, that of December, 1908, presents a promising and creditable appearance.

Business Items

George T. Ladd has established offices at 1620 Farmers' Bank building, Pittsburg, Penn., as representative of the Bass Foundry and Machine Company, of Fort Wayne, Ind.

The York Manufacturing Company, York, Penn., manufacturer of ice-making and refrigerating machinery, has received 26 recent orders aggregating 992 tons of refrigeration. One of these plants is for Yokahoma, Japan, Japan, and one for Smyrna, Turkey.

J. G. Aldrich, who was formerly with the Power and Mining Machinery Company, of Cudahy, Wis., has accepted the position of chief engineer of the Industrial Gas Power Company, of Milwaukee. Mr. Aldrich will continue to make a specialty of gas-engine and producer work, in which branch of endeavor he has been active for the past eight years.

The Larson Lumber Company, of Bellingham, Wash., has ordered from the Minneapolis Steel and Machinery Company, a 22x42 Twin-City Corliss engine. This engine will develop about 500-horsepower. It will have a flywheel 14 feet in diameter, grooved for twenty-four 1½-inch ropes. The machinery for the main drive has also been ordered from the same company.

The Rockwell Furnace Company has been awarded the contract covering the complete furnace equipment for the new locomotive shops of the Delaware, Lackawana & Western Railroad at Scranton, Penn. The furnace equipment consists of 35 of the latest-type furnaces operated with 300-B.t.u. water gas, which is made in Loomis-Pettibone producers. These shops will be capable of turning out complete locomotives, and are to be in operation in three months.

In order to take care of the increased business the L. J. Wing Manufacturing Company has increased its capital from $25,000 to $100,000 and has secured offices at its present address, the West street building, 90 West street, New York, twice the size of those at present occupied by them, and into which they expect to be removed by the 15th of February. While the ventilating business of the company has greatly increased, the principal increase is in the sales of the Wing "Typhoon" turbine blower made by this company.

The Buckeye Boiler Skimmer Company, South End, Toledo, Ohio, maker of the Buckeye boiler skimmer, has received a letter from the Harris Toy Company, Toledo, Ohio, in which they say: "We have had in use for about a year one of your boiler skimmers, attached to our McNull water-tube boiler, and have found it a very profitable investment. Before putting on this device, we were obliged to clean out our water tubes every two or three weeks in order to keep up a satisfactory amount of steam. After installing your Buckeye boiler skimmer, we found it only necessary to clean our boiler once in three months and in opening up the tubes we find but very little mud and scale."

An attractive brochure is printed by the Keystone Lubricating Company, Philadelphia, bearing the title, "Grease versus Oil," and containing instructive comparisons of the efficiency of the two great types of lubricant that are used to grease the wheels of industry. Some of the inner reasons for the extensive use of the liquid lubricant, oil, at the present day, to do the work that should properly be done by grease, are interestingly explained. A feature of the argument for Keystone grease as an ideal lubricant, at minimum first cost and operating cost, is an account of exhaustive tests made by the head chemist of William Cramp & Sons, the Philadelphia ship-builders, on the chemical constitution and mechanical and anti-friction qualities of the product. This booklet, of which many thousands have been printed and distributed, may be obtained gratis on application to the home office of the company, Philadelphia, or to any of its agencies.

New Equipment

The Rogersville (Tenn.) Ice Company has been incorporated. Capital, $10,000.

The Empire Electric Power and Supply Company, Carthage, Mo., will enlarge plant.

The Spreckles Sugar Refining Company, Philadelphia, Penn., will erect a power house.

The question of a municipal electric light plant at Union, Ore., is under consideration.

The Concully (Wash.) Copper Mining Company is planning to install an electric plant.

The Holton Power Company is erecting a new power plant near the present one in Holtville, Cal.

The Alton (Ill.) Water Company is said to have decided to expend about $70,000 in improvements.

The City Council, Dodgeville, Wis., has under consideration the question of installing a municipal electric-light plant.

The Valley Power Company, Cashmere, Wash., proposes to increase its output. It is said about $125,000 will be expended.

Fred. C. Schaub, Cody, Wyo., has been granted a franchise to construct an electric-light and power plant in Meeteese, Wyo.

The Oelwein (Iowa) Light, Heat and Power Company is planning improvements to plant which will cost about $25,000.

C. D. McCarthy has been granted franchise by the City Council, Stevensville, Mont., to construct an electric-light plant.

The city of Bellevue, Iowa, proposes to rebuild the municipal electric light plant at a cost of about $7000 W. J. Fay, city clerk.

The Marengo Electric Light and Power Company, Marengo, Iowa, is in the market for a fire tube boiler 125 to 140 pounds pressure.

The citizens of Samson, Ala., voted to issue $25,000 bonds for construction of electric-light plant and water-works. W. J. Gresham, mayor.

The municipal electric-light plant at Oconomowoc, Wis., is to be enlarged, for which purpose an appropriation of $11,000 has been made.

The Crystal Coal & Coke Company, Godfrey, W. Va., is in the market for a second-hand power plant. About 400 k.w. in two units will be needed.

The Washington Power Company, Spokane, Wash., will soon begin the construction of a new $750,000 power plant at Little Falls on the Spokane River.

It is reported that the Laclede Gas Light Company, St. Louis, Mo., contemplates making extensive improvements at an expenditure of about $10,000,000.

The City Council, Plano, Tex., is making arrangements to establish a municipal electric-light plant. J. C. Skinner can give further information.

The Asheville (N. C.) Electric Company has under consideration plans for improvements and extensions including construction of new power plant.

The Yukon (Okla.) Mill and Grain Company will receive bids until Feburary 15 for water-tube boilers, pumps, Corliss engine, etc., as per specifications.

The Citizens' Electric Light and Power Company, East St. Louis, Ill., has been granted a franchise to construct and operate an electric-light plant.

The North Yakima & East Selah Irrigation Company, North Yakima, Wash., contemplates the installation of a pumping plant of about 3000 horsepower.

R. B. Flesch & Co., is said to have been granted a franchise by the town council of Fowler, Kan., for an electric-light plant, water works and ice plant.

A New Lighting Station for Brockton

A Modern Alternating-current Turbine Plant Supplying 2200-volt A. C. Service and Direct-current Lighting through Rotary Converters

BY E. T. REED

To take care of increasing business and obtain a location where coal and water supply would be more convenient, the Edison Electric Illuminating Company, of Brockton, built a new power station in East Bridgewater to supplement an old plant in the heart of the city of Brockton. It was necessary in the old plant to run engines noncondensing. Coal and ashes had to be carted and city water used in the boilers. In the new plant the Matfield river supplies water for condensing and boiler feed, and coal is landed in the yard from a spur track from the New York, New Haven & Hartford Railroad.

The new plant was put in operation about a year ago. The building is of brick and concrete construction. The stack is self-supporting and made of steel

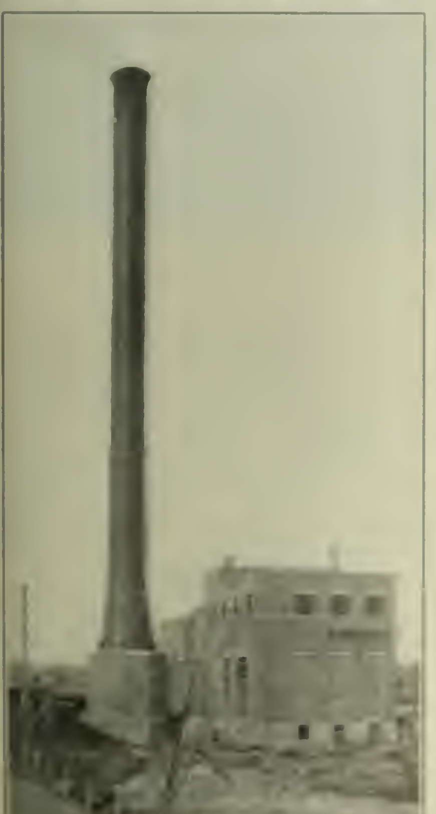

FIG. 1. POWER STATION AT EAST BRIDGEWATER

plate lined with brick. It is [illegible] feet in diameter and 235 feet high. The turbines and boilers are set in parallel rows, allowing for extensions in the future.

BOILER-ROOM EQUIPMENT

At present the boiler room is equipped with three 525-horsepower Stirling boilers with Babcock & Wilcox [illegible] superheaters furnishing steam at 200 pounds pressure and 150 degrees superheat. Provision is made for two rows of boilers with a firing aisle between, and coal is [illegible]

[illegible]

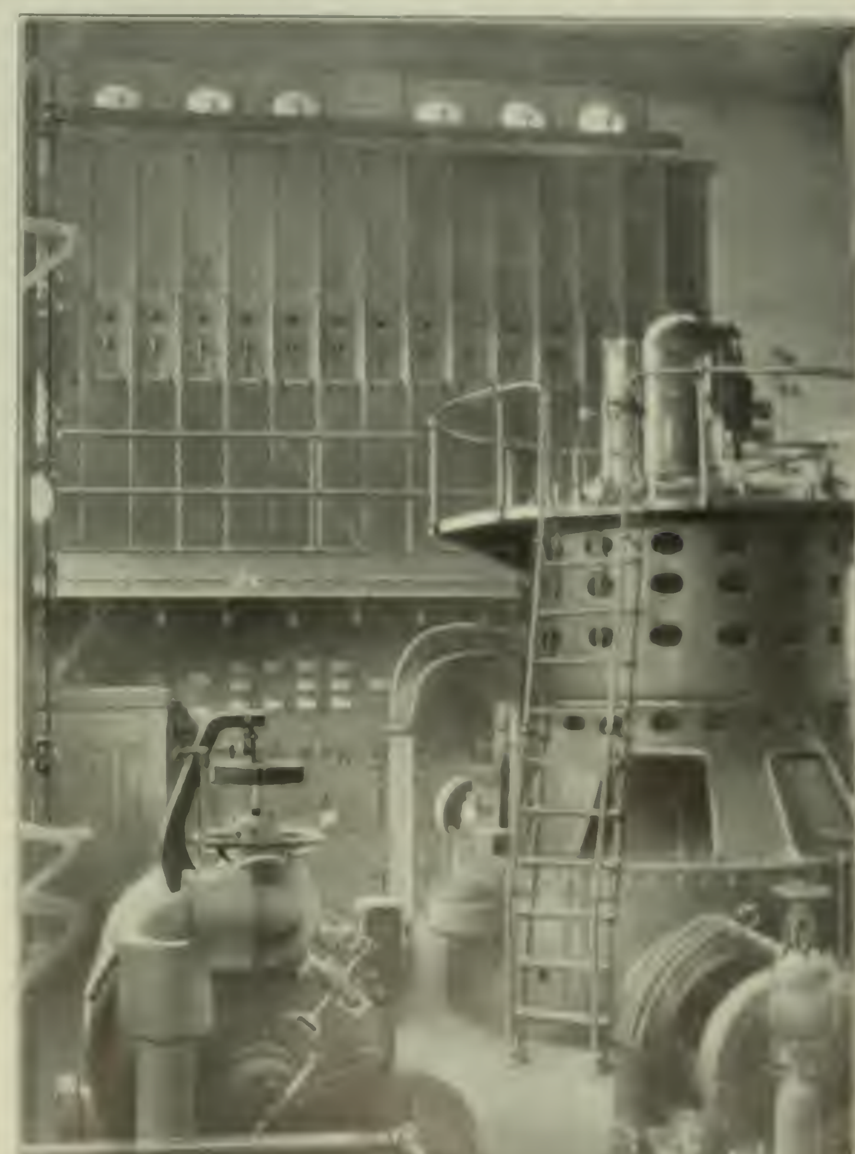

FIG. 2. [illegible]

[illegible]

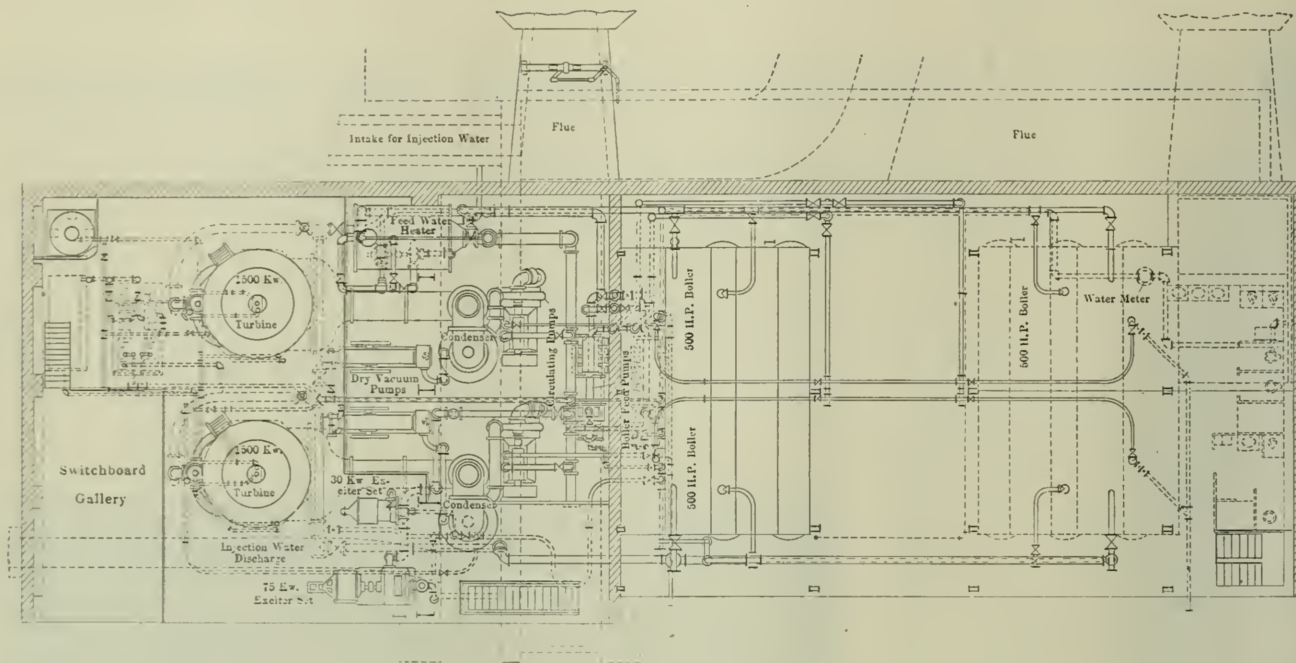

FIG. 3. PLAN OF POWER PLANT AT EAST BRIDGEWATER

8-inch branch, while the third boiler is connected to a 10-inch branch which is intended to care for four boilers. The superheated-steam main is 10 inches in diameter and is situated underneath the turbine-room floor. The saturated-steam main is also in the basement, and it is connected in the same way to the drums of the boilers. There is a connection between the superheated- and saturated-steam mains whereby superheated steam can be used on auxiliaries if necessary. The exciter turbines use superheated steam, but can be run on saturated steam if desired. All superheated-steam piping is of cast steel with welded flanges and is covered 3 inches thick with H. W. Johns-Manville 85 per cent. magnesia.

Two Blake duplex compound outside-packed plunger pumps, with cylinders 9x14x8x12-inch, take water from a Cochrane open feed-water heater and supply the boilers through two 5-inch brass mains, two 1½-inch branches extending to each boiler. The feed pumps can draw water from either the cold or hot wells in case the heater is cut out, and are equipped with regulators which keep the pressure on the feed mains the same at all times.

All auxiliaries exhaust through a 12-inch main to the heater which raises the temperature of the water to 210 degrees Fahrenheit. The feed-control valves on the boilers have valve stems extending to within easy reach of the floor, and there

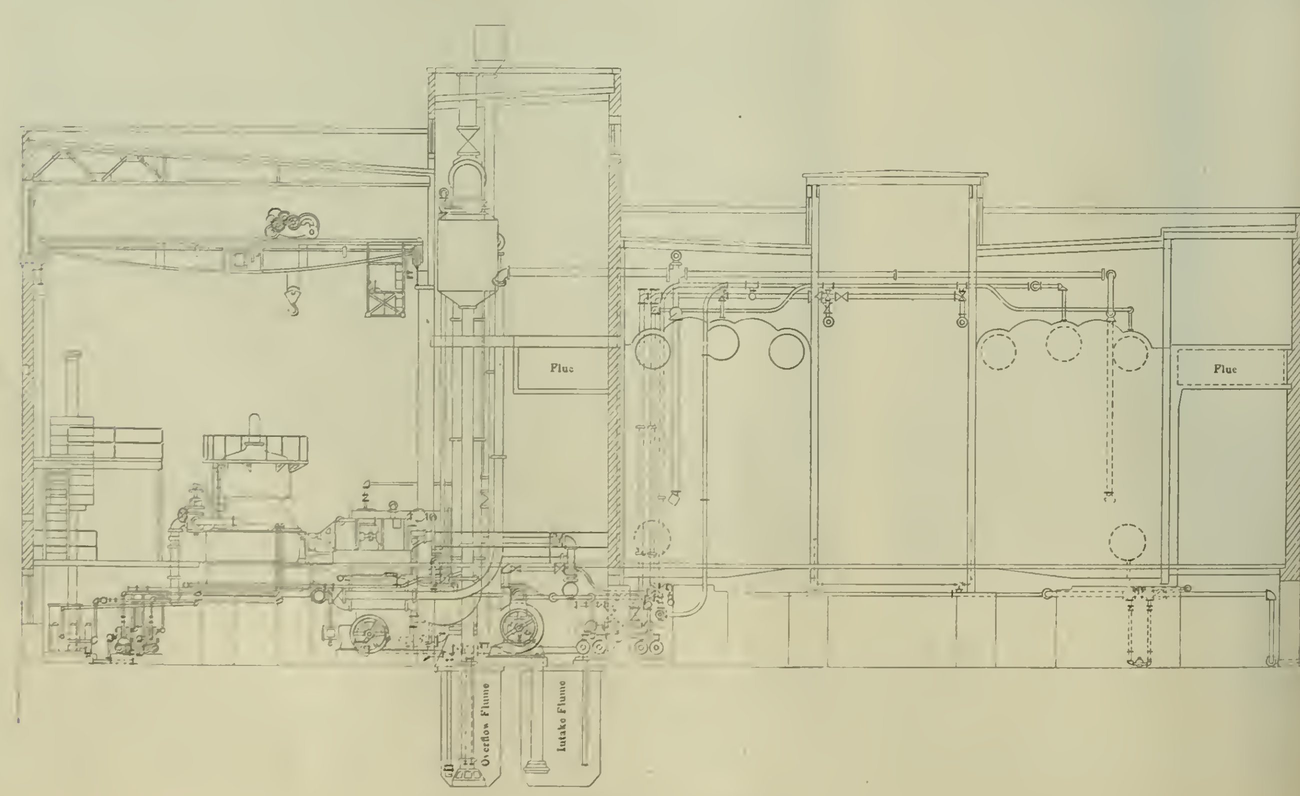

FIG. 4. SECTIONAL ELEVATION THROUGH PLANT

FIG. 5. SWITCHBOARD IN POWER STATION

is a stop valve and check between the regulating valve and the boiler.

A 5¼x4¾x5-inch duplex Blake service pump and tank furnish water from the cold well for all purposes about the plant, except the wash basins and shower baths in the toilet room. A 4-inch city water main is connected to all water connections and is used in cases of emergency. The hot and cold wells run parallel with the turbines and are under the basement floor, the condenser auxiliaries being grouped about them. A 4-horsepower three-phase motor, direct connected to a Worthington volute pump, elevates the water from the hot well to the feed-water heater, a low-water alarm giving notice when the water supply to the heater fails.

Thermometers are installed in the superheated and saturated steam pipes, turbine exhaust, boiler flue, supply and discharge pipes of the condensers and in the feed water at the pumps and at the boilers. Readings are taken every two hours. A Venturi meter measures the amount of water fed to the boilers, and by means of a weir at the end of the discharge pipe from the condensers, the amount of water escaping can also be measured. Ellison gages show the draft pressure at the boilers. A Bristol recording steam gage is connected to the steam main and a recording thermometer of the same make keeps a record of the steam temperatures at the turbines. A Stewart City boundary is now being installed. All high-pressure drips are returned to the boilers by a Holly steam loop.

THE TURBINES

There are two turbines installed and these are General Electric 1500-kilowatt four-stage condensing units running at 900 revolutions per minute. They are equipped with mechanical valve gear, and each unit exhausts through a 48-inch exhaust pipe and atmospheric to a Hender barometric condenser. Each condenser is supplied with circulating water by a 14-inch centrifugal pump driven by an 8x15x9-inch Westinghouse compound engine. The noncondensable gases are removed from the condensers by Hender 9x20x12-inch single stage dry vacuum pumps. The circulating pumps are controlled by a regulator in the steam pipe, which increases the speed of the pumps if the vacuum falls. At the river the intake is protected with a 2-inch screen and at the entrance with a 1-inch and ½-inch screens. All auxiliary pumps and engines are equipped with Richardson sight-feed oil pumps.

Oil is used in the step bearings of the turbines, and a Turner oil filter and two 6x2¼x10-inch Worthington outside-packed plunger pumps are installed in the basement to furnish an oil pressure of 800 pounds, which is reduced through baffles to 400 pounds at the bearings. An accumulator with a 10-inch plunger and 14-foot drop is connected with the oil-piping system, and will maintain the pressure on one turbine for ten minutes, in case of the failure of the pump. The oil piping is of extra-heavy brass with extra-heavy brass Chapman gate valves and cast-steel fittings. The accumulator is connected through a system of rods and levers to ... valves on the steam supply to the pumps and these keep the accumulator at a fixed height at all times. If the accumulator should start to descend, an

FIG. 6. ROTARY CONVERTERS IN SUBSTATION

electric alarm notifies the operator, and this alarm is tested every day when the pumps are changed.

There are two exciter turbines rated at 75 and 35 kilowatts, respectively, and these run noncondensing, the former at 2400 revolutions per minute and the latter at 3600 revolutions. A 9½x9½x10-inch Westinghouse air pump supplies compressed air for blowing out the electrical machinery, and to handle the large apparatus it contains, the station is equipped with a 20-ton Whitney electric crane.

communicate with the two generators through disconnecting switches and with three feeder oil switches which are mechanically controlled from the board. Each pole of the oil switches is in a separate compartment, and all potential and current transformers are also separated.

The switchboard consists of ten slate panels. One Tirrell regulator, two exciter, three feeder, one station and one local panel. Two of the feeder panels control two 13,200-volt, three-phase lines

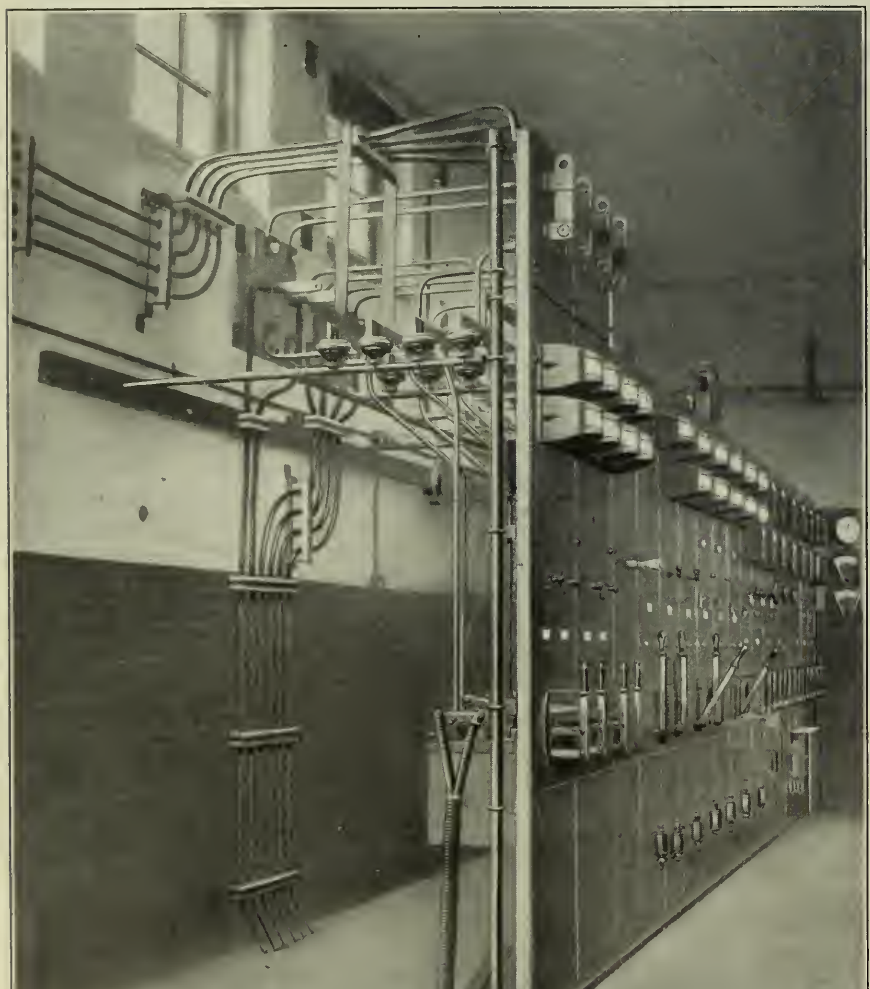

FIG. 7. SUBSTATION SWITCHBOARD

Electrical Equipment

The generators are General Electric, three-phase, revolving-field, 60-cycle, alternating-current machines with star connections and grounded neutral. The voltage is 13,200. The exciters are compound with interpole windings, and the voltage is 125 at all loads. The generator leads are run through brass conduits to the floor and then through fiber conduits to the oil switches installed in a high-tension brick structure over the switchboard. The busbars are 2x¼-inch flat copper, each bar being in a separate compartment. They

to a substation in Brockton, and the third feeder panel supplies current at 13,200 volts to transformers for the station and East Bridgewater.

Two 20-kilowatt 13,200-200-110-volt station transformers are connected to the auxiliary feeder through an oil switch and supply current for lighting the station and also to motors for the pumps and the coal hoist. East Bridgewater is supplied with current at 2200 volts, three-phase, by two 75-kilowatt 13,200-2200 transformers connected through disconnecting switches to the auxiliary feeder, and a 30-kilowatt tub transformer furnishes street lights for East Bridgewater.

On the regulator panel is mounted the Tirrell regulator with switches for use on either exciter, each exciter having two relays. Swung from this panel is a small panel carrying the synchronizer and two kilovolt meters; one is connected to the busbars and the other can be connected to any phase on either machine by means of plugs. The potential transformer for the Tirrell regulator is connected to the busbars without fuses.

Each exciter panel has an ammeter and voltmeter. One voltmeter is connected to the buses, and the other can be used on either machine. Exciter rheostats are mounted on the back of the panels and field rheostats are underneath the floor.

The generator panels have three ammeters, one indicating wattmeter, a power-factor indicator, a field ammeter and on each panel there is a switch for operating the synchronizing motor on the turbine governor. A polyphase-recording wattmeter is mounted on the back of each generator panel.

The feeder panels have one ammeter and can be connected with any phase by a jack switch. The station panel has one voltmeter and one ammeter. The voltage is 114, and the three-wire system is in use. Lighting for the plant is distributed through three panel boxes of eight circuits each. One is placed in the boiler room, one in the turbine room and one in the basement. There is one circuit for arc lamps in the yard and one for flaming-arc lamps on the ceiling. There is a double-throw, three-pole switch on this panel, whereby lighting can be thrown on the exciter in case of failure of the transformers. Another three-pole switch furnishes 220 volts, three-phase, for auxiliary motors.

The 2200-volt panel for East Bridgewater has two circuits; one 2200-volt three-phase, and the other for street lights. All feeders have automatic oil switches with time-limit relays which are tripped with current from the exciter busbars. All switchboard apparatus was furnished by the General Electric Company.

At the end of the switchboard on similar panels are the gages and speed indicators for the turbines. Each machine has a speed indicator, steam gage on the first stage, also vacuum and step pressure gages. A Holman & Maurer mercury vacuum gage is mounted on these panels and can be used on either turbine.

Brockton Substation

This is located in the business center of the city and is connected with the main station at East Bridgewater by two 88-ampere, 13,200-volt transmission lines. The lines are seven miles in length and are made up of No. 2 copper wire carried on Locke insulators. The lines run overhead from the East Bridgewater station to a lightning-arrester house, which is situated about one-half mile from the substation, and from here are brought underground to the basement of the substation and connected to oil switches located in masonry cells remote from the switchboard panels.

At present the substation equipment comprises nine 75-kilowatt, 13,200-volt, 60-cycle, oil-cooled transformers, with one-third and two-thirds voltage starting taps for rotary converters; three 375-kilowatt, 13,200 to 2200-volt, 60-cycle, three-phase, two-phase, oil-cooled transformers, supplying the 2200-volt, two-phase service; three 220-kilowatt, 250-200-volt, direct-current, 60-cycle, six-phase, shunt-wound converters, supplying the three-wire direct-current system; a 44,000-volt testing transformer and a 12-cell Westinghouse storage battery and motor-generator charging set furnishes current to operate the trip coils on the high-tension oil switches. Located in the basement is a 2-horsepower air compressor connected by pipe line to the main floor, where the air is used for cleaning purposes.

The switchboard is constructed of the best quality of Monson slate and consists of the following panels: Two three-phase, high-tension transformer panels, one of which is spare; two three-phase incoming-line panels, three alternating-current rotary-converter panels, three direct-current rotary-converter panels and five direct-current feeder panels. Opposite each converter is located a six-phase starting panel and a Type I, right-hand, 20-kilowatt voltage regulator.

All panels are made with a [illegible] bevel, and the front and edges are treated with a coating of lacquer, giving a smooth dull black marine finish. All instrument cap nuts and handles are finished with a dull black oxide. All high-tension feeder panels are supplied with indicator lamps, red and green. The red lamps burn when conditions are normal, and green when the switch is opened by overload or short circuit, attention being immediately called to the open circuit by the ringing of a gong.

In the basement of the substation are located oil switches for controlling all high-tension lines, and these are mounted in masonry cells below the main switchboard. The entire installation, with the exception of the storage-battery equipment, was furnished by the General Electric Company.

The substation controls the current supply for Brockton, Whitman and Stoughton. Stoughton at present is fed by a 2200-volt line to a transformer house at Montello, a suburb of Brockton, where the voltage is stepped up to 6600, and at Stoughton stepped down to 2200 volts for distribution. In the near future Stoughton will be fed by a 13,200-volt high-tension line now under construction.

The Electric Light & Power Company of Abington and Rockland, which lights Rockland, Abington and Hanover, is soon to be supplied from the East Bridgewater station, the high-tension line and transforming apparatus now being installed. The Stoughton, Abington and Rockland lines will tap the main feeders in a new [illegible] house. They will be connected to the feeders by oil switches controlled from the substation. The maximum load is now about [illegible] kilowatts but will soon be considerably increased.

Adjoining the substation is the old plant, which is held in readiness in case of emergency. Part of the feeder panels in the old station are still in use, supplied from feeders in the substation. In the old station is also located the street-lighting service, comprising a nine-panel, two-phase plug board and nine tub transformers.

Petroleum Industry of the United States

As apparent in the accompanying table, the production of crude petroleum in the United States during 1908 showed a large increase over that of 1907.

PRODUCTION OF CRUDE PETROLEUM IN THE UNITED STATES

(In Barrels of 42 Gal.)

Field	1907	1908
California	[illegible]	[illegible]
Colorado	[illegible]	(a) [illegible]
Gulf { Texas	[illegible]	[illegible]
Gulf { Louisiana	[illegible]	[illegible]
Illinois	[illegible]	[illegible]
Lima { Indiana } { Ohio }	[illegible]	[illegible]
Mid-continental (b)	[illegible]	[illegible]
Kentucky-Tennessee	[illegible]	(a) [illegible]
Appalachian (c)	[illegible]	[illegible]
Wyoming	[illegible]	(a) [illegible]
Others	[illegible]	(a) [illegible]
Total	[illegible]	[illegible]

(a) Estimated to be same as in 1907.
(b) Kansas and Oklahoma.
(c) Pennsylvania, New York, West Virginia and eastern Ohio.

California is now producing about [illegible] barrels of oil per year, that being the estimated output for 1908. In 1907 the yield was [illegible] barrels, valued at [illegible], or about [illegible] cents per barrel. In 1906 the average price was [illegible] cents per barrel. In 1908 the average price at the wells to the producers was about [illegible] cents per barrel and at the end of the year it was perhaps higher than [illegible] cents per barrel. All the old contracts have been worked up and the new ones being made vary from [illegible] cents per barrel. [illegible]

Gate Valves in Steam-Pipe Lines

Practical Suggestions for Locating and Using Them in These Days of Saturated Steam at High Pressure and Superheated Steam

BY W. H. WAKEMAN

The use of saturated steam at high pressure, and superheated steam at any pressure, has rendered obsolete some of the globe valves that formerly did good service in our main steam lines, therefore others must be substituted. However, the fact that certain hard-rubber, or composition, disks are quickly destroyed by steam at high temperature does not necessarily condemn all kinds of globe valve, even for severe conditions, while for ordinary plants the composition disk is as good now as it was twenty years ago. In view of these facts the use of gate valves in steam-pipe lines is uncalled for, and furthermore it is not an intelligent application of knowledge along this line, because a gate valve is always more difficult to operate and more expensive to repair than a globe valve. There are gate valves that contain composition disks, so may easily be replaced when worn out, making the valve as good as new, provided the seat is not injured; but if the seat requires repairs it is a hard and expensive job to scrape the surface until it becomes perfectly true.

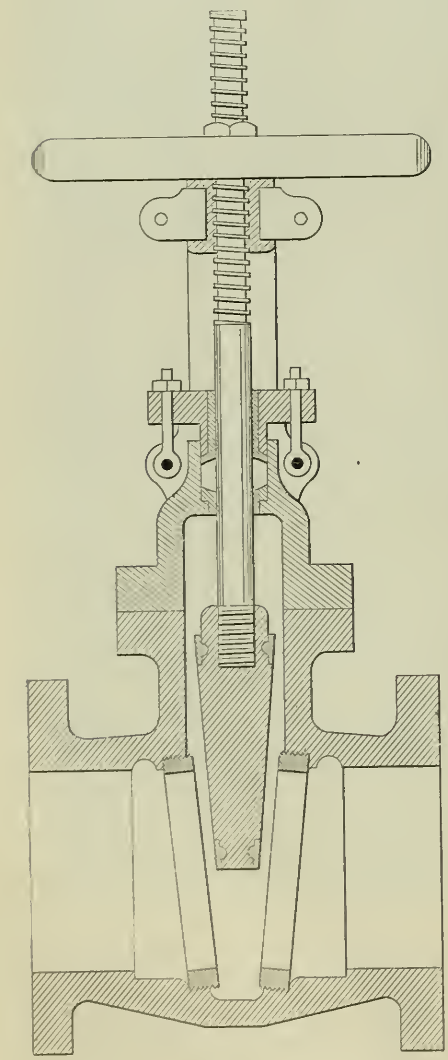

FIG. 1

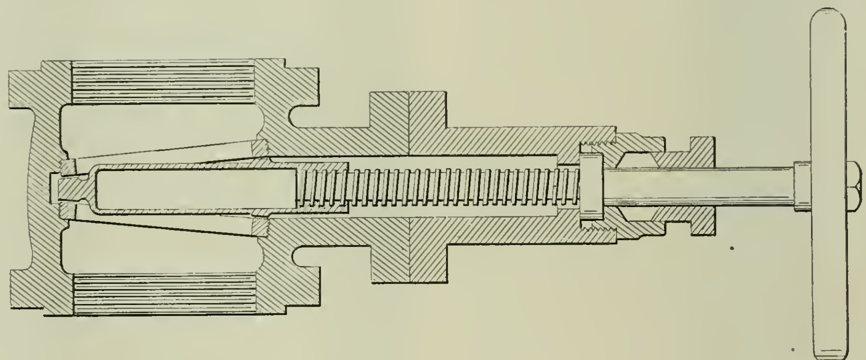

FIG. 2

There is more than one way to locate and use a gate valve, and as they are not all made alike, suggestions along this line should prove valuable.

If a valve of this kind is located with the stem in a vertical position, as shown in Fig. 1, friction is reduced to a minimum, because the heavy gate is suspended on the stem, the surfaces in contact being small in consequence. The only objection to this arrangement, as far as the valve itself is concerned, is that a pocket which is formed at the bottom between the two inclined seats is located just right to catch sediment and scale, and thus prevent the gate from going down to its proper place, but fortunately there is little danger of an excessive amount of sediment collecting in a steam-pipe line.

This valve is fitted with what is technically known as a rising stem, because the wheel stays in the same place (except that it revolves) when the valve is operated, while the stem travels with the gate. This point must be taken into consideration when locating a large valve in close quarters. A left-hand thread must be cut on the stem in order to cause the wheel to operate in the correct way, which is to turn with the hands of a watch to close the valve, and in the opposite direction to open it.

Fig. 2 is fitted with a nonrising stem, consequently the space occupied by the valve is a fixed quantity at all times. This must also be a left-hand thread. It is concealed in the bonnet and the gate, and cannot be lubricated properly, which causes it to wear much more rapidly than if it were exposed and well oiled. The collar shown on the stem soon wears enough to give objectionable lost motion, as it cannot be oiled.

A valve of this kind is located in an 8-inch horizontal branch steam line in my plant, and the stem is in a horizontal position. The consequence is that when this valve is opened and closed, the gate must slide on its edge, traveling on a rough guide, and the resulting friction causes grunts and groans that are very disagreeable because they denote inferior design and imperfect workmanship, although the name of one of the best known construction companies in New England is cast on the bonnet.

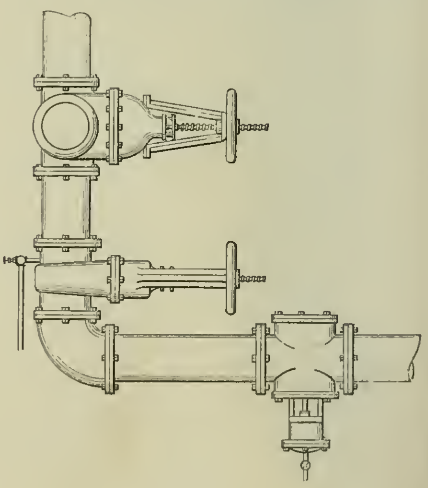

FIG. 3

This branch line was designed to supply steam for two engines, only one of which is in use at present during a part of the time; and after that engine is shut down it seems proper to close the gate valve mentioned, as it is located near the header, which extends across five boilers, and much heat would otherwise be lost. The ordinary plan for doing this is to close the throttle valve and, after the engine has stopped, to shut the gate valve, then allow steam in the pipe to condense, as a good trap removes all water resulting from the cooling process. If this plan is followed here the gate valve leaks badly and heat is wasted the same as if it was left open. This is due to the fact that when the gate chatters over the rough guide mentioned it is in equilibrium; consequently it is not held against the seat. The threaded stem is a very loose fit in the gate; therefore, when the latter is forced as far as it will go, it does not rest squarely on the seat, and it leaks.

This action is proved by the following result. If the gate valve is closed while the engine is running full speed, the gate is not in equilibrium, as pressure is reduced on the engine side; therefore, the gate is pressed firmly against the seat and when the valve is closed it is perfectly tight. After the engine has stopped the throttle valve is closed.

The upper valve in Fig. 3 (which represents a section of piping in our engine room) is represented as being located in a horizontal line coming directly toward the reader. It is fitted with a rising stem, or outside thread and yoke. The valve below it is quite differently located, for although its stem is in a horizontal position, the body is in a vertical pipe. In this case the gate always rests on the seat, giving smooth action in opening and closing, and a tight valve when shut. Both sides of the gate are intended to be steam-tight.

One advantage of a gate valve in this service is that if the wheel is turned with ordinary speed, which is always slow in good practice when the valve is to be opened, the opening for the admission of steam will be very small at first and will increase slowly, thus giving time for pressure to rise gradually, and avoiding the shocks and jars caused by turning too much steam into a comparatively cool pipe. It is difficult, but not impossible to secure the same result with a globe valve, because a similar movement of the wheel gives so much greater opening for the passage of steam. This type of valve has several advantages, but this is not one of them.

It follows as a natural consequence that it takes a comparatively long time to open a gate valve, which is an annoying feature when haste is necessary. I have noticed, however, that some engineers lose more time than is necessary under conditions shown in Fig. 3. The small valve connected above the gate is first opened to draw off the water of condensation, then the larger one is slowly opened, admitting steam to the reducing valve in the horizontal pipe below it. Soon a light pressure accumulates and brings the reducing valve into action. As soon as this is evident, the large valve may be opened quickly. It is not necessary to continue the slow process until the long stem is run out to its full length.

Globe Valve Substituted for a Gate Valve

Fig. 5 illustrates a section of piping where a globe valve was substituted for a gate valve to my great satisfaction. Formerly it was necessary to exert a considerable force to start the gate (as there was no bypass provided), then it required nearly two revolutions of the wheel to open the valve slightly, and when the reducing valve began to operate the gate moved easily because the pressure was balanced, but it took about six revolutions more to secure a full opening. With the globe valve in use, the instant that the wheel is moved, steam begins to pass through, and after the reducing valve begins to control the pressure in the system, requiring but a few seconds for the operation, about two revolutions of the wheel opens the valve to its full capacity. When steam is to be shut off there is practically no friction to be overcome because the disk is in equilibrium until it rests on the seat. The contrast between this and operating the gate valve which was used in this place for twelve years is very great.

Fig. 7 illustrates a connection between one of six boilers and the header which receives steam from all of them. A gate valve is used here with its stem in a horizontal position. When this boiler is to be "cut out" the valve is shut in the usual way, but the disk is always balanced, or in equilibrium and this condition is never changed, because pressure cannot be reduced on one side of it. The result is that when the boiler is cooled off and the main stop valve loosened, steam may leak in [illegible] according to the position [illegible] the gate was [illegible]

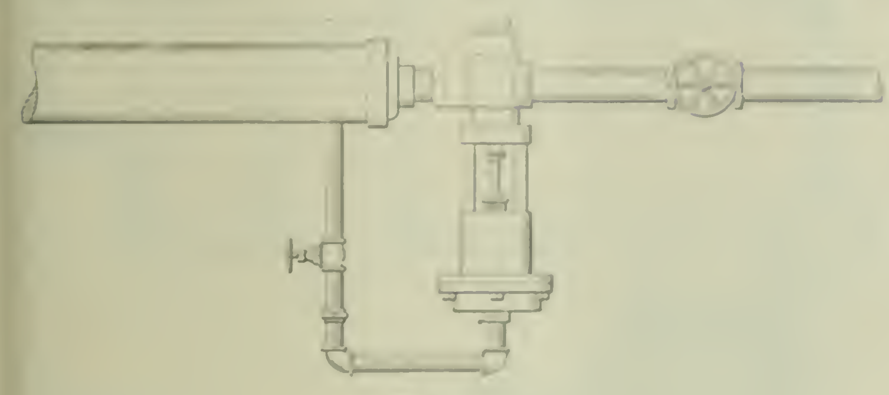

FIG. 4

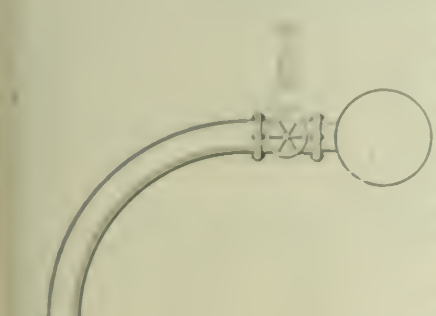

FIG. 5

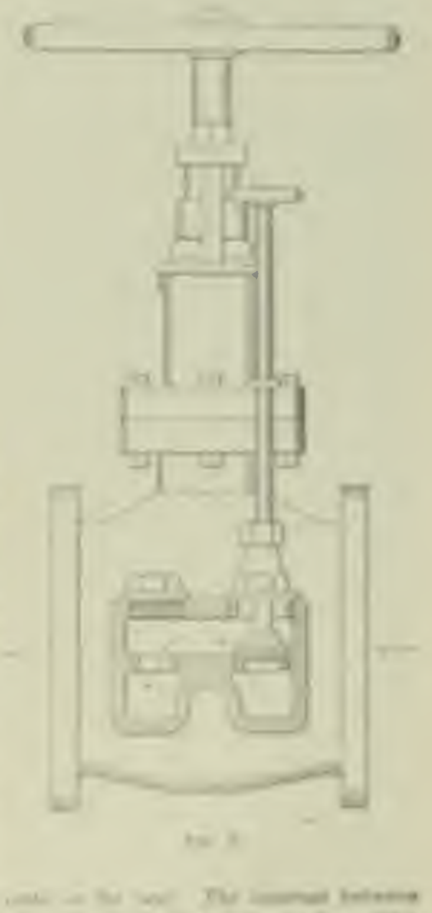

FIG. 6

limit of its travel. If it was practicable to lower the pressure on one side of it, the result would be more satisfactory, as explained in connection with Fig. 2. If the stem of this valve was located in a vertical position, as represented by the dotted lines, it would undoubtedly give better results. However, there is not head room enough for this purpose, especially for a rising stem. A globe valve with a pin, projecting from the lower side of the disk, that travels in a guide provided for this purpose would be much better.

Fig. 6 is a gate valve fitted with a bypass, the operation of which is apparently not as well understood by firemen and engine runners as it ought to be. Steam enters as indicated by the arrow and, acting on one side of the closed gate, presses it to its seat with great force; therefore, it is necessary to overcome excessive friction before the valve can be opened, especially with steam at very high pressure. To overcome this objection the bypass is provided. By opening the small globe valve which is cast with the body of the large valve, steam is admitted from the right-hand side of the gate around it to the left-hand side, as shown by the arrows. This fills the space at this point and raises the pressure until the gate is balanced and nearly all friction removed; consequently, the valve can easily be opened, after which the bypass is shut. When a man closes the bypass before he opens the main valve, thus reducing the pressure on the outlet side, it is good evidence that he does not understand the value of a bypass. If this device is wanted in a case where it was not included in the original valve, it can be provided by tapping a small pipe into the main line on each side of the large valve and putting a small valve in it.

As a general rule a gate valve is designed so that it is not convenient to get bolts into the flange on the bonnet, as the space allowed for this purpose is too small, making it necessary to drop some of the nuts down behind the flange and screw the bolts into them. Bolts that are carried in stock by supply houses have heads that are supposed to be artistic in design, but when a wrench is applied to them it is sure to slip off, to the disgust of the workman who wishes to do a good job. To overcome this objection I have found it a good plan to take round norway iron and cut it into suitable lengths to go through the flanges and two nuts, then by cutting a thread on each end and tapping nuts to match, it is possible to make studs to be used as bolts that can be applied to good advantage, and a proper wrench will not slip off, especially if square nuts are adopted. There are a few places in a steam plant where square nuts cannot be turned, but they are much fewer than is generally admitted, judging by the large proportion of hexagon nuts used, which soon become almost round if a wrench is applied to them a few times; consequently, they are not screwed down tight enough to prevent packing from blowing out under pressure. This applies to the quality of nuts usually found on the bonnets of gate valves and ordinary flange joints.

The James Watt Memorial Building

By W. H. Booth

Greenock is a small town down the Clyde a few miles below the city of Glasgow. Its occupation is chiefly shipbuilding, and its title to fame historically rests on the fact that James Watt was born there in the year 1736 on the nineteenth day of January. James Watt, by his invention of the air pump and separate condenser, laid the foundation of modern practice in steam engineering. It was the first stage in the compound working of the steam engine and marked the abolition of the practice of doing two operations in one vessel, for in the Newcomen engine the cylinder was alternately a jet condenser and a working steam cylinder. We deplore today the initial condensation which takes place in a cylinder that has been merely momentarily exposed to the condenser pressure and temperature, but what must it have been when the cylinder was drenched with cold water?

FIG. I. JAMES WATT MEMORIAL BUILDING

The story goes that Watt, who was mathematical-instrument maker to the Glasgow university, had intrusted to him a model of a Newcomen engine to repair. Being a man of scientific bent of mind and specially trained in a trade that would cultivate his thinking faculties, he naturally would begin to think about the steam engine. He came of a family of some local standing in Greenock, for his father was a maker of ship blocks and was a member of the local council and a magistrate; his grandfather was a teacher of surveying and navigation, and his uncle was a surveyor and civil engineer at Ayr. The story of his youth about the tea kettle appears to have been invented as a bit of telling biography. If he had really thought so early about the steam engine, he would have done something with it earlier than he did.

Watt was delicate in health and had little scholastic training. At the age of eighteen he was sent to London to learn the trade of instrument maker. There he stayed only a year on account of bad health. Returning to Greenock he set up in business in Glasgow as a mathematical-instrument maker, and the university authorities, perhaps through influence, gave him a helping hand and appointed him instrument maker to the university, with rooms in the building. He did not make very much at his trade and eked out his small income by mending and even making fiddles.

This would bring us to about the year 1756. Watt apparently spent some ten years at the university, and in 1767 was employed to make a survey and estimate for a canal to unite the Clyde with the estuary of the Forth. After this he obtained more civil engineering work and was engaged in work in connection with the deepening of the Clyde and other rivers, with harbor work and canals.

It was in 1759, however, that Watt began to study steam, and for some years he made experiments on that critical and elusive fluid. He would then be about 23 years of age. It was about 1763-4 that the Newcomen model fell into his hands for repair, and in 1769, when 33 years of age, he took out his patent in which he says:

"My method of lessening the consumption of steam, and consequently fuel, in fire engines, consists of the following principles:

"First—That vessel on which the powers of steam are to be employed to work the engine, which is called the cylinder in common fire engines, and which I call the steam vessel, must, during the whole time the engine is at work, be kept as hot as the steam that enters it; first, by inclosing it in a case of wood; secondly, by surrounding it with steam or other heated bodies and, thirdly, by suffering neither water nor any other substance colder than the steam to enter or touch it during that time.

"Secondly—In engines that are to be worked wholly or partially by condensation of steam, the steam is to be condensed in vessels distinct from the steam vessels or cylinders, although occasionally communicating with them; these vessels I call condensers; and while the engines are working, these condensers ought at least to be kept as cold as the air in the neighborhood of the engines, by application of water or other cold bodies.

"Thirdly—Whatever air or other elastic vapor is not condensed by the cold of the condenser, and may impede the working of the engine, is to be drawn out of the steam vessels or condensers by means of pumps, wrought by the engines themselves or otherwise.

"Fourthly—I intend in many cases to employ the expansive force of steam to press on the pistons, or whatever may be used instead of them, in the same manner in which the pressure of the atmosphere is now employed in common fire engines. In cases where cold water cannot be had in plenty, the engines may be wrought by this force of steam only, by discharging the steam into the air after it has done its office.

"Lastly—Instead of using water to render the pistons and other parts of the engines air- and steam-tight, I employ oils, wax, resinous bodies, fat of animals, quicksilver and other metals in their fluid state."

Here is [illegible] art of steam engineering a [illegible] one might say, half forgotten [illegible] to read some of the denial [illegible] well known effect of cylinders [illegible] the steam, or much of [illegible] them, one might almost [illegible] the separate condenser was [illegible]

Dr. Roebuck was the first to extend [illegible] Watt. He was the original [illegible] of the Carron Iron Works, where carronades were first cast, and [illegible] productions of the Carron [illegible] be seen today on the ramparts of Quebec, bearing on their trunnion ends the words Carron and the dates 1905, 1906, 1907.

Presumably Dr. Roebuck tired of the expense or did not appreciate the value of the invention or perhaps he found the cost greater than he could afford, for we next find Watt being liberally helped by Matthew Boulton, a Birmingham man. To Boulton, of Birmingham, the world owes it that Watt's great invention was put into successful operation. Watt's patent was much contested, but Boulton found the necessary fighting funds which enabled Watt to establish the validity of his patents. Watt invented a cutoff in 1769 and described it in a letter to Dr. Small. He used the cutoff in 1776, but did not patent it until 1782, when he patented it and the double-acting engine with the rod parallel motion in place of the link chain and quadrant-ended beam, as seen in the old engines at South Kensington Museum. As someone else had patented the crank, Watt had to invent the sun-and-planet gear to take its place. It is claimed that Watt had invented the application of the crank before 1778, but that some other man had patented it. Practically Watt left the steam engine as it is today. Nothing has yet gone beyond his essential principles.

His native town of Greenock has long wished to have some memorial of Watt, but so far as Scotland is concerned Watt's monument has been like Wren's "Circumspice" for the river Clyde as it now is is the direct result of the great vessels which are built on its banks and driven by Watt engines. The Watt Memorial House is, therefore, about one-tenth general public and nine-tenths Dr. Carnegie, for only about $5000 was generally subscribed until Andrew Carnegie subscribed $50,000 in two installments, and later a subscription, limited to 25 cents, raised a further sum of something between $1500 and $2000 under the care of an engineer, John Rankin, of Greenock. The scheme, as carried out, is by no means as ambitious as originally intended, owing to the small response that the public made. Ultimately it took the form of a small technical institution costing something over $35,000, the remainder of the fund, about $20,000 serving as an endowment and for furnishing, so that not more than $15,000 has been really available by way of endowment.

The memorial building stands at the corner of William and Dalrymple streets, on the site of the house in which Watt was born. It is only two stories high and at the corner about 20 feet from the ground the building is constructed with a reentrant square corner, leaving a square platform at that hight of about 10 feet, on which stands a pedestal surmounted by a statue of Watt, 8 feet 6 inches high and cast in bronze from the modeling of Henry C. Fehr, of London, and a replica of a similar statue already at Leeds. The base of the house is rough-faced granite to a hight of about 7 feet, above which the walls are of dressed stone. Within are two class rooms, attractive, for the teaching of navigation and marine engineering. It is hoped these will be found of service to officers desirous of passing their examinations when in port. The roof is flat, so as to serve as a deck whereon to take solar observations, for even at Greenock the sun is sometimes very much in evidence.

In the engineering class room are drawing benches with lockers and models, some of which have been given to the institution, and there are some 200 volumes in the little library on engineering and navigation. The room is oak-paneled to a hight of 8 feet. A fireplace of Gibsonian stone is in the Scottish baronial style. This room is on the ground floor. On the first floor is the navigation room similarly equipped, oak lined, and with a panel ornamental ceiling. The building was opened on Monday, June 1, 1908, and Watt's statue was unveiled by Dr. Carnegie. The inscription on the marble plate reads:

James Watt

Born 19th January 1736

This Memorial Building is Erected

on the Site of His Birthplace

The street floor, upper on Dalrymple

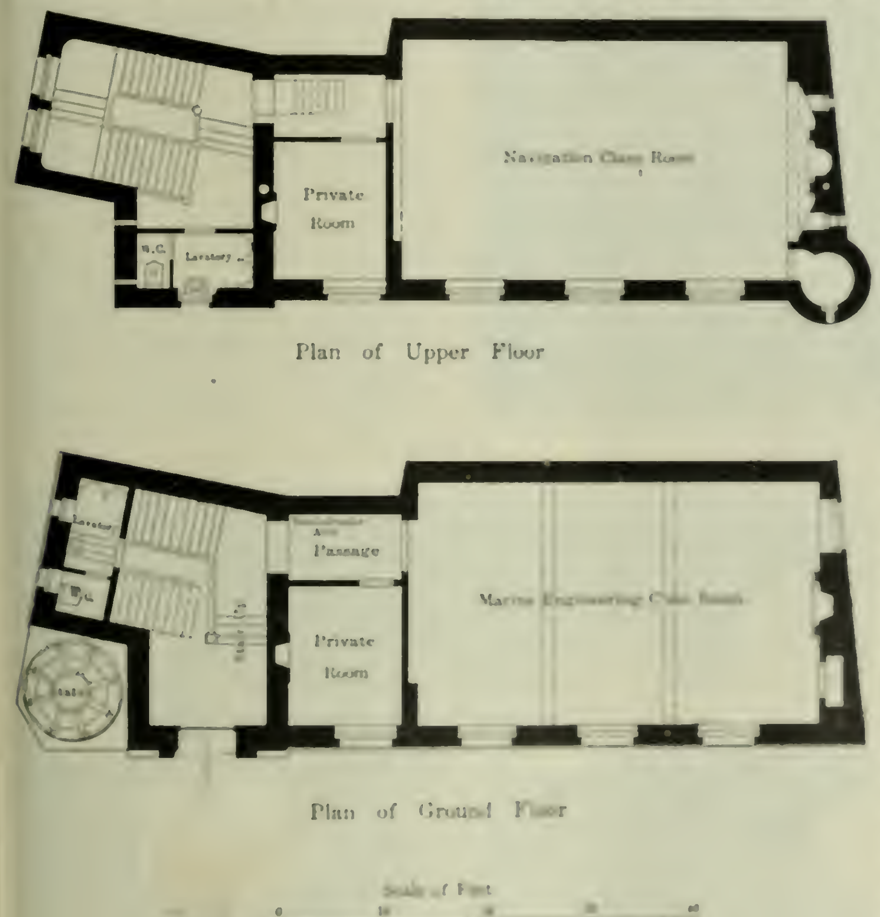

FIG. 2. FLOOR PLANS OF BUILDING

street and is made of teak. Above the door is the Greenock coat of arms with the inscription:

Sigillum Burgi de Greenock.

The electric-light fittings are of hand-wrought iron with armorplate finish, and there is provision for special lighting for demonstration purposes. The supply comes from the corporation mains, the switchboard being in the entrance hall.

The architect to whom the work was intrusted was David Barclay, of 245 St. Vincent street, Glasgow, and to him we are indebted for the plans of the building. Since the building was to represent a house that formerly stood on the site, though not intended to be a copy of the old house, it was decided that to some extent it should represent a style of Scottish architecture.

The primary object of the building was to mark the site of the house in which James Watt was born, and the memorial house is itself small since it is confined to the site of the original house which it memorializes. The locality is near to the harbor, for one old tenement house alone intervenes. This it is generally desired should some day be removed should there be funds available for the purpose. If so, the view of the memorial house would be opened up to the river. As in all industrial and growing towns some localities become reduced in character, so has this. It has suffered very considerable decadence since the Watts lived on the site and a general demolition of some of the neighboring properties would be a worthy public improvement if the finances of the town would permit or the public generally would interest themselves in the matter and step in to finish the work inaugurated by Dr. Carnegie.

The architects prepared, we are given to understand, several designs for a memorial, and of these one at least was purely memorial, but Dr. Carnegie expressed a desire that there should be some building that should serve a useful purpose as well as being an ornament, and therefore the final choice fell on the design as carried out. Since the building was to be so small, too much was not attempted, and the teaching to be given within it was narrowed down to the subjects named, marine engineering and navigation, each of which is allotted one of the large rooms.

FIG. 3. ENGINEERING CLASS ROOM

In accordance with the object of the building, the finishing of the rooms is perhaps more elaborate than usual with class rooms, the walls being paneled in timber and the mantelpieces being of carved stone, but the wall paneling is so designed as to serve for blackboard purposes and the exhibition of diagrams. The upper floor ceiling is vaulted and decorated with Cymric ornaments, while the small rooms of the staircase tower will serve for museum purposes. The stone carving records ancient and modern engineering and shipbuilding. The statue itself is in the dress of 100 years ago, and Watt appears to be reading a steam gage. The pedestal is supported by flying buttresses of antique design carved with some elaboration with emblems of engineering tools.

Seeing that the site was so small, the house appears to have been designed to fill a useful purpose about as well as could be, and the purpose it will fill is closely connected with the trade and industry of the town. It might be pointed out that the Clyde, down which have been launched some of the largest ships ever built, was once a mere shallow creek, and but for the steam engine and all that the steam engine has rendered possible, it would have remained so. Watt's invention set the steam engine along the road of improvement and started the struggle for coal economy which has today culminated at or near the long-sought one pound per horsepower per hour. But today, though we possess the turbine and the surface condenser and accurate machine tools, we are still striving after Watt's axiom, the keeping of the cylin-

Modern British High-Speed Steam Engines

Design of the Type of Governor in Most General Use; System of Forced Lubrication; Some Makes of High-speed Engines

BY JOHN DAVIDSON

Governors

As previously stated, in all cases the engines are governed by means of a centrifugal governor attached to the crankshaft, which controls the speed of the engine by acting directly upon a throttle valve of a balanced type. Where the load of the engine is nearly uniform this system of governing leaves nothing to be desired, either in speed regulation or economy. The type of governor used by almost all firms is practically the same, and the general design is illustrated in Fig. 10.

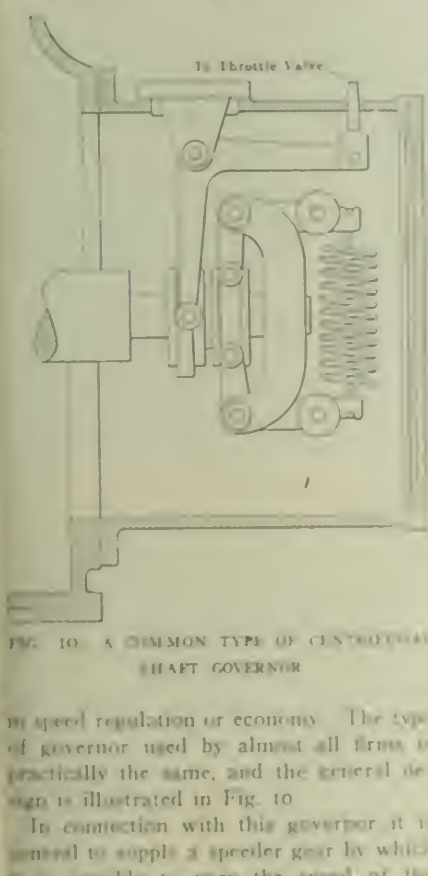

FIG. 10. A COMMON TYPE OF CENTRIFUGAL SHAFT GOVERNOR

In connection with this governor it is general to supply a speeder gear by which it is possible to vary the speed of the engine at least 5 per cent. above or below normal, while the engine is running. This is generally effected by means of an additional spring attached to the spindle end or bell-crank lever of the governor, in such a way that it may act with the main governor spring, so that if the tension of this spring is varied the speed of the engine will be varied accordingly.

Recently the governor gear has been put under forced lubrication, so that no part of the engine requires attention, all being lubricated from the main oil pump. The throttle consists of a single double-beat Cornish valve designed in such a way that it is not affected by difference in temperature. In Fig. 11 is shown a section of this valve.

FIG. 11. DOUBLE-BEAT CORNISH THROTTLE VALVE

The throttle-valve spindle is made steam-tight where it leaves the valve box by simply being passed through a long bushing, inside of which are turned several water grooves. This method of packing the spindle has been found much more satisfactory than fitting stuffing boxes of the ordinary type, as it is most essential to guard against friction in any part of the governor gear, and where stuffing boxes are introduced it is easy for the attendant to upset the governor and cause hunting by simply screwing up the gland.

During the last two or three years, governing by means of varying the expansion has again been taken up, but this time has only been combined with throttle governing. Great trouble was previously experi-

FIG. 13. ECONOMY OF VARIABLE EXPANSION

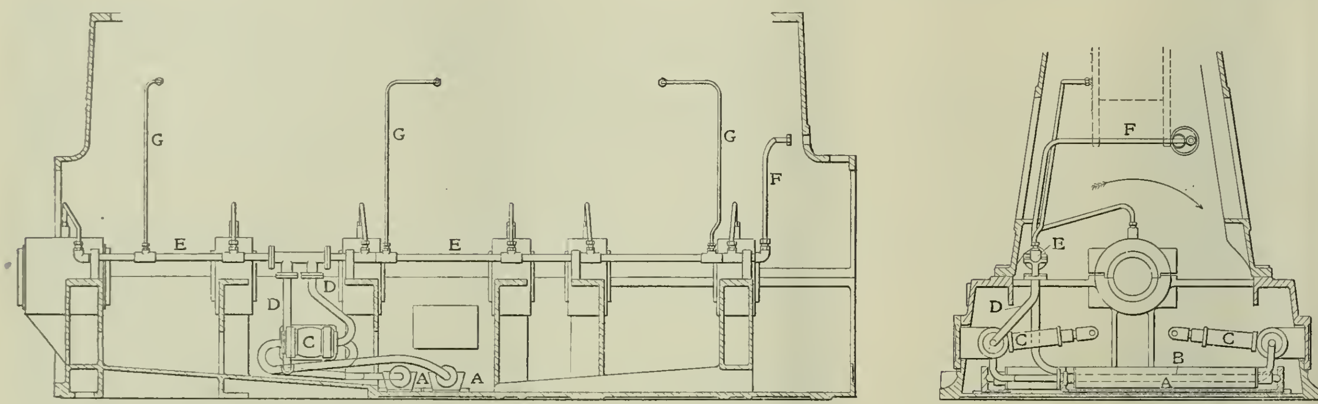
enced from centrifugal governors acting directly upon the eccentric driving the valve. In the later type of expansion gear the degree of expansion is varied without varying the travel of the valve, and simply by rotating the [illegible] on its spindle through a small angle. This valve may easily be adjusted in this manner by the governor as the inertia of the valve gear has not to be overcome. In Fig. 12 is shown one method of effecting this arrangement. The centrifugal governor acts on the throttle valve in the usual way. From no load up to 75 per cent. load the engine is entirely under control and governed only by the throttle valve. At this load [illegible] the throttle-valve spindle is moved further by the governor, but in doing this by means of [illegible] and an upright shaft, the main piston valve is caused to rotate through a small amount by means of [illegible] which [illegible] as shown on the [illegible] of the piston valve. The [illegible]

FIG. 12. METHOD OF VARYING [illegible]

at *A*, and the ports in the liner are made in triangular shape, as shown at *B*.

In the drawing at the right is shown to a large scale one of the ports and the edge of the valve, and the corresponding edge of the valve when at the earliest cutoff position. The lead of the valve in this position is represented by *C*. If, however, the valve is rotated through a small amount, as shown by the dotted lines, it will be noted that the lead has increased to the amount shown by *D*, and consequently the cutoff made later. By this means it is possible to obtain a range of cutoff sufficient to carry a load varying between 75 per cent. of full load and 25 per cent. overload at the expense of the lead, and at the same time obtain better economy at all loads between these two positions than if the engine was controlled entirely at the throttle valve.

For electrical purposes standard practice is to make all engines capable of developing 25 per cent. overload, condensing, and capable of developing full load noncondensing when required. If an engine is controlled entirely by throttle governing, it is necessary that full boiler pressure should only be used at the maximum overload, or when running noncondensing, and when running under what should be the most economical load, viz., full load, the engine is using steam very considerably throttled. The diagram in Fig. 13 shows this point clearly, and it will be seen that when the engine is only controlled by the throttle valve throughout its range, the steam consumption per brake horsepower at full load is 16.4 pounds, whereas if the engine is fitted with an expansion gear and arranged so that the throttle governor only controls the engine between no load and 75 per cent. of full load, there is a saving of 0.8 pound per brake horsepower per hour, or 5 per cent. The steam consumption is also slightly better at 75 per cent. load, and if the average load on the engine ranges between 75 per cent. load and 25 per cent. overload, it will be seen that the saving in coal per annum is no small item.



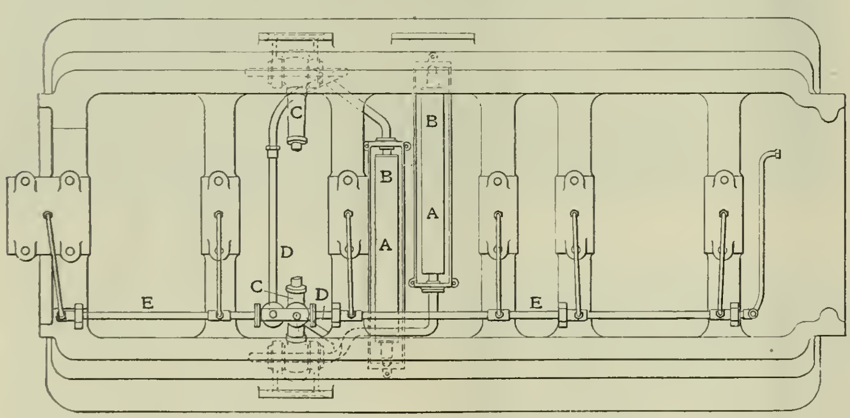


FIG. 14. SYSTEM OF FORCED LUBRICATION

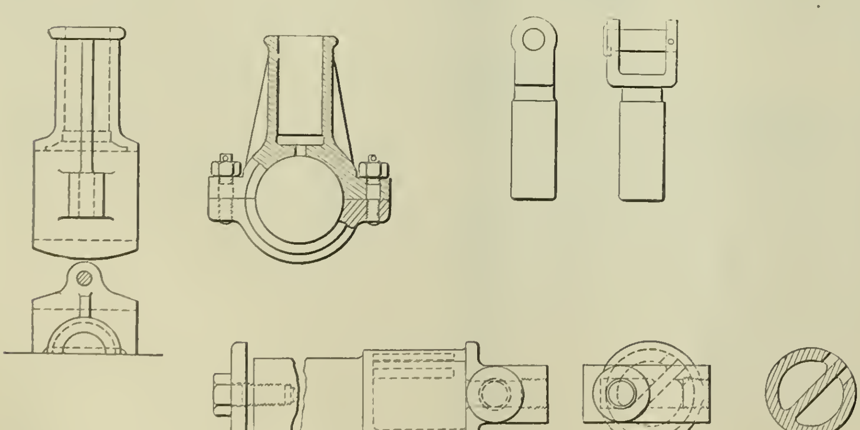

FIG. 15. OIL PUMP DETAILS

For instance, suppose an engine of 500 brake horsepower is working 12 hours per day and 6 days per week at an average load of between 75 per cent. load and 25 per cent. overload, the amount of coal required per annum will be 2000 tons, and taking coal at $2.50 per ton and an average saving of 5 per cent., as above, the amount saved will be $250 per annum.

Forced Lubrication

The system of lubrication may at first sight appear to be elaborate, but when considered in detail it will be found to be a simple arrangement. In Fig. 14 is illustrated the arrangement of forced lubrication as fitted to a three-crank triple-expansion engine. In the lowest part of the base are fitted two troughs *A A* into which are fitted strainers *B B*, which consist of perforated tubes around which is wrapped fine copper gauze. The object of the troughs is to prevent any dirt or sediment of any kind, which may be collected by the oil or get into the crank case, being drawn into the pump and so delivered into the main oil pipes. A certain amount of water also drips from the glands of the cylinders, and although additional glands are fitted at the top of the frame where the piston and valve rods pass through, leakage cannot entirely be prevented. If this water, however, does collect at the bottom of the base, it cannot be drawn into the pumps unless it is allowed to collect to such an extent that the level reaches to the top of the troughs. It is not likely therefore to cause any damage unless the engine attendant is careless, because the oil floating at the top of the

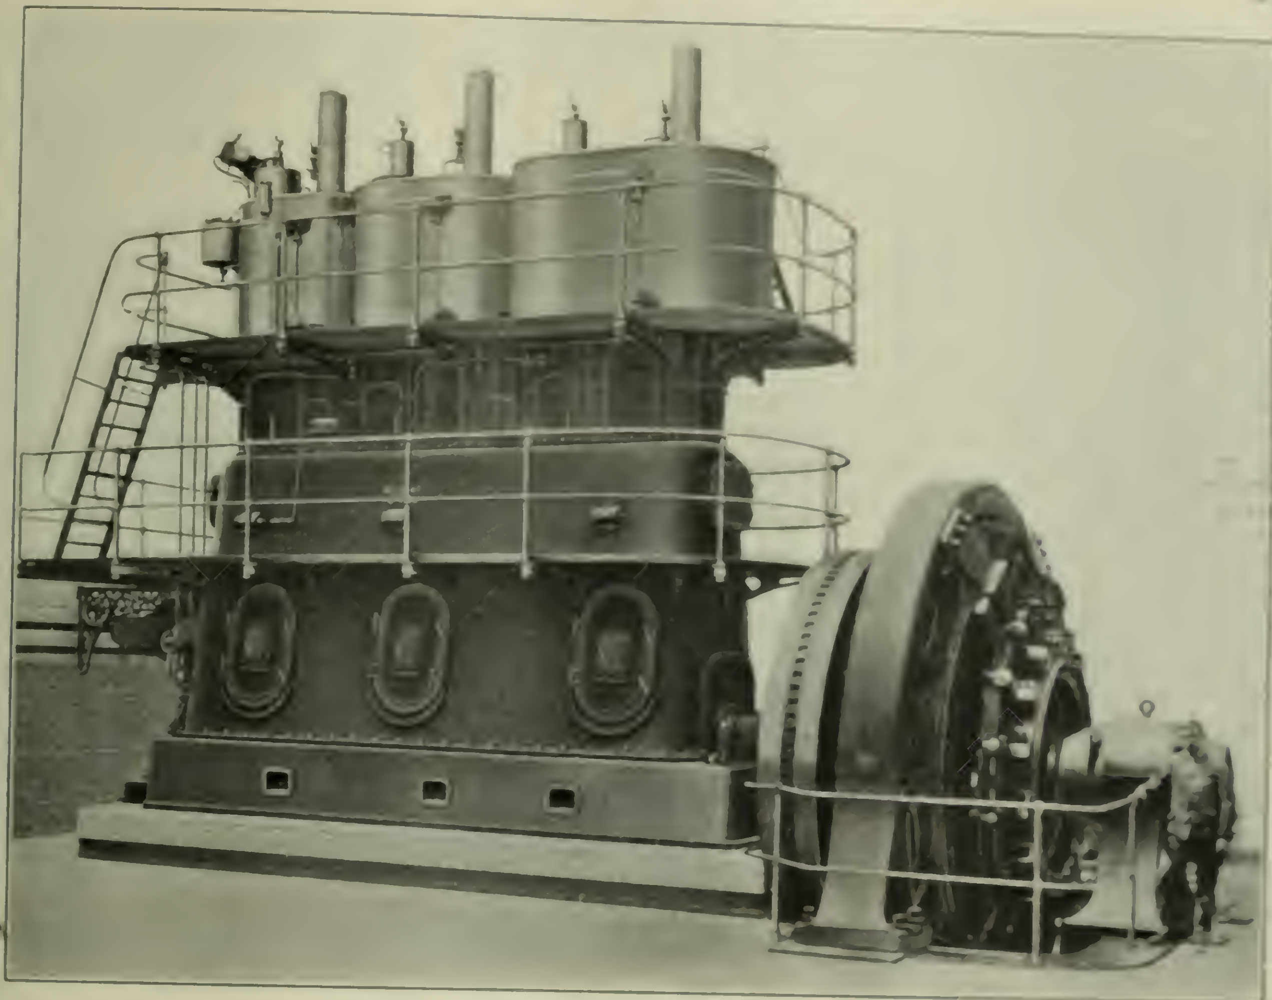

FIG. 16. BELLISS-[illegible] GENERATING SET

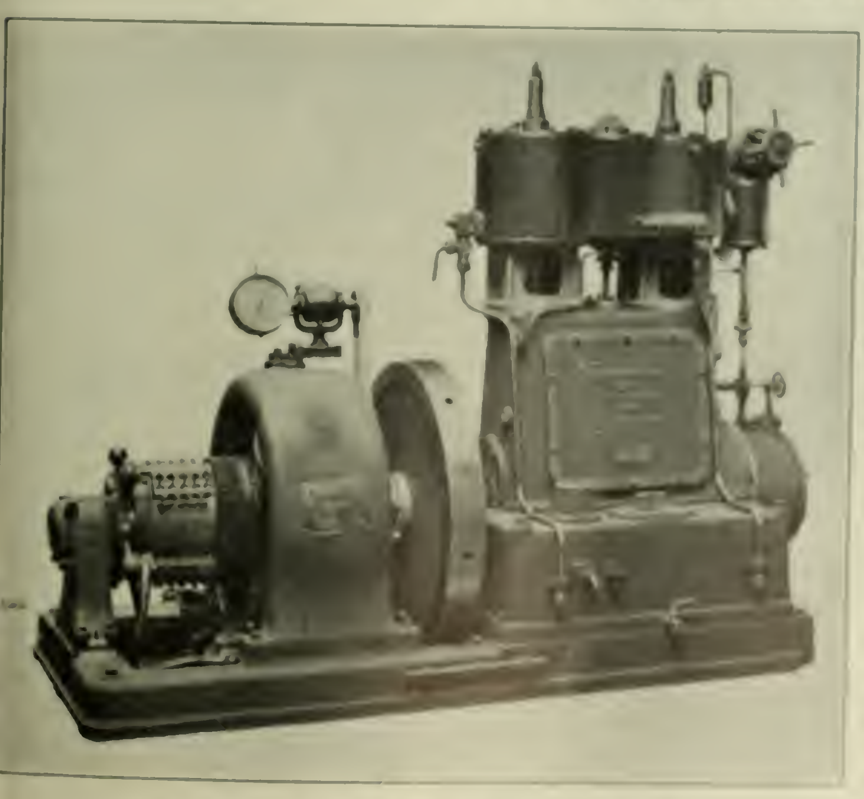

FIG. 17. SMALL TWO-CRANK [illegible] ENGINE

water overflows into the trough and is so delivered into the mains.

In the case of large engines similar to the one illustrated, it is usual to fit two oil pumps, each being of sufficient capacity to maintain the full oil pressure. These pumps are generally worked from one eccentric driving the valve gear and are of simple construction, viz., the valveless type. The oil pumps are shown at C C and details of similar pumps are illustrated in Fig. 15. The drawing is self explanatory. The oil is delivered from the pumps through pipes D D, in Fig. 14, to the main oil pipe E, and from this main branches are taken, as shown, to each of the main bearings and crosshead slides. One end of the main pipe is coupled to a pressure gage by means of the pipe F, and a bypass valve is also fitted to this main so that the pressure may be regulated as required, the usual pressure being [illegible] lb. or [illegible] per square inch.

The crankpins receive their supply of oil by means of a hole drilled through the crankshaft from the journal of the main bearings to the crankpin. One end of this hole is always in connection with a groove turned in the main bearings. In the crosshead journals a similar groove is formed, and the oil is led through this groove by means of a pipe attached to the side of the connecting rod up to the crosshead pin. In the case of small engines an additional groove is cut in the crosshead brasses and oil is conducted from this to the slides, but for large engines it is advisable to use a separate supply pipe direct from the main, as shown at *G* in Fig. 14. The eccentric and eccentric-rod crosshead pins, together with the crosshead slides, receive their supply of oil in a similar way, so that all of the working parts of the engine are automatically lubricated by means of the two pumps *C C*. The oil leaking from the various parts drips down into the crank case, but before being drawn into the pump again, it has to pass through the strainers already referred to. Where two pumps are fitted, a valve is generally attached to one end of the trough, so that when the strainer is withdrawn it automatically shuts off the supply of oil to that pump, and thus prevents the possibility of any grit being drawn in. It is thus possible to remove and clean a strainer while the engine is running.

Standard Makes of High-speed Engine

Belliss & Morcom. The largest firm of high-speed engine builders in England is Messrs. Belliss & Morcom, Ltd., of Birmingham. This firm alone has manufactured over 3000 engines. The largest engines built are suitable for driving generators of 1500 kilowatts capacity, and in Fig. 16 is shown a photograph of one of the Belliss-Dick, Kerr sets installed in the new Summer Lane electricity-supply station of the Birmingham Corporation.

Eight of these sets are installed and each is capable of developing as a continuous output 1500 kilowatts and 25 per cent. overload for short periods of time. They run at 166½ revolutions per minute and are supplied with steam at a pressure of 180 pounds per square inch. The normal output in brake horsepower is 2140, the maximum being 2680.

Of each set the high-pressure cylinder is 25 inches in diameter, the intermediate 36½ inches, and the low-pressure 55 inches, the stroke being 33 inches. Piston valves are fitted to all cylinders, these being driven direct from the crankshaft by a single eccentric. Messrs. Belliss' patent automatic-expansion gear, which is very similar to that previously described, is fitted to the high-pressure cylinder, the position of the valve being determined by a special relay cylinder which is operated from the governor controlling the throttle valve. With this arrangement the engine is governed by automatic expansion at the high loads and by the throttle at light loads.

In Fig. 17 is illustrated a small two-crank compound engine built by Messrs. Belliss & Morcom for the Peninsular and Oriental steamship "Mooltan. This engine is shown coupled to a Siemens dynamo capable of developing 40 kilowatts, the engine being capable of developing 58 brake horsepower when running at a speed of 450 revolutions per minute. The

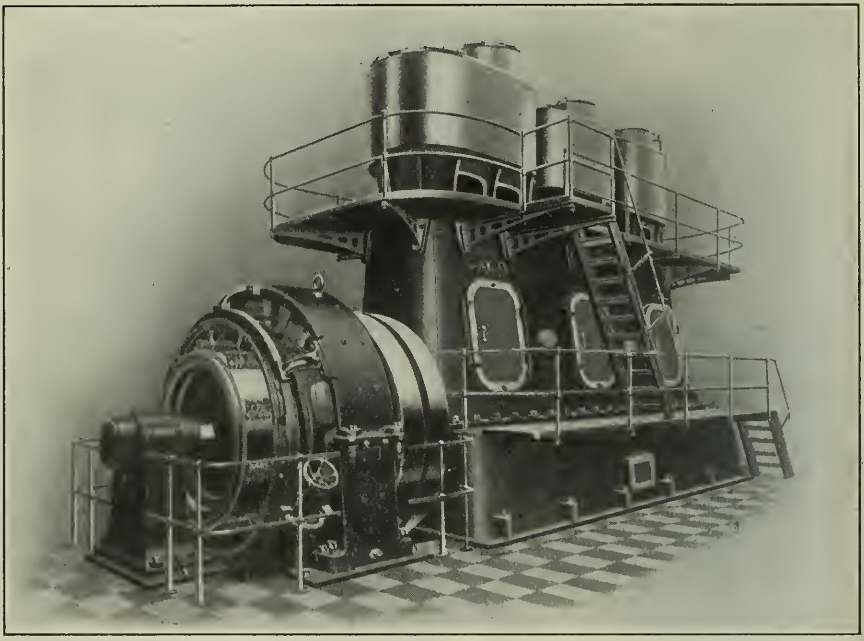

FIG. 19. EXTERIOR OF BROWETT-LINDLEY ENGINE

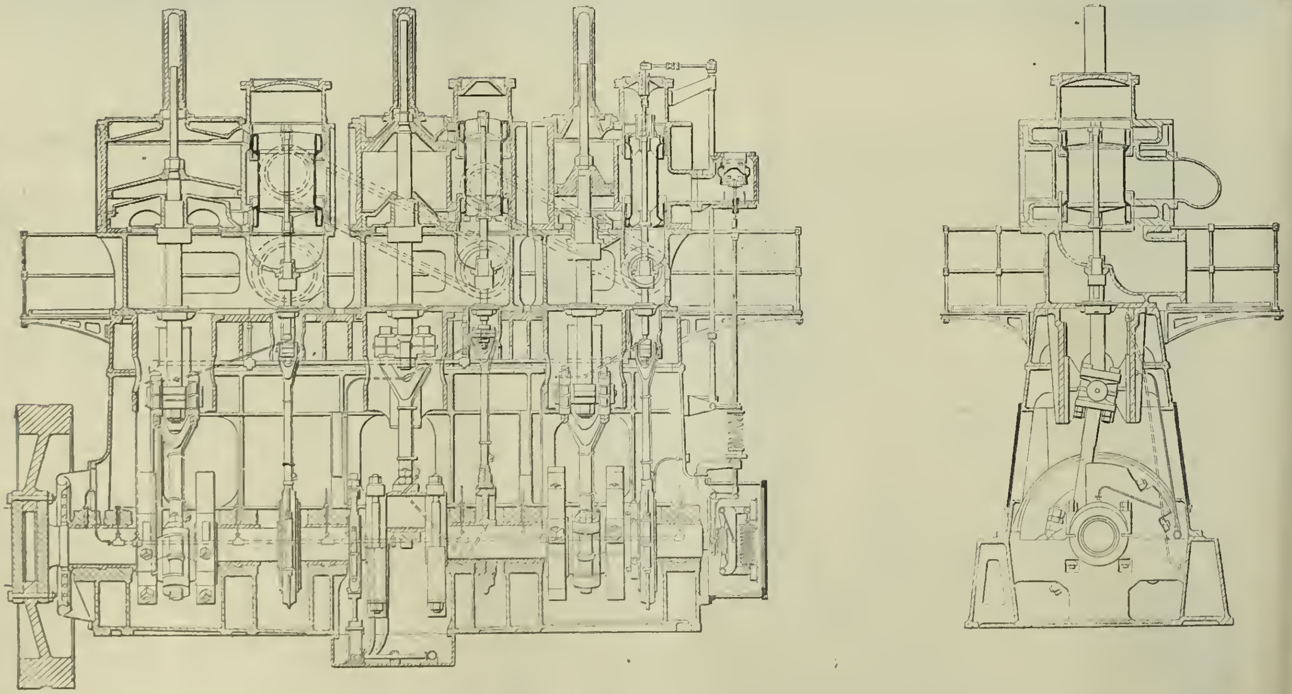

FIG. 18. TRIPLE-EXPANSION BROWETT-LINDLEY 2400-HORSEPOWER ENGINE

sets, of which there are five installed supply current for 1400 incandescent lamps of 16 candlepower each, four hundred 12-inch electric fans, six forced-draft fans, four large ventilating fans, a searchlight of 8000 candlepower, six coaling lamps of 20,000 candlepower, electric headlight and sidelights and two Brockie-Bell lamps of 40,000 candlepower each.

Browett, Lindley. Another large firm which manufactures engines of all powers from 20 to 3000 horsepower are Messrs. Browett, Lindley & Co., Ltd., of Patricroft, Manchester. This firm manufactures engines in the usual varieties, viz., single-crank simple and compound engines, two- and three-crank compound engines and three-crank triple-expansion engines. Their standard design of two-crank compound engine has already been illustrated in Fig. 3, and this drawing shows generally the arrangement of cylinders and motion work of the engine.

Engines of the type illustrated in Fig. 3 are manufactured in powers ranging from 300 to 1000 horsepower. The productions of this firm are undoubtedly of substantial design and material is not in any way stinted throughout the engine. All parts are accessible and at the same time the frame work of the engine is unusually rigid.

In Fig. 18 is shown in full section one of the largest-sized engines manufactured. This engine is capable of developing 2400 indicated horsepower as a normal load and 3000 as a maximum for periods of about two hours. It is of the triple expansion type and has cylinders 25x39x60 inches in diameter and a 27-inch stroke. It will develop the power stated when running at a speed of 200 revolutions per minute if supplied with steam at a pressure of 150 pounds per square inch and exhausting into a condenser. Piston valves are used throughout, and the cut-off of the high-pressure valve is under control of the governor, so that when working at the higher loads the engine is governed by variable expansion. At lighter loads throttling takes place in combination with the alteration to the cutoff.

The crank-shaft for this engine is forged in one piece, and the flywheel bolted to a large coupling formed at one end. The bolts in this coupling pass right through the crank-shaft, flywheel and dynamo coupling, so that no energy has to be transmitted through the crankshaft due to any shocks which may be received from the generator end. The economy of the high-speed engine compares most favorably with the best engine on the market, and this size of engine requires only 11.8 to 12.1 pounds of steam per brake horsepower when supplied with steam at a pressure of 150 pounds, superheated 150 degrees Fahrenheit, and working condensing at 26 inches of vacuum. The figures quoted are not results obtained from one particular engine, but represent what is obtained in every-day practice from a large number of engines. An exterior view of the engine illustrated is given in Fig. 19.

The Problem of Furnace Design for Water-tube Boilers

By Harold V. Coes

The water-tube boiler, while possessing many advantages for large power units, has one distinct inherent disadvantage in the difficulty of obtaining perfect combustion in the furnace as now designed. Until very recently and even now, with a few exceptions, it has been the practice to place the relatively cold heating surface in direct contact with the flames, thus defying at the very outset one of the laws governing complete and perfect combustion.

Messrs. Booth and Kershaw, in their work entitled "Smoke Prevention and Fuel Economy," lay down the following requisites for perfect combustion:

1. A draft velocity of not less than 30 feet per second, over the fire to draw in air above the fire bed for combustion with the gases distilled from the freshly charged fuel.

2. A thorough mixing of this air with the fuel gas, which can usually be done by allowing the air and gas to flow together over the length of the furnace. The air must be admitted in numerous fine jets, as through a perforated plate in the door.

3. A sufficient temperature to insure ignition at the bridge end of the furnace.

4. Space in which the combustion can complete itself undisturbed.

Consider the water-tube boiler and see how many of these requisites are violated or observed, and why, and how to remedy the shortcomings.

Unless horizontal baffles or arches are used, the air entering the doors short-circuits and passes directly up the tubes. It is true that the tubes mix the gases and air, but this is after the temperature has been reduced, so that if they do unite it will be at some point beyond the tubes, where the heat derived cannot be effective. Consequently the gas and air pass up the tubes unmixed instead of being thoroughly mixed and passing over the fire. Since each component of the fuel requires a definite amount of air to oxidize it, and since the gas and the air have to be thoroughly mixed to attain this result, if the tubes are put close to the grate, as in the water-tube boiler (thus chilling the flames), the highest temperature is not reached. Some of the hydrocarbons cannot be burned or oxidized except at high temperature, and as we both lower the temperature and do not mix the gases and air we violate the third requisite.

By placing the tubes close to the grate, we violate the fourth essential of good combustion, as one of the most important considerations in the design of a furnace is the combustion chamber.

Character of Fuel the First Thing to be Considered

The first thing to be considered in the design of the combustion chamber is the character of the fuel to be burned. The ignoring of this fact is responsible for a great many failures to attain perfect combustion. Trying to burn high volatile bituminous coals under a water-tube boiler with an anthracite setting causes still more failures and dissatisfaction. The greater the volatile content of the coal the more difficult becomes the problem. In burning the fine grades of anthracite, such as that from the mines of eastern Pennsylvania, the heating surfaces can be set relatively close to the grate, as there are practically no volatile hydrocarbons distilled from such coals, and as the flame length is proportional to the volatile matter in the fuel.

In such cases the tubes near the bridge-wall may be only a few feet from the grate and give good results, but the moment high volatile coal is burned under this setting trouble begins, as it is absolutely impossible to operate a boiler under these conditions without objectionable smoke and a correspondingly low furnace efficiency. The reason for this is that the high volatile fuel burns with long flames, and if the tubes or heating surfaces are not sufficiently removed to prevent the flames from impinging on it, and before the flames can be properly mixed with the requisite amount of air, they are chilled to a point below the combustion temperature. This causes the carbon to be precipitated either in the form of soot or smoke and, as smoke, to pass off up the stack with the rest of the products of combustion in a dense black cloud, which is sure evidence of poor heat transference and poor combustion.

The fact that this takes place in most water-tube boilers using soft coal on the grates is due primarily to the fact that in many instances water-tube boilers equipped with anthracite grates and settings were used in soft-coal districts, with the consequent results of poor combustion and low efficiency.

It is thus clearly seen, and this is the main point for consideration, that the furnace should be designed for and adapted to the fuel to be used in it.

How the Furnace Should be Designed

The combustion chamber should be of such size that combustion may be complete and undisturbed and permit the flames to burn out before coming in contact with the heating surface. As previously stated, the length of a flame is in almost direct proportion to the volatile content of the fuel, depending somewhat on the [illegible] this volatile matter. The short-circuiting of the air and gases and the prevention of the flames from reaching the heating surfaces can be accomplished simultaneously by the use of firebrick arches, tile roofs or dutch ovens; although the dutch oven is seldom used except with some form of automatic stoker.

One of the most effective ways of increasing the volume of the combustion chamber and of keeping the volatile gases from contact with the tubes in a water-tube boiler, is to build a tile roof across the furnace, covering up the lower portion of the first and second passes and reversing the circulation of the gases, the products of combustion now passing first over the bridgewall, up through the third pass, down to the second and up the first pass to the flue. This constitutes a dutch oven to all intents and purposes in the boiler itself.

The length of this tile roof or flat arch depends upon the flame length, for the flames should be extinguished or burnt out before going up the pass. And as stated before, the flame length depends upon the volatile content. The longer this arch is made the longer is the travel of the hydrocarbons in contact with it, and consequently the longer is the time interval for perfect combustion to take place. With the lower volatile Eastern coals, this arch need not be over 4 feet in length in order to obtain complete combustion. As the percentage of volatile matter increases the length of the arch or roof increases in almost direct ratio. It is also affected by the rate of combustion, so that with a knowledge of these two elements a furnace setting can be designed which will be absolutely smokeless under all operating conditions.

One type of arch which has given satisfaction, especially when used with fine anthracite, is that used in the Webster furnace. This consists of several arches strung across the grate in such a manner as to prevent the cooling of the fire when the charging doors are open. These arches are particularly effective when induced draft is used, as the difference in static pressure may in this case amount to several tenths of an inch of water, causing an inrush of cold air as soon as the doors are open and the consequent chilling of the tubes and lowering of the furnace temperature, unless the foregoing means are used to prevent it.

Hight of Boiler Tubes Important

A very important consideration irrespective of the type of furnace is the hight of the boiler tubes above the floor, or, what amounts to the same thing, above the grate. This again, of course, depends upon whether a tile roof is used or not. Formerly it was customary to install the Babcock & Wilcox boiler with the bottom of its header from 7 to 7½ feet above the floor line. This distance has gradually been increased for burning high volatile bituminous coals to 9 feet, and in some recent installations has been placed 10 feet above the floor line. And even this figure will probably be increased under some new gravity underfeed stokers.

The tile roof, furthermore, has a reverberatory action which keeps the furnace temperature at maximum, thus insuring the ignition temperature of the hydrocarbons and a heating of the air passing over the fire, with a thorough mixing of these two elements and the resulting good combustion. If the air for combustion can be preheated by any of the advantageous methods at disposal, the better will be the combustion.

The use of steam jets and that type of apparatus should not be tolerated, for they do little if any good, and that at the expense of good combustion. Operating engineers believe that they prevent clinkers. The only reason that a steam jet stops clinkers is because it lowers the furnace temperature below the fusing point of the clinker, which is a good reason for not using it, since any agent that tends to lower the temperature of combustion is a poor one.

There is a method, however, for small installations which merits consideration, and that is a combination turbine-driven disk fan, which uses a very small percentage of exhaust steam, but which materially aids in distributing the air for combustion. Of course for large installations some one of the mechanical-draft installations would be used. But then, again, large installations generally have an engineering staff capable of properly designing and specifying the kind of furnace to be used.

Amount of Coal Burned

The amount of coal that can be burned per square foot of grate surface per hour varies over a wide range for various installations and various conditions. The problem depends upon the load to be carried, kind and amount of draft, type of boiler and the character of the fuel. In some of the large central stations using the finer grades of anthracite this amounts to from 25 to 30 pounds. During the peak load, by increasing the draft, this figure may be increased to 50 pounds per square foot.

With soft coal, except where stoker-fired, it is not generally good practice to burn more than about 20 pounds per square foot on a flat grate, on account of the difficulty of good air distribution. When soft coal is fired with an automatic stoker, as is done in large stations, from 65 to 70 pounds of coal per square foot of grate per hour may be burned. This has recently been done by a new type of gravity underfeed stoker.

The type of grate to be used is a matter of choice, there being many good types on the market. Whether a dumping or a shaking grate will be used depends upon the amount of ash and clinker in the fuel. If this is rather small the shaking grate will give good results; if high, then the former should be used.

The one thing to bear in mind is the fact that the burning of coal is governed by just as accurate physical laws as is the generation of steam. Just as much care, thought and time should be spent upon the design and selection of a furnace as upon any other part of the boiler. For after all, this is the heart of the boiler, and any saving that is made in the furnace is a direct saving, for no processes of manufacture have taken place until the coal is fired; consequently, the saving in raw material represents hard cash.

The Function of Compression

By R. T. Strohm

Judging by what one reads and hears, the question of compression or no compression seems to be causing no little mental agitation. There are those who have come out broadly for the elimination of the compression heel from the indicator diagram, on the ground that compression in steam engines is not necessary, and that most engines would run better, both mechanically and economically, if it should be dispensed with.

Such statements, to say the least, are combatable. To begin with, it is rather absurd to think that steam engineers have been making the egregious blunder, for many decades, of clinging to compression and thereby wasting steam. It is scarcely believable that if eliminating compression increases economy, the fact would not ere this have been discovered and put to practical use. Engine builders who have guaranteed certain definite results as to economical performance have designed and manufactured engines in which compression figures largely. Is it possible that they have thus long been ignorant of the suggested means of lowering steam consumption?

Argument of this character, alone, does not nullify the statement that compression is unnecessary. That much is admitted. But there are other ways of attacking the problem. Compression in steam engines is not only desirable, to a greater or less extent, but is a necessity. There are two good reasons for this condition. One is that silent and smooth running is thereby secured. The other, and just as important reason, is that the economy of the engine is improved thereby. It will be observed that these statements are diametrically opposed to those referred to in the opening paragraph. It now remains to adduce something in the way of support and proof.

The reciprocating parts of an engine do

not move with a uniform velocity. Instead, the velocity increases from zero at the beginning of the stroke to a maximum at the middle of the stroke, and then decreases to zero at the end of the stroke. During the period of acceleration, the pressure of the expanding steam is the force causing the acceleration. But during the period of retardation, the retarding force may be either a cushion of steam, a reaction from the crank pin, or a combination of the two. If compression is used, the increasing pressure of the steam trapped in the compression space will furnish the resistance necessary to overcome the inertia of the reciprocating parts, and it is evident that, by adjusting the amount of compression, the reciprocating parts may be brought to rest without subjecting the crank pin or wrist-pin to any great pressure.

In Fig. 1 is shown a curve of inertia pressures in a reciprocating steam engine, *a b* representing the stroke, and vertical distances from *a b* to *d e* representing inertia pressures. It will be seen that at the

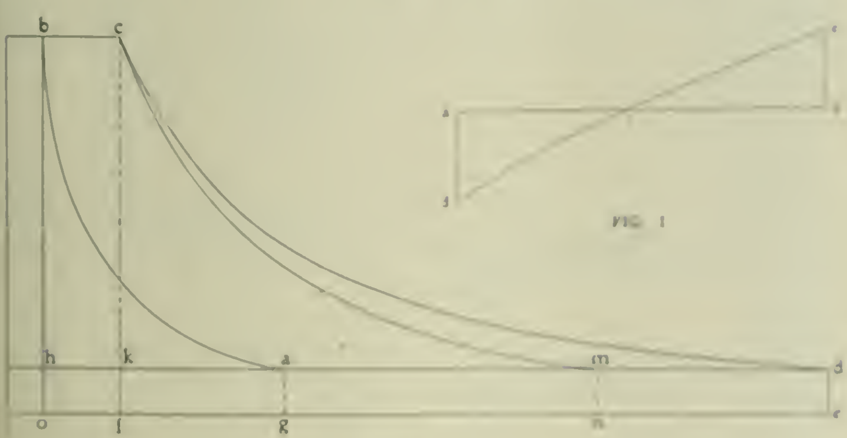

FIG. 1

FIG. 2

beginning of the stroke, the inertia pressure is negative, and of a value *a d*. As the parts become accelerated, the inertia pressure grows smaller, until, at the point of maximum velocity *c* the inertia pressure is zero, since at that point the crank pin and crosshead are moving with the same linear velocity. From *c* to *b* the crosshead motion decreases in velocity, and at *b* the inertia pressure *b e* is again large, but this time positive in value. The increase of velocity of the reciprocating parts during the portion of the stroke represented by *a c* is due to the expenditure of a portion of the energy of the expanding steam. The decrease of velocity from *c* to *b* is due to the fact that the reciprocating parts are giving up the energy received during the earlier portion of the stroke.

If the reciprocating parts are brought to rest by means of a cushion of compressed steam, the resisting force increases from zero to a maximum, just as the inertia pressure changes in similar fashion; and furthermore, the resistance is introduced against the piston, which forms a large proportion of the weight of the reciprocating parts, and this point of application of the resistance is therefore the most direct and the most rational. If no compression is used, the inertia thrust of the rapidly moving parts will be transmitted to the crank pin with ever increasing intensity.

Now, is it not manifestly better to bring the reciprocating parts to rest by a cushion of steam than by the influence of the crank pin? By means of the steam cushion, the pressure is transmitted directly to the cylinder head, which in turn is attached to the most rigid portion of the engine frame. As a result, the inertia of the reciprocating parts is absorbed, and they are brought to rest with the least unbalancing or vibrating effect. On the other hand, if the reaction at the crank pin is relied upon to accomplish the desired end, the pressure is applied through intervening links in the connections of which some slack exists, and the tendency is to produce pounding. The balancing of an engine to overcome the disturbing effects of the rotating and reciprocating parts is a very pretty problem, indeed, and while there are a few engines in which a practically perfect balance has been secured, there are many that are far less accurately balanced, and the elimination of compression from such engines would be followed by running conditions that no sane engineer would regard as desirable or safe.

Large Flywheel Energy Not Wasted

It has been argued that it is a wasteful proceeding to use part of the energy stored in the flywheel to compress the steam contained in the clearance space. This idea is based on a misconception, surely. It is not necessary to take any considerable energy out of the flywheel to accomplish compression. If the point of compression is so chosen that the amount of energy required for compression is just equal to that given up by the reciprocating parts in coming to rest, it will be unnecessary to take additional energy from the flywheel. This would be the ideal condition, so far as smooth running is concerned.

But there is another side to the question of compression. Compression is of practical value in neutralizing the evil effects of clearance on the steam consumption. There will be few engineers to combat the statement that clearance is a mechanical necessity. As long as bearings and pins are subject to wear, just so long will it be necessary to allow a greater or less amount of clearance between the piston and the cylinder head at the extreme ends of the stroke. Now, the effect of clearance is to increase the steam consumption per unit of work done, and the greater the clearance, the greater is the loss. This can be very readily shown by illustrative examples.

Take a case in which 1 cubic foot of steam at 105 pounds per square inch, absolute, is expanded to a pressure of 15 pounds absolute, there being no clearance and no compression. Under these conditions, the ratio of expansion is 7. The work during expansion or compression according to the law $PV = a$ constant is found by the formula

$$W = 2.3026\, P_1 V_1 \log \frac{V_2}{V_1}$$

where

W = Work in foot-pounds,

P_1 = Initial absolute pressure, in pounds per square inch,

V_1 = Initial volume, in cubic feet,

V_2 = Final volume, in cubic feet.

Since the expansion of saturated steam follows most closely the equilateral hyperbola, $PV = a$ constant, the above formula will be used in calculating the work areas under the curves in Fig. 2. Also, where rectangular areas are concerned, the work may be found by the formula

$$W = P_1 (V_2 - V_1)$$

in which the several terms have the same significance as before.

In Fig. 2, let $b c$ represent 1 cubic foot of steam at a pressure of 105 pounds per square inch absolute, the pressure being represented by the height $b f$. First, assume neither clearance nor compression, and let the steam expand to the pressure of the atmosphere. Then, the expansion curve is $c m$, and the work represented by the column areas is found by the foregoing formulas as

[illegible] foot-pounds.

[illegible] foot-pounds.

[illegible] foot-pounds.

[illegible] foot-pounds.

Therefore, [illegible] foot-pounds, the [illegible] work done by 1 cubic foot of steam with no clearance nor compression.

Now, add 0.5 cubic foot for clearance, as indicated by *o l*. Then, in reducing to 15 pounds pressure, as before, the piston will sweep through 10 cubic feet, and the final volume of the steam will be 10.5 cubic feet. As the initial volume was 1.5 cubic feet, as represented by *f l*, the ratio of expansion remains unchanged. Then,

$$c\,d\,e\,f = 2.3026 \times 105 \times 144 \times 1.5 \log 7 = 44{,}133 \text{ foot-pounds.}$$

$$b\,c\,f\,o = 105 \times 144 \times 1 = 15{,}120 \text{ foot-pounds.}$$

$$o\,b\,c\,d\,e = 44{,}133 + 15{,}120 = 59{,}253 \text{ foot-pounds.}$$

$$h\,d\,e\,o = 15 \times 144 \times 10 = 21{,}600 \text{ foot-pounds.}$$

Therefore, $b\,c\,d\,h = 59{,}253 - 21{,}600 = 37{,}653$ foot-pounds. This amount of work was accomplished by 1.5 cubic feet of steam, so that the work per cubic foot was $37{,}653 \div 1.5 = 25{,}102$ foot-pounds, as compared with 29,422 foot-pounds without clearance. This shows the manner in which adding clearance decreases the work done per unit of steam used.

Now assume compression to commence at *a*, so that when the piston reaches the end of its stroke there will be 0.5 cubic foot of steam at 105 pounds absolute pressure in the clearance space. Under these conditions the clearance space is filled with steam at the initial pressure, so that the amount admitted up to cutoff is merely that represented by *b c*, or 1 cubic foot. The work of compression is represented by the area *o b a g*, and as before it is found that

$$o\,b\,a\,g = 2.3026 \times 105 \times 144 \times 0.5 \log 7 = 14{,}711 \text{ foot-pounds.}$$

Also,

$$g\,a\,d\,e = 15 \times 144 \times 7 = 15{,}120 \text{ foot-pounds.}$$

The area *a b c d* representing the net work performed is equal to

$$o\,b\,c\,d\,e - o\,b\,a\,g - g\,a\,d\,e = 59{,}253 - 14{,}711 - 15{,}120 = 29{,}422 \text{ foot-pounds.}$$

The total work done with a clearance of 0.5 cubic foot and no compression was 44,133 foot-pounds, and the total work with neither clearance nor compression was 29,422 foot-pounds. The difference between these is 14,711 foot-pounds, which must be represented by the area *c d m*. But, the area *o b a g* also represents 14,711 foot-pounds. In other words, the gain due to increased expansion after adding clearance is exactly offset by carrying compression up to the initial pressure, and the net work, represented by the area *a b c d*, accomplished by 1 cubic foot of steam is equal to the work obtained from the same amount of steam expanded without clearance or compression, since in each case the work amounts to 29,422 foot-pounds.

This proves conclusively that when compression is carried up to the initial pressure, so that the clearance space at the beginning of the stroke is filled with steam at the admission pressure, the wasteful effect of clearance is nullified, and the steam economy is the same as though there was no clearance nor compression.

It is possible that someone may argue that in ordinary cases the compression is not carried up to the initial pressure, and that during compression there is a definite loss due to radiation and condensation of the entrapped steam. These facts are freely admitted. But such an admission does not destroy the truth of the statement that compression is economical. It has been shown that the evil effect of clearance is wholly offset by compressing to the initial pressure. If the compression is less than this, the saving is correspondingly decreased, but in any case it is better than dispensing with compression altogether, and filling the clearance space with live steam at the beginning of each stroke. For this steam does no work on the piston until after the valve closes, and then, by its expansion, it adds somewhat to the diagram, as indicated by the area *c m d*, Fig. 2.

Finally, the necessity of having compression grows less as the speed of the reciprocating parts or the percentage of clearance decrease. In high-speed automatic engines the clearance is usually large, and it will be found that, almost without exception, diagrams from this class of engine show compression curves running from two-thirds to three-fourths the hight of the diagrams. In Corliss engines the percentage of clearance is much less and the piston speed is lower, and in many such engines it is possible to reduce the compression to such a degree that the heel of the diagram is almost square, without affecting the smoothness of operation or steam economy of the engine. But though this may be done in the case of slow-speed engines having small clearance volumes, and has been successfully demonstrated in such cases, it ought not to be formulated into a general statement and heralded as being applicable to all types and classes of engine. For most assuredly it is not.

Central Electric Light and Power Stations in the U. S.

In the accompanying table are shown the data of a preliminary report, by the Department of Commerce and Labor, on central light and power stations in the United States, exclusive of Alaska, Hawaii, Philippine islands and Porto Rico.

PRELIMINARY REPORT ON CENTRAL ELECTRIC LIGHT AND POWER STATIONS.

	1907.	1902.	Per Cent. of Increase.
Number of establishments	4,714	3,620	30.2
Commercial	3,462	2,805	23.4
Municipal	1,252	815	53.6
Total cost of plants	$996,613,622	$504,740,352	97.5
Total income (1)	$175,642,338	$ 85,700,605	104.9
Lighting service	$125,755,114	$ 70,138,147	79.3
All other electrical service	$ 43,859,577	$ 14,048,458	212.2
All other sources	$ 6,027,647	$ 1,514,000	298.1
Total expenses	$134,196,911	$ 68,081,375	97.1
Salaried employees:			
Number	12,990	6,996	85.7
Salaries	$ 11,733,787	$ 5,663,580	107.2
Wage-earners:			
Average number	34,642	23,330	48.5
Wages	$ 23,686,537	$ 14,983,112	58.1
Supplies, materials and fuel	$ 44,458,568	$ 22,915,932	94.0
All other expenses (including interest on bonds)	$ 54,318,019	$ 24,518,751	121.5
Steam and gas engines (including turbines):			
Number	7,674	6,095	25.9
Horsepower	2,684,228	1,392,122	92.8
Water wheels:			
Number	2,474	1,390	78.0
Horsepower	1,347,487	438,472	207.3
Total kilowatt capacity of dynamos	2,642,403	1,218,735	116.8
Output of stations, total kilowatt-hours	5,858,121,860	2,507,051,115	133.7
Estimated number of lamps wired for service:			
Arc lamps	(2) 555,921	385,698	44.1
Incandescent lamps	(2) 41,807,944	18,194,044	129.8
Stationary motors served:			
Total horsepower capacity	1,649,026	438,005	276 5

(1) Exclusive of income for current used for light and power that was furnished by railway companies, and which is included in the report for street and electric railways.

(2) Exclusive of lamps used by the establishments reporting to light their own properties.

The final report will contain an analysis of the above totals and present detail statistics by States and for other phases of the industry.

The statistics relate to the years ending December 31, 1907, and June 30, 1902. The totals include central stations only. They do not include isolated plants, or plants that were idle or in course of construction, and in but few instances plants operated by electric-railway companies.

It is interesting to note that in connection with the conservation of water power a recent advance in transmission voltage, by the placing in service of a 110,000-volt line in Michigan, is a clear indication of the rapid elimination of distance as an obstacle to electric-current service.

Independent Steam Gage Movements

I was much surprised to see a description of a steam gage movement which is mounted upon the base of the spring, so as to be independent of the case, appear in a recent issue of POWER as a new thing. I am sure that it has been upon the market for seven or eight years, and it is not at all original with the company to whom it is credited in the description. The description mentions among the advantages of this construction that "jar and vibration do not affect its accuracy nor sensitiveness." I think that experience has shown that jar and vibration have more effect on a gage of this type than they do on a gage where the movement is fastened to the back of the case, although there is not a great difference, and what is true of one is as true of the other.

It has never been proved that the air space at the back of the case was beneficial in any way, due to the fact that when the necessary amount of heat reaches the case to cause it to expand, as well as the movement, to such an extent that the reading of the gage would be affected, this amount of heat would, before the reading would be affected due to expansion, damage the tube to such an extent that the gage would be useless, anyway.

Solution on Indicator Cards

Can any reader inform me what solution is used on prepared indicator cards and how it is applied?

D. O. [illegible]

Freeport, Ill.

A Sawdust Stoker

In a large sawmill boiler room were 11 boilers, two of which were fitted with dutch-oven furnaces and hand-fired. The remaining nine boilers were divided into two batteries of two boilers each, and one battery of five. There was no dividing wall between the boilers of each battery, the boilers being hung from I-beams. The sawdust was carried in [illegible] from conveyors and dropped through openings between the boilers.

Combustion under these conditions was very unsatisfactory, as a large cone of sawdust was formed under each opening and between each cone was a large [illegible] of bare grate. A plan which worked well was to arrange things so that the sawdust falls into the curved pipe [illegible] to the [illegible], and is then blown into the furnace by a jet of steam or compressed air. The jet strikes the edge of the [illegible] in such a manner that the sawdust spreads out like a fan, covering the entire grate surface.

[illegible]

[illegible]

Compound versus Simple Engines

In a recent number were published a letter and indicator diagrams, by George W. Harding. The diagrams were intended to prove that a compound engine develops twice the horsepower that a simple engine does.

The data furnished with Mr. Harding's diagrams show that the [illegible] pressure was from 13 to 15 pounds, gage, and the vacuum was from 21 to 22.5 inches. Now if this had been a simple engine it would have been exhausting into 21 or 22 inches of vacuum instead of 13 to 15 pounds gage pressure. Mr. Harding's diagrams only show that the work was nearly equally divided between the high- and low-pressure cylinders, nothing more.

He wishes to know why engines are compounded if not to develop more work by again using the steam that has done work in the high-pressure cylinder. Engines are not compounded to develop more power, but to save fuel. It is cheaper to build a 200-horsepower simple engine than a 150-horsepower compound engine. It would seem that the compound engine is not as generally understood as it should be by many engineers.

Let us see what advantage the compound engine really has over the simple engine. For example, take two engines of [illegible] horsepower each, one a compound, the other a simple engine. The steam pressure will be [illegible] pounds gage for each engine. [illegible]

[illegible]

in the compound engine than in the simple engine; therefore, there is a greater economy in favor of the compound engine.

West Halifax, Vt.

Finding Engine Clearance from Indicator Diagrams

In a recent number a writer presented two methods for finding engine clearance from the indicator diagram, which were incorrect in one important and essential point, as he used the atmosphere line as a base line, while as a matter of fact the atmosphere line has nothing to do with the determination of clearance.

The correct method of obtaining the clearance from the diagrams is as follows: Select the best diagrams that can be obtained from the engine, having smooth expansion and compression curves. Lay off the absolute zero-pressure line parallel to the atmosphere line and at a distance below it to represent 14.5 pounds on the scale of spring used for the diagram. Draw the line *A B C D,* Fig. 1, cutting the smoothest portion of the expansion or compression curve at the points *B* and *C*. Then locate the point *D* so that the distance *C D* equals *A B*; the perpendicular line *D E* will then represent the point of zero volume, and the per cent. of clearance may be obtained by dividing the length *E F,* in inches, by the length of the diagrams *F G,* in inches, and multiplying by 100.

The explanation for this construction is that the expansion curve and compression curve for saturated steam, and for air when the compressor is running very slowly, are nearly enough in form to an equilateral hyperbola, whose axes are the zero-volume line (clearance line) and the absolute zero-pressure line, that they may be assumed to be so. On such a curve, if a line such as *A B C D* be drawn intersecting the curve in two points and touching the two axes, then it is true that the two portions *A B C D* are equal.

If the second method should be used the line which is an extension of the diagonal of the constructed rectangle should be continued to the absolute zero-pressure line. This method should not be recommended, as there are too many chances for error in construction, and it is more difficult to get right.

If the engine is an old high-speed machine, there is a chance that leaks in the valve or error in the indicator will show on the expansion line, and in this case it is better to use the compression curve, Fig. 1.

On many Corliss engines, and others of slow speed, the compression may be so short as to give a very small curve, and then the construction must be on the expansion line, Fig. 2. In any determination of this kind the greatest care must be exercised to obtain accurate results; a fine-pointed hard pencil must be used and the distances *A B* and *C D* should be measured with dividers.

W. T. Heck.

Lafayette, Ind.

A Peculiar Lighting Condition

Concerning the answer to my letter, "A Peculiar Lighting Condition," by Walter G. Mullen, page 70, January 5 number, I will say that he gave the correct *cause* of the trouble, but his reason for the opening of the circuit-breaker is not exactly right.

He says: "If now the switch *A* is opened all of the circuit *C* must pass through the circuit-breaker; this momentary rush of current may be sufficient to trip the same in the manner spoken of." Now, it takes much more than the current of circuit *C* to trip the breaker, as it was installed to carry this current continuously. What really happened is this: Consider the two circuits, *B* and *C,* to be

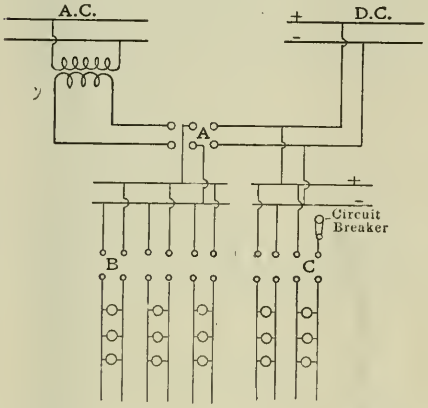

DIAGRAM OF WIRING FOR LIGHTING SYSTEM (REPRODUCED)

each grounded on the negative side, the whole considered as a direct-current system. This gives two negative paths for the current of all the circuits on switch *A,* and not alone that of circuit *B*.

One path is the normal one through the negative pole of switch *A* to the negative bus of the exciter, and the other is through the ground on *B* to the negative side of *C,* through the circuit-breaker to the negative bus.

At the instant switch *A* is opened, a resistance is introduced into the circuit at the negative break, which as the length of the break increases becomes high enough to shunt all of the return current of all of the circuits on switch *A,* through the grounded path, through the circuit-breaker, causing it to open. Since there are a hundred or more lamps on switch *A* the resultant overload on the circuit-breaker is at once apparent.

Of course, this rush of current was of short duration, lasting only while the positive pole of switch *A* was breaking the circuit, yet it was sufficient to trip the circuit-breaker.

Mr. Mullen's explanation of why the lamps of circuit *C* would burn with the circuit-breaker open was entirely correct.

C. L. Greer.

Handley, Tex.

A Motor Trouble

In reply to Mr. Sheehan's puzzle, I would say that if the generators were bought as generators and one used as a motor, it would operate as a differential motor, which was the reason it stalled; and the man had to shift his clutch in order to allow the motor to produce torque.

The reason, of course, for the motor reversing was the series field overcoming the shunt field and reversing the polarity, causing the armature to reverse its direction of rotation. The weak field at the instant of reversal and the heavy armature current would cause the violent sparking; as would the lead of the brushes. If the shunt field had become open for some reason the motor would have acted in the way stated.

Ensley, Ala.

Probable Cause of Air Compressor Explosions

In the issue of January 12, I note a letter from F. W. Holman, with the above title, in which he suggests leaky discharge valves as the "most plausible" explanation of the cause of certain destructive compressed-air pipe explosions. As far as my knowledge extends, the letter does not suggest even a possible cause of such explosions.

The letter says: "Air which had been compressed evidently leaked back into the cylinder, where it became recompressed. This recompression will make it hotter and hotter until it either reaches a point where radiation will take the heat faster than the temperature can rise, or the temperature will rise until the oil catches fire."

In the case under consideration the air was compressed to 17 pounds gage and, with an initial temperature of 60 degrees Fahrenheit, the temperature after compression would be 190 degrees. If the air at this temperature could be recompressed, the final temperature would then be much higher, and if this operation could be repeated many times, the theoretical temperature attained might go as high as the most unbridled imagination could carry it; but no such result could come from leaky discharge valves.

The discharge valves would have to be in very bad condition to leak back 5 per cent. of the air compressed per stroke, and this return leakage into the compressor cylinder would occur during the intake stroke, continuing perhaps, if the leakage was very bad, during a small portion of the compression stroke; not far, because with adiabatic compression, full pressure would be reached when the piston reached the middle. When the piston starts for the intake stroke the air in the clearance space, heated by compression, must first re-expand down to atmospheric pressure and, coincidently with its re-expansion, its temperature will fall entirely back to what it was before the compression began. The air leaking back through the discharge valves also re-expands and its temperature falls correspondingly and, mingling with the incoming air at atmospheric pressure and temperature, the temperature of the whole cannot be raised appreciably by the leakage. This air which has leaked back becomes an inseparable part of the cylinderful and when the mass is compressed and discharged it is carried along together and no portion of it can be isolated and worked back and forth, as assumed, to have its temperature cumulatively augmented.

These attempts to solve the mysteries which still seem to be connected with some of the explosions that occur in connection with compressed air are certainly not to be discouraged. It would seem that the oil rather than the air is the thing to be studied. It is a noticeable thing that the initial explosions seem to occur more frequently in the pipes after the air has left the compressor rather than in the compressor cylinder head, where the temperature may be assumed to be the highest.

Compressed air alone, no matter how hot it may be, cannot possibly explode. The explosion is, of course, due to the ignition of a mixture of air and a volatile constituent of the lubricating oil. This volatile ingredient being present in sufficient quantity, there must still be provided time and opportunity for the mixing to be completed. This operation goes on rapidly, so that the conditions may be ripe for the catastrophe very close to the compressor. With the mixture ready for the explosion, ignition may occur spontaneously if the temperature is sufficient or a spark may be produced by friction and cause the explosion at a lower temperature.

Oil often burns bodily in the compressor cylinder heads and in the receiver without any explosion, receivers and contiguous piping sometimes becoming red hot. This might be going on in some case and provide the means of firing the explosive mixture which might be formed farther along in the pipes.

The obvious deduction is that we should use oils from which the more readily volatile constituents have been distilled, that we should use as little as possible of even the best oil and that, wherever there is a possibility of the used oil accumulating, provision should be made, and availed of, for frequent draining.

FRANK RICHARDS.

New York City.

The Barrus Universal Calorimeter

In the December [illegible] number there appeared an article entitled, "Barrus Universal Calorimeter," by Charles N. Cross, parts of which I beg to take exception to. Mr. Cross says the steam passes from the sampling pipe directly to the heat gage and thence through the separator to the atmosphere. The correct arrangement of this instrument is just the reverse, the steam first passing through the separator, where the major portion of the moisture is removed, and then through the heat gage to the atmosphere.

[illegible]

On the other hand, by placing the separator before the heat gage, the steam drops all but about [illegible] per cent. of its moisture in the separator, and is then in a proper condition for the expansion through the heat gage.

CHARLES B. [illegible], JR.

Philadelphia, Penn.

Trouble on Arc Circuit

The transformer in the accompanying illustration evidently had its primary winding connected across a single phase when operating on [illegible] volts. The change of line voltage to [illegible] volts necessitated the changing to [illegible] transformers, with the connections as in the diagram, the secondaries being connected in parallel and the primaries in [illegible]

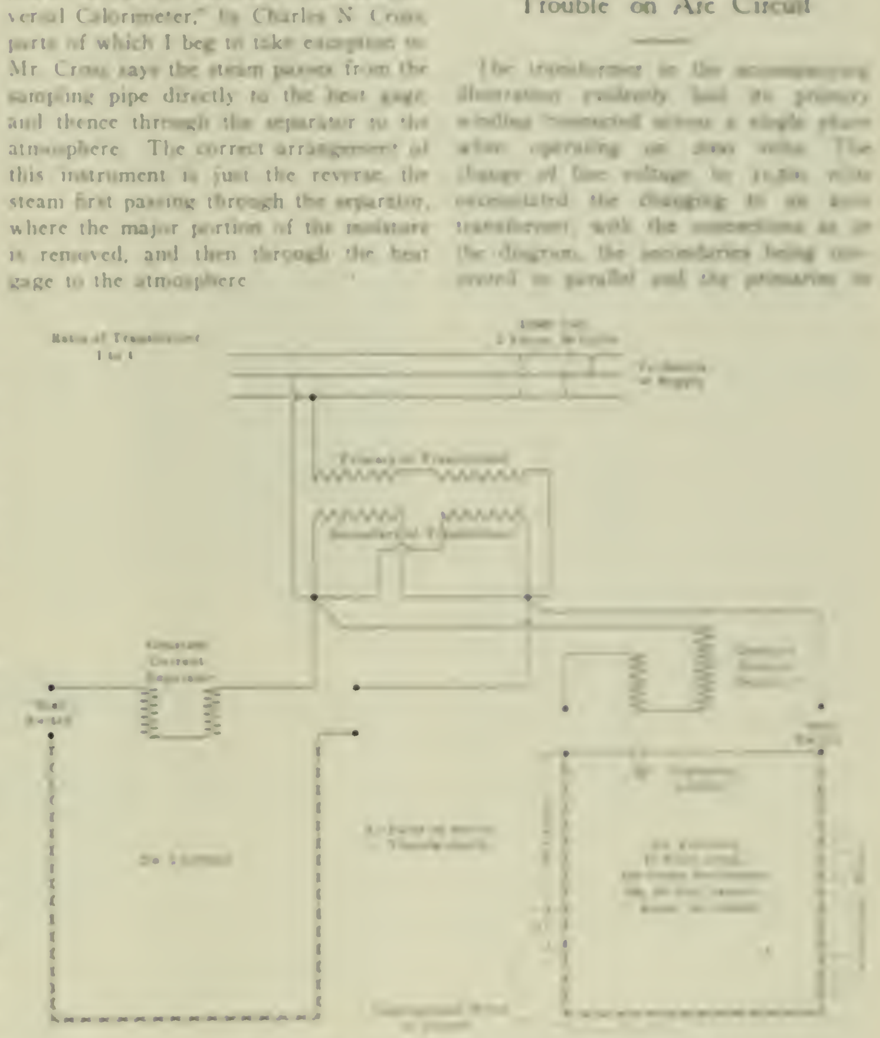

FIG. 1. TRANSFORMER AND CIRCUIT CONNECTIONS

[illegible]

[illegible]

ning arrester to ground, also that the aërial line of 40 lamps would burn all right and the ammeter show 7 amperes, but that upon sending the circuit underground trouble started, the rest of the circuit being fed from underground cable having only 4 amperes flowing through it. The regulator acted as if the line was short-circuited.

The trouble should have suggested itself at once. If there was a discharge through the lightning arrester and also trouble was found where the circuit entered the ground, evidently the trouble had to be between the arrester and the underground circuit, showing that the cable had been punctured by the high voltage. The ground wire of the arrester and the other side of the arrester itself had this high potential across it also, causing it to discharge across the gap. There might also have been a possibility of the

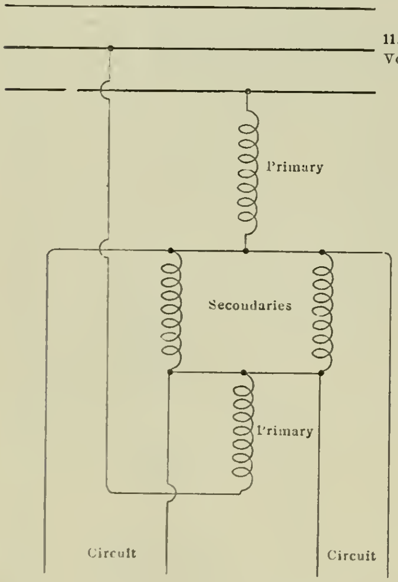

FIG. 2. SECONDARIES IN PARALLEL BETWEEN PRIMARIES

cable being broken down all along in the underground conduit.

The fact of making an insulation test using from 10 to 100 volts and finding one megohm resistance would not guarantee the cable from breaking down when 11,500 volts were sent through it. Finding 500 megohms resistance by such a test would not insure safety from breakdown with this high potential. The correct way would be to test a sample piece of cable directly on 11,500 volts from the conductor to the lead sheath.

The lightning arrester evidently was not built for a circuit of 11,500 volts, the discharge gap being too small to prevent this high-pressure current discharging to ground. In dry air, 11,500 volts will jump an air gap nearly 0.6 inch long and 10,000 volts will readily jump across a ½-inch gap.

The reason for 4 amperes flowing through the rest of the circuit and 7 amperes being indicated by the ammeter was that 3 amperes were escaping to ground, showing again that the underground cable had been punctured. The lamps fed from underground evidently would flicker on account of receiving only about one-half their normal current, which was too small to give enough excitation to the series coils in the lamps that attract the armature holding the upper carbon in suspension. This condition in the lamps would cause them to pick up and drop at short intervals.

The earth return circuit from the underground cable through the lightning arrester would cause the regulator to act as if the line were short-circuited, as it was only regulating 40 lamps, the other 70 lamps having no regulation at all. The trouble would probably disappear if the lightning arrester were removed, thus destroying the return circuit through the earth to the ground wire. When operating on 11,500 volts or even 8000 to 9000 volts, the best and only sure way is to get an equipment of electrical apparatus designed for high voltage, for example a transformer whose primary will stand 12,000 volts across the phase.

In Fig. 2 is given a method by which the insulation strain will be reduced about 1200 volts. In this diagram the secondaries are connected in parallel between the primaries.

Necessity of Good Pipe Work

The editorial on the necessity of good work in suction piping is very much to the point. If one end of a pipe is under water and the other end attached to a pump in which there are no leaks, and the pump continually loses its water, it is only reasonable to suppose that air leaks in, as the following case will show:

There had been a 12-inch bell-and-spigot joint pipe line, 1400 feet long, laid down a river to a pump located at an elevation of 16 feet above the average level of the water. The pipe joints were supposed to have been properly made, but the pump worked miserably and often had to be stopped and primed after losing its water. The contractor finally agreed to dig up the pipe and ascertain where the trouble was. It became my duty to test every joint as exposed. There was a foot valve at the rims and I adopted the method of stopping the pump and opening a bypass from the delivery to the suction pipe, letting about 30 pounds onto the latter. We left this pressure on for ten minutes, keeping a pan under the joint so as to catch and determine the amount of water that leaked out. In this way we discovered 21 leaks of from 1 to 14 ounces in the ten-minute test, the total of all being 7½ pounds, or 314 pounds per minute. When they were all made tight the pump worked all right.

Most of the leaks were at the bottom of the joint where the lead meets, and was partially cooled, after flowing down the sides of the joint, and possibly due to the fact that the joint does not always get as good calking there as on the more accessible top and sides.

The difference between good and poor work is shown in the fact that we have in daily use a 6-inch galvanized wrought-iron pipe, 700 feet long, with a lift of 24 feet, which is perfectly tight and has been for thirty-one years.

Firing Stationary Boilers

The remarks on firing stationary boilers, by J. F. Bradley, in the January 5 number, in which he quotes Mr. Wadleigh as saying: "The fireman should know that the place to shut off or regulate draft is at the stack damper and not by the ashpit doors, the latter being for the purpose of *regulating the air supply*," arouses my curiosity as to how Mr. Wadleigh differentiates between regulating the draft and regulating the air supply.

Mr. Bradley's theory that smoky coal will clog the tubes quicker with the damper partly closed than with the ashpit doors partly closed is true. The fact that it took him a long time to figure out the why and wherefore thereof is no indication that he is slow at "figuring," but that the question of properly operating a steam boiler is one that bothers a whole lot of people.

Regulating draft is primarily a question of fuel economy; secondarily, a question of load variation. I assume that we are dealing with hand-fired boilers, in which case the fuel is fed intermittently, which fact necessitates the intermittent admission of air to the fire.

In my judgment, the ashpit doors should be left wide open while the boiler is in service, and *after* each fresh firing, the stack damper should be opened wide until the gases have been consumed, when the damper should be partially closed the correct amount to take care of whatever load happens to be on the boiler.

After the volatile gases in the coal have been consumed, the passage of excessive air through the furnace results in loss of heat by carrying it up the chimney.

The ideal draft regulation provides for full draft after every fresh charge of fuel, a gradual diminution, according to the load on the boiler, and finally cutting down the draft to the last degree permissible. Such regulation will not increase the deposit of soot in the tubes for the reason that combustion will be more complete and less soot will be made.

Filtering Oil

When I had charge of a producer-gas plant and gas engines it at first seemed impossible to get rid of the carbon in the oil that drained from the engine bearings. However, I finally took three cast-off filters of different sizes, took out the filtering arrangements and connected them as shown in the sketch. I put a ½-inch brass coil in can *A* and connected it to the exhaust pipe of the water pump. This gave me just about steam enough to keep the oil warm. I also connected a live-steam pipe to it, so I could shut off the exhaust steam and turn on the live steam, raising the temperature of the oil to 140 degrees. I did this to determine the proper temperature and get the best results. Can *B* was made as shown by putting a perforated plate in the top, the full diameter, which rested on lugs made fast to the sides of the can. The bottom side of this plate was covered with two thicknesses of cheesecloth. Lower are two perforated plates, the space between them being filled with excelsior, and still lower is a similar section, the space being filled with pine chips.

The can *F* was partly filled with water before putting oil in it. I found I got the best results by passing the oil through the pipe *G* and up through all the different parts of the filter.

The operation of the filter is as follows: The oil descends from the engine bearings through the pipe, passing down to within 8 inches of the bottom of the can *A*, rising up around the heated coil to the end of the pipe *H*, and flowing down to the base of can *B*, up through the water, pine chips, excelsior and cheesecloth and out through the overflow to the can *F*. It then passes down through cheesecloth at *J* and is pumped back to the elevated tank. This did the trick with a temperature of 90 degrees Fahrenheit.

Blow-down pipes are placed in the bottom of each can, and all the dirt that collects can be blown off. The pine chips are renewed once a week and the steam hose played on them to cleanse of dirt, etc.

HOMEMADE OIL SEPARATOR

Hygrometry

On page 63 of the January 5 number, W. V. Treeby attempts to criticize a statement made by J. H. Hart in an article on "Hygrometry," which appeared in a recent issue. It would appear that Mr. Treeby has an entirely wrong idea as to the meaning of the word saturated as applied to steam. If he will brush the cobwebs off of his physics and consult some handbook on steam, he will find that saturated water vapor or steam does not mean that the vapor or steam is "saturated with heat units."

When steam and water are present in the same vessel, and there is no tendency for the water to change into steam, or the steam into water, except as heat is added or taken away, the water and steam are then said to be in thermal equilibrium. When steam is thus in equilibrium in contact with water, it is said to be saturated. When there is no moisture of water in the liquid condition suspended in or mixed with the vapor, but it is still in the saturated condition as determined by its pressure, temperature and volume, it is called dry and saturated. When there is moisture or water suspended in or mixed with the vapor, the steam is said to be "moist" or "wet." In such cases the steam or vapor part of the mixture must itself be in the saturated condition as defined above, so that wet steam is simply a mixture of saturated water vapor and liquid water.

John French.

Brooklyn, N. Y.

Boiler Setting

The boiler setting illustrated on page 71 of the January 5 number has so many bad features, without any good ones that I have been able to see, that I doubt very much if any set of conditions would warrant its use.

If such a setting could be maintained in good order, which is obviously impossible, we are still confronted with the fact that the soot-blower door is between the fire and the boiler, and cold air would leak through the cracks around the soot doors and mix with the furnace gases before they pass into the boiler tubes.

Aside from this, the soot door produces a source of air leakage in the brickwork and removes a section of brickwork right where a refractory material is most needed for the purpose of raising the temperature of the gases to the igniting point before passing into the tubes. Add to this the loss due to radiation through the thin cast-iron soot door, and it is very easy to account for the loss of a very respectable part of the fuel at this one point.

Turning to the dividing wall midway of the boiler, in practice it would be found impossible to maintain a tight joint between the top of this wall and the shell of the boiler so that instead of the gases following the path that the designer expected, some would "short-circuit" over the top of the wall directly to the chimney without having passed through the boiler at all.

The worst feature of this setting is the absence of a roomy space between the fire and the boiler, where the gases, when distilled from fresh fuel, will have a chance not only to expand and mix with the oxygen of the air coming through from the ashpit, but must flow by or through a mass of incandescent firebrick, thereby raising the temperature of the gases to the igniting point before entering the tubes.

If we are dealing with a working gage pressure of [illegible] lb., [illegible] possible the temperature of the water in the boiler will be [illegible] degrees Fahrenheit, while with the ordinary setting the brick furnace and combustion-chamber lining can be kept at [illegible] degrees Fahrenheit to promote combustion. [illegible]

This setting provides a "water space" at the [illegible] but the furnace gases must pass through the comparatively cold boiler tubes before reaching it, which necessarily lowers the temperature to such an extent that any unburnt portion of the gases must be lost.

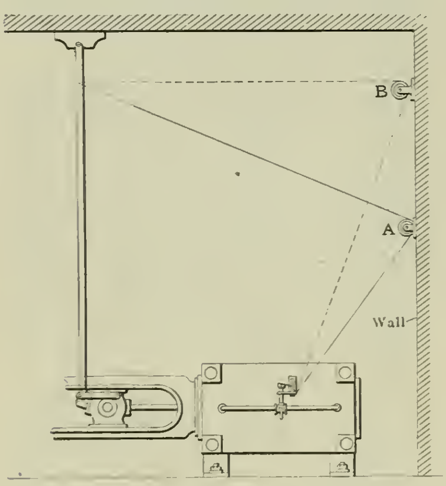
Faulty Indicator Reducing Motion

When I was the master mechanic of a certain company in a small town, the manager and chief engineer of the town lighting plant brought several indicator cards to my office and asked me if I could see anything wrong with them. After studying them, I told him that they were very good, and, in fact, I would consider the valve adjustment all right. The cards were taken from a small Corliss engine that they had just installed to drive an alternator. The engine was second-hand, but seemed all right except that the belt flopped badly. The next day I went to the plant and immediately discovered the



REDUCING-MOTION RIG

engineer's error. He had made a reducing motion out of a piece of 1x4-inch pine stick, pivoted to a block fastened to the ceiling, the other end linked to a pin screwed into the crosshead.

The pendulum hung vertically when the crosshead was in the center of its travel. The link was so connected to the pin in the lower end of the pendulum that it swung an equal distance above and below the center line of travel of the pin in the crosshead. In locating his carrying pulley he had placed it as high as he could reach by standing on the cylinder, which brought it to about the position as shown at *A*, in the illustration, which caused a very misleading diagram to be produced.

We raised the carrying pulley to the position shown at *B*, so that the cord (see dotted line) would lead from the pendulum at a right angle when the pendulum was in the center of its travel. When the valves had been readjusted the belt ran without flopping.

Denver, Colo.

Steam Condensing Plant

G. A. Orrok, in his letter in the December 22 number, on surface condensers, mentions that careful experimenters are reported to have obtained rates of condensation in steam surface condensers as high as 40 or 50 pounds per square foot. It may be interesting to readers to know that in the experiments at the Hartlepool engine works on a small contraflo condenser, designed for use as a winch condenser on board ship, I obtained rates of condensation up to 80 pounds per square foot, and have no reason to believe that I reached the limiting rate of condensation. This condenser had 100 square feet of cooling surface, and the steam was condensed at atmospheric pressure, the air blowing off through a relief valve and no air pump employed. In the tests in which 80 pounds of steam were condensed per square foot of surface, the circulating water entered at 39 degrees Fahrenheit and made its exit at 195 degrees Fahrenheit. The tubes were 5/8 inch external diameter and the velocity of the water through them was 4.6 feet per second.

I believe that with a higher velocity of water a greater rate of steam condensation could have been obtained. It should be noted, however, that the steam was at atmospheric pressure. Steam under a high vacuum is much less dense and, therefore, in a much less favorable condition for a high condensation rate.

With reference to the statement that the heat transmission in surface condensers is proportional to the cube root of the velocity of the circulating water through the tubes, I believe that the heat transmission varies sometimes as the cube root, sometimes as the square root, and sometimes almost directly as the velocity of the water. In fact, the law connecting the transmission of heat with the velocity of the water is of a somewhat complicated nature, but the subject is too big to enter upon on the present occasion.

In Charles L. Hubbard's article on condensers, in the same number, he refers to the relative quantities of condensing water required by a parallel-flow jet condenser, such as that illustrated in his Fig. 5 (reproduced here) and by a surface condenser, and states that the water required by the former is less than that required by the latter. I think that this statement is somewhat misleading.

Assume that the vacuum is 27 inches of mercury (with barometer at 30 inches) and that the condensing water is received at 65 degrees Fahrenheit. The temperature of saturated steam at 27 inches vacuum is 115 degrees Fahrenheit, but as air is always (under practical working conditions) present in the steam the discharge temperature of condensing water and water of condensation in a condenser such as that shown in his Fig. 5 must be considerably below 115 degrees—say 105 degrees. The latent heat of steam at 27 inches of vacuum is 1034 B.t.u., so that the heat withdrawn from the steam is 1044 B.t.u.

Let

W = Pounds of steam per hour,

Q = Pounds of condensing water per hour,

t = Temperature of discharge of condensed steam and condensing water.

Then, as the heat gained by the water must equal the heat lost by the steam,

$$Q \times (105 - 65) = 1044\, W$$

and therefore

$$Q = \frac{1044\, W}{105 - 65} = 26$$

pounds of condensing water.

Surface condensers are variously constructed and worked, and the results obtained with them vary accordingly. The best results as regards consumption of

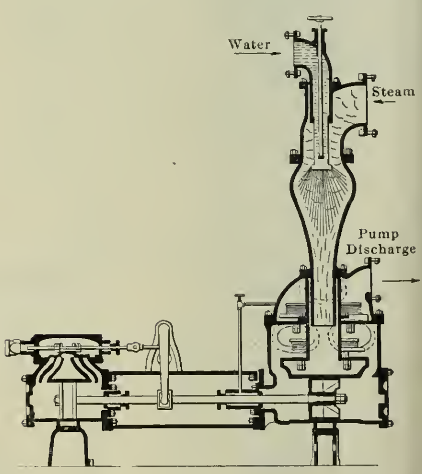

FIG. 5. A COMMON FORM OF JET CONDENSER (REPRODUCED)

condensing water are obtained with surface condensers of the countercurrent type, that is, in condensers in which the general direction of flow of the circulating water is opposite to that of the steam. The exit temperature of the circulating water in such condensers may be anything between its inlet temperature and the inlet temperature of the steam, depending on the design of the condenser and the quantity of water employed.

Professor Weighton in tests on an experimental contraflo condenser at Armstrong College, Newcastle-on-Tyne, England, obtained exit-circulating water temperatures practically the same as the inlet temperatures of the steam and, in fact slightly in excess of the temperatures corresponding to the vacuum maintained It is all a question of design and proportions.

Hence with a 27-inch vacuum and circulating water at 65 degrees Fahrenheit i would be quite possible (although it migh not pay in practice) to have an exit-circulating water temperature of 112 degrees Fahrenheit.

The heat withdrawn from the steam would then be 1037, and we would have

$$Q = \frac{1037\ 11}{112 - 65} = 22$$

pounds of condensing water, considerably less water therefore being required than in the case of the jet condenser.

As aforesaid, a design of surface condenser to give this result might not pay; but, in steam-turbine installations, where the temperature of the circulating water is in the neighborhood of 80 to 85 degrees Fahrenheit, as is common when cooling towers are employed, it usually pays to arrange the surface condensers to use less water than would be possible with a jet condenser of the nature of that shown in Fig. 5 of Mr. Hubbard's article.

Mr. Hubbard referred to cooling towers and mentioned that with the best forms it was claimed that the water could be reduced in temperature 40 or 50 degrees. With the wooden natural-draft towers, which may be said to represent standard practice in turbine power stations in Great Britain, the water is usually cooled to about 80 to 85 degrees Fahrenheit, the inlet temperature of the water to the tower affecting its exit temperature to a comparatively small degree.

R. M. Neilson.

Glasgow, Scotland.

Valve Problem

The answers to the valve problem on page 59 of the January 5 number, are interesting but very conflicting. For instance, G. A. Glick and B. A. Snow both claim that 358 pounds per square inch would be necessary to raise the valve against 100 pounds pressure per square inch on top, whereas J. C. Hawkins says that 100.9 pounds pressure per square inch will be sufficient. I agree with him, as under practical working conditions it is only necessary to consider the area that actually covers the openings, and not the total area of the valve disk.

I know of large pumping engines having valves similar to the one I illustrated on page 970 of the December 8, 1908, number, only much larger, and I should judge that the actual valve passages were not more than half the area of the valve disk, yet I am certain that the pressures in the pumps were never more than a few pounds above that in the lines, whereas according to Mr. Snow and Mr. Glick they ought to be about double.

Under practical conditions I do not believe that any valve seats so closely as actually to touch surface to surface all over, which it would have to in order to fulfil the conditions assumed by Messrs. Glick and Snow. The surfaces only touch in a few places, the remainder being separated by a film of liquid or gas—whichever may be used—in this: that the adhesion and surface friction is enough to resist the actual flow, but as the difference in pressure on each side of the valve becomes less and less, the elasticity of the material where the surfaces actually touch is compressed, thus slightly increasing the thickness of the film and allowing the pressure of the liquid, or gas, to be transmitted over a greater area until, as the pressures become equal, and the under side of the valve is receiving the full pressure, a slight increase will lift the valve. I believe it is possible to surface a valve and its seat so accurately that the pressures will have to be proportional to the top and bottom areas before the valve will start.

George P. Pearce.

Exeter, N. H.

A Homemade Condenser

In the December 29 number, M. D. Caspar asks for advice for making a condenser for the returns from an exhaust steam heating system.

The only device that he needs, as far as I can see, is an ordinary low-pressure pump connected direct to the return main and large enough to handle the volume of water that may accumulate. This pump may discharge into a heater or hotwell, etc., as conditions warrant. A pump will handle the water as it collects, provided the pump is placed at a lower level than the system, so that the water will flow to it by gravity.

Charles A. [illegible]

[illegible], Penn.

Coal Consumption

I was much interested in the article on coal consumption per kilowatt-hour by Mr. [illegible], in the December 29 number, on page [illegible], in which he notes the difference between two plants, one containing engines fitted with a long-range cutoff and the other with engines having only one eccentric. His figure of [illegible] pounds per kilowatt-hour is the lowest I have ever heard of. I fail to see where the type of valve gear would make the difference noted. The only advantage I see in the long-range cutoff is the ability to handle sudden overloads. If the engines were running at their most economical load, which they must be doing to make a kilowatt-hour on the given quantity of coal, the single-eccentric engine would cut off just the same as the double-eccentric engine, and the only difference indicator diagrams might show would be in the compression curves, and they would probably be the same. I am inclined to believe the difference in the coal consumption can be traced back to some other feature of the plant.

[illegible] H. Lane.

Kansas City, Mo.

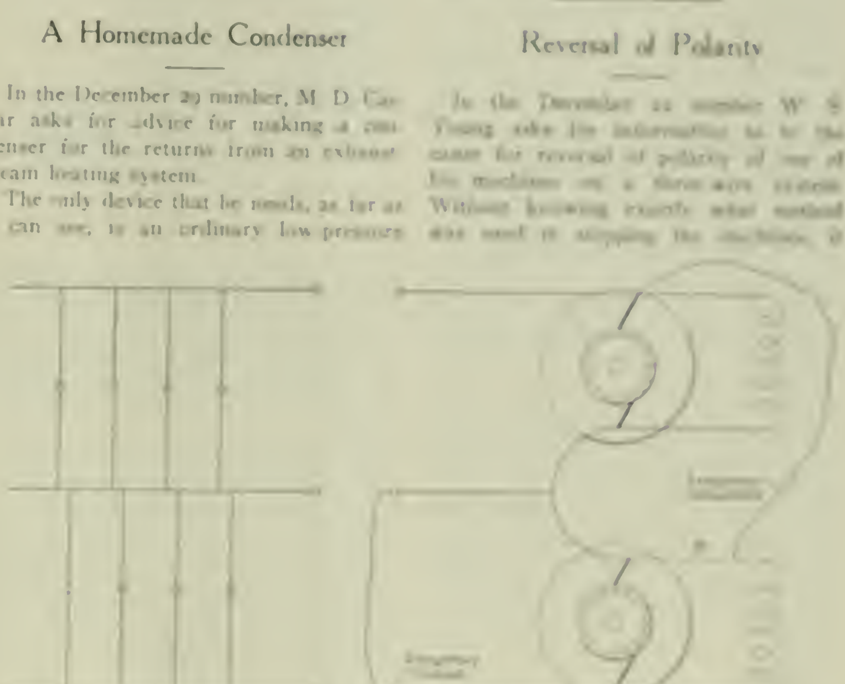
Reversal of Polarity

In the December 22 number W. S. Young asks for information as to the cause for reversal of polarity of one of his machines on a three-wire system. Without knowing exactly what method was used in stopping the machines, it would be hard to tell the real cause. If there were any motors on that side of the system, it might possibly have been caused by a "back kick" of one of them at the time of shutting down.

I once had charge of a three-wire system using the same type of machines, one of which frequently became reversed without any apparent cause.

A method of righting a reversed machine on a three-wire system, requiring only a few minutes' time and no change of connections, except temporarily changing one field wire, is shown in the accompanying diagram.

To operate, raise the brushes from the commutator of the reversed machine, disconnect the shunt field wire from the negative side and connect it temporarily to the positive brush of the other machine. Make a "jumper" across the brush leads of the reversed machine [illegible]



METHOD OF RIGHTING A REVERSED MACHINE ON A THREE-WIRE SYSTEM shown, and brings the voltage up on the other machine. Then shut down and remove the "jumper" connection and the temporary field connection, leaving it connected to the neutral winding in the usual way, as shown by the dotted lines at *P*. Then put down the brushes and the polarity will be correct. Either machine can be righted in the same way, but always be careful to have the brushes raised, and to remove the jumper before starting up the machine which has been reversed.

S. KIRLIN.

Dallas, Tex.

An Air-cooled Condensing Plant

In the twelve years that I have read POWER there have been many valuable articles in its columns, treating on condensing plants, their installation, cost of operation, maintenance, etc., but I have failed to read of any that cost practically nothing to install and nothing to operate.

Some years ago in the oilfields of western Pennsylvania all wells were pumped by steam power, gas engines not being in general use at that time. In one particular locality the only water-pumping station was abandoned about this time as a nonpaying investment. As well water was unfit for boiler use, the use of the surface condenser and rainwater were the only means of obtaining the necessary water for operation.

The condenser was made of old 6-inch pipe that had outlived its usefulness in the oil wells. It was laid out on the ground in such a way that the water of condensation would drain back to a barrel sunk in the ground under the pump which was attached to the crosshead of the engine. The amount of pipe required depended on the size of engine and the load it was carrying. Usually 600 to 800 feet were sufficient for each 20-horsepower engine.

The exhaust steam of the engines was expelled into this pipe, where it would be condensed and returned to the pump; in some instances the loss was so small that from six to ten barrels of makeup water was sufficient for 40 horsepower of engines each twenty-four hours. The makeup water was supplied from storage tanks in which was caught rainwater from the roofs.

It might be said that plants were operated twenty-four hours a day, except Sundays, by one man who worked on the lease in daytime and went to his home at night. The boiler was equipped with a gas- and steam-pressure regulator, combined with a low-water alarm which blew a large whistle, calling the pumper from his slumbers in case the water got low in the boiler. There were several plants operated in this manner for a number of years without any serious accidents and no one looked upon it as remarkable.

J. A. MAWHINNEY.

Franklin, Penn.

Testing Watt-hour Meters

In the issue of January 5 I note an article by O. F. Dubruiel on "Testing and Adjusting Watt-hour Meters." A power station not already equipped with stop watches, voltmeters and indicating wattmeters would do much better to buy a portable standard integrating watt-hour meter, otherwise known as a rotating

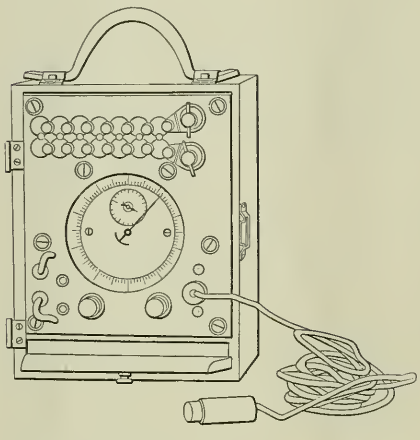


FIG. 1

standard, for from $60 to $65. These are now made by all the large companies and are very much simpler and easier to use. No voltmeter or stop watch is required, as any variation of voltage or load affecting one meter affects the other in the same way.

The meter has the appearance shown in Fig. 1, and can be changed from 110 to 220 volts by simply changing the small leads shown at the lower left-hand corner of the faceplate. The meter is stopped and started by means of a push switch at the end of the cord and the dial registers the number of revolutions of the standard meter; by counting the number of revolutions of the meter under test, clos-

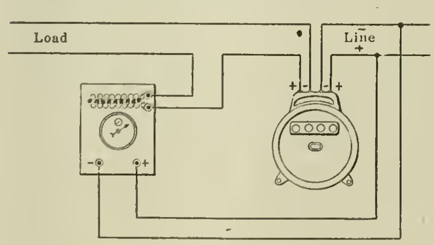

FIG. 2

ing the switch on starting and opening it on stopping, a direct comparison is obtained and the percentage of error may be easily calculated. One man can easily test several meters a day. Better still, it is quite practical with this instrument to test a meter on the customer's premises.

The connections are very simple, as shown by Fig. 2, and a table accompanies each meter giving percentages from 6 per cent. slow to 6 per cent. fast for all standard makes of watt-hour meter. The instrument is adjusted for different current capacities by means of the plugs at the top of the face plate.

JOSEPH B. CRANE.

Broadalbin, N. Y.

Engine Foundations

There can be no hard-and-fast rule for building foundations of any character, especially for engine work. In best practice it is found that foundations for this class of work should be governed by the weight of the machinery placed on them. A safe construction for a foundation is to know the weight of the machinery, and build the foundation one-half heavier than the engine, i.e., if the engine weighs 150,000 pounds the foundation should weigh 225,000 pounds. This applies to small installations, as well as to large and heavy work.

Every heavy foundation should have a base which separates it from the foundation proper. It is better to have a foundation which will have some "give and come" to the action of the engine. The slight movement if taken up on an earth or sand bottom, would in time wear it away, especially where water soaks in alongside, and the settling is liable to make the engine work out of line.

Where concrete floors are used in engine rooms there should be a space of about 1/8 inch between the floor and foundation to permit the vibration of the foundation and not to impart the jar to the floor.

The writer recalls where the floor for an engine was waterproofed at great expense, the earth being of salt-marsh formation, where test piles with a 1500-pound hammer "keep going" after 85 feet of driving. Thirty-foot piles were driven under the engine and the waterproofing placed on the top. When the erecting engineer came to install his work he found only 18 inches between the floor line and top of the waterproofing. The drawings called for a foundation 3 feet 6 inches in hight, or extending 24 inches above the floor line. The "young man" followed his instructions and the top of the engine bed was placed 36 inches above the floor level.

This engine has been in use about 1[illegible] years and is satisfactory in every way except the hight of the engine bed above the floor. Since then there have been two engines of fully as large capacity placed in the same room, with the foundation spreading 14 inches outside of the engine bed in every direction, and only 12 inches above the floor line. These engines have also proved satisfactory.

Somerville, Mass.

Some Useful Lessons in Limewater

A Simple Method of Remembering What Has Been Told in Previous Lessons; Softening Temporary-hardness Water; Some Chemical Shorthand

BY CHARLES S. PALMER

The only sensible way for common workaday folk to learn the value of a thing is to use it; and so we will try to put this limewater to work at once. We have found out that the plain lime carbonate is insoluble, and that is what makes most of the soft scale from temporary-hardness water. Then what we want to aim at is to get this plain lime carbonate out of the water before it goes into the boiler. Now you have found out that you can go to the plain carbonate of lime in two ways. One is by starting with limewater, and adding carbonic acid (from the breath, from the gases of burning coal, from bottled "fizz," or from acid and marble or soda); the other way is by taking out the extra carbonic acid from the extra, or double, or bicarbonate of lime (temporary-hardness water) by heating it, when the extra carbonic acid goes off, and down comes the plain carbonate of lime.

You must get these two ways fixed in mind; and one good thing to do is for you to stop right here and set down this simple formula. Don't be satisfied with merely looking at this once, but write it for yourself several times, until it is stamped into your memory so that you can see it in your mind's eye any time. Here it is:

Limewater *Soluble*	<——>	*Plain Lime Carbonate* *Insoluble*	<——>	*Extra Carbonate of Lime* *Soluble*

The double-headed arrows mean that you can go from one substance to another; and if you stop to think of what you have done, you will see that this is a kind of shorthand reminder of it all. You did go from limewater to plain carbonate, by adding some carbonic acid; and you passed from this to the extra carbonate of lime, by adding more carbonic acid; then you came back from the extra carbonate of lime to the plain carbonate by taking out this extra carbonic acid. And this last step is what that heater is for. So you see how handy this formula is.

The double arrows tell, even, much more than can be told here. Thus briefly, the plain carbonate of lime, or limestone, is first changed into lime by burning in limekilns; and you can imitate that by burning some marble in the front part of your furnace. About all the other steps indicated by the arrows have been shown in the various tests that you have made or are making.

Now you begin to get the fundamental chemical notion that "salts," such as plain carbonate of lime and extra carbonate of lime, are made up of acids and bases. In this case, the lime is a base. There are strong acids and there are weak acids, and, also, there are strong bases and there are weak bases. When a base is soluble in water, it will turn litmus blue, and such water-soluble bases are called alkalies; and so it comes that limewater is an alkaline base. Some bases, like iron rust, are good bases, and can neutralize acids, forming "salts," but iron rust is not very soluble in water, and so it is not alkaline like the soap, the ammonia water and the soda. (This "soda," by the way, is really a "salt" made up of carbonic acid and the metal sodium, but the sodium is so much more active as a base than the carbonic acid is active as an acid that the soda, as a whole, acts like an alkali. But we will study that more carefully later.) Now you begin to get this fundamental notion of the base part and the acid part of every "salt." You begin to see that you can get, by mixing the base and the acid in various quantities, "salts" which may be even in base and acid, i.e., plain salts, or "salts" with more of the acid, as in the case of the extra carbonate of lime, and, in other cases, even "basic salts" with more of the base than acid in them. But this is the point that we are aiming at. You have one way to soften temporary-hardness water by driving off the extra carbonic acid with heat. The formula reminds you of that step; but why not work the same scheme in another way? Why not get some handy base to mix with this soluble extra carbonate of lime, and bring it back to the plain carbonate? That is another way to soften temporary-hardness water.

Softening Temporary-hardness Water

It has perhaps occurred to you that if the lime in water is a base, and if the soluble lime salt, lime bicarbonate, is an extra carbonate, why not mix some of the limewater with this extra carbonate and get the insoluble simple carbonate? So we make some more of the artificial temporary-hardness water by blowing through the plain limewater until the white cloudiness that first comes is redissolved, and, as before, we filter it to get as clear a solution as possible. Now we mix the two, the plain limewater and the solution of extra or bicarbonate of lime which you have just made. You have learned that as the limewater had some base, and as the bicarbonate of lime has extra acid, you ought to get the neutral white sediment down; and that is just what happens.

Down it comes, or, rather, it comes out of solution, but it doesn't settle with any surprising quickness. However, you have got it out of solution, and that is something to be thankful for. If you give it time to settle, plain limewater would take the lime sediment out of temporary-hardness water just as well as heating it would, because both methods change the extra or bicarbonate of lime to the neutral or insoluble carbonate. But in the solution you have used you worked with water of the same strength, or having the same relative amounts of lime and bicarbonate, while the water that you would run across in practice will run all the way from only a little carbonate-of-lime hardness to nearly as much as equal volumes of limewater solution and extra-carbonate solution will throw down. You ought to stop and study this process—by the way, the books call this Clark's process for softening temporary-hardness water—and you will see that it amounts to getting the sediment of plain carbonate of lime by mixing the base, lime, with the extra-acid salt of lime. Indeed, you can get a kind of simple chemical equation by the following formula:

Limewater *Soluble*	+	*Extra Carbonate of Lime Soluble*	=	*Plain Carbonate* *Insoluble*

The books write this same process in the form of some curious letters and figures, and pretty soon we will begin to get acquainted with some of these things, for they are only so many helps to thinking and doing. One thing that you want to remember is this: That, within all reasonable limits, you can do anything down in the dusty boiler room that anyone can do in the best laboratory in the world. This is so, since Mother Nature is right at your elbow keeping the action of those chemicals as carefully as though she had a member of the Royal Chemical Society, and whatever she happens to [illegible] laboratory in Paris, Berlin, London, or New York she [illegible] to your boiler room. The laws of chemical action follow [illegible] everywhere. You know this because you learned the laws of mechanics [illegible] boiler rooms [illegible] skyrocket up into the air, follow it in its glorious explosion, and follow each of the glittering sparks as they float down through the air. So no one has any monopoly on chemical action, nor on brains, either.

But to get back to Clark's process of softening temporary-hardness water. You can see that it would be no end of bother to make even a barrel of filtered limewater; and a useless bother, if we could put quite a large quantity of lime in a small bulk of water and make it do its work with the large volumes of water which have to go into the boiler. If you go back to the lime from that barrel, you will remember that it takes several hundred parts of water to dissolve one part of lime as you filtered it clear. But you will note that when you put several lumps of lime into water, it crumbles and can be stirred up to a milk, a thin, porridge-like liquid. This is called "milk of lime," and it is a mixture or "emulsion" of lime in limewater. You can see that very little of this milk of lime will do the work of a whole lot of filtered limewater, in the neutralizing of the extra carbonate of lime, and bringing it back to the insoluble plain carbonate of lime. Thus, you see that you could use this way to soften temporary-hardness water.

But it is best to know how much of the milk of lime to use with any special water, and with the same water at different times of the year, and you can learn all of this by keeping along with these lessons. You will find that the man who learns to figure the problems that he runs up against as a rule comes out ahead in the great game of life; while the man who dodges figures, whether in the office or in the boiler room, is simply letting somebody else do his rightful work and get his rightful pay. So we will gradually get at some of these figures, and the ways of calculating the milk of lime needed to soften any grade of water.

Some Chemical Shorthand

And, now, toward the end of this shift, just a word about some chemical shorthand that you will find very handy, if you don't try to choke yourself with too big a mouthful at the start. Just take it by bits. You know how to read and write; and you would be ashamed not to; and in the same way, you want to know how to read and write chemistry; not all that can be written—and much of that does not concern you at all—only the common elements. Now what is your name? Smith? Well, S is your initial, isn't it, and don't you use it for short? Good, then S stands for Smith, the unit man who walks under your hat. So in the same way, C stands for carbon, the unit chemical that is in coal; O stands for oxygen, the unit thing in the air that helps your coal to burn; Ca stands for the metal calcium that is at the bottom of your friend, lime; and H stands for hydrogen, which is found in water, in wood, in soft coal, and many other things. Thus far we have studied limewater, with a glance at carbonic acid; but there is the burning of the coal that must come as soon as we have got well along with this question of water supply, and you will find it very handy to use some few of these initials of the chemical units or elements. For you will not only want to use this chemical shorthand in a simple way in these boiler-room studies, but you will outgrow this simple material one of these days; you will get gloriously mad with yourself, and go to reading better and bigger books, and you will find that all of them use this chemical shorthand, so we may just as well begin to get acquainted with it right here and now.

Then C stands for carbon; Ca for calcium, the metal at the back of what you call lime in general, with all of its compounds; O stands for oxygen, the thing in the air that helps burning; and H stands for hydrogen, a metallic gas—that is straight—a metallic gas, and yet cousin to carbon and coal in the way it burns. There is a lot of hydrogen burning under your boiler, and there is hydrogen in all water, and, of course, in all water compounds. We will not hurry, for it takes time to get things in the head so they will be right and stay there. But, if you are patient with yourself, you will learn these and many more, so you can handle them easily and surely. But the only way really to learn about a thing is to use it, from the start. Let us use these shorthand symbols for the elements that we have run across in this limewater lesson.

Now, lime is the rust or oxide of a metal, and we tell that long story in this short formula, CaO. That is lime, the stuff in the barrel that you are sitting on. The formula says that lime is made up of calcium and oxygen, and every time that you see or use this formula, you are reminded that lime, common quicklime, is made up of calcium and oxygen. You don't have to remember it; it remembers itself, and reminds you all about its own makeup. So, then, lime is an oxide of the metal calcium; and yet we never lose any flesh worrying over calcium itself. Not that calcium may not have a whole lot of most interesting information of its own. Thus, if you should get some of the metal (and it is a trick to get it), you would see a white metal—very light weight for a metal, about twice as heavy as water, while common iron is nearly eight times as heavy as water, copper nearly nine, and lead more than eleven times as heavy as water.

This metal, calcium, cannot be kept lying around in any old way, as the common metals can; for, if left in the air, it rusts itself away and changes to lime, and you know that lime cannot be kept long, for it takes on water and other things from the air and gets "air-slacked." This metal calcium melts at a higher temperature than lead, but it can be cut, drawn and rolled; in short, it has the "metallic" action in general. But this metal never shows its head in the metallic form, unless one gets after it with special plans and methods; and all that does not bother us a bit, because it is not the metal as metal that we are concerned with, but some few of its compounds that have had the nerve to make your water hard in several facetious ways. It is the compounds of this metal, calcium, which we are studying: Lime, the oxide, CaO; the simple carbonate, $CaCO_3$; the bicarbonate, $Ca(HCO_3)_2$; and the like, that we want to get at, for we have only begun to open up the mystery of that barrel of lime.

But to sum up what we have touched on thus far, there are two ways of softening temporary-hardness water: One is by driving off the extra carbonic acid by warming, as in your heater, and the other by driving down the extra carbonic acid by an extra base as lime; and in both cases we get the plain carbonate of lime thrown down. Of course, we must have the right tank for the water to settle out clear, in either case; but we have laid the fundamentals, and now it is up to you to study what kind of heater or settling tanks you are using, and whether they are suited to your work in design, in material, in size, in the piping and connections, and the like. But you should try this second way of softening temporary-hardness water, by adding a few drops of the limewater emulsion, milk of lime, to some of the temporary-hardness water, say a teaspoonful of the milk of lime to a pint of the hard water, with quick stirring, and then allow time to settle. Each part of this simple experiment will tell you something that will relate to the action of the water softener that you may have in the boiler room. Thus it may take some time for the plain carbonate to settle out, and that may suggest why your settler may not always work as it should.

Some Simple Tests

There is one other thing that you will want to do before you close this shift; that is the way to tell, by a simple test or two, whether you may have temporary-hardness or permanent-hardness water. When you add some of the milk of lime to the water, with good stirring, and then add a teaspoonful of nitric acid, if the whole solution clears up, you have only temporary-hardness water. But if you take some of the solution of barium chloride (or nitrate), and add a few drops to a sample of water, you may get a white cloudiness; now add a teaspoonful of hydrochloric acid or of nitric acid to this, with shaking or stirring, and if it clears up, the water is of the temporary-hardness, or carbonate kind; but if the cloudiness of the water persists after adding the nitric acid or the hydrochloric acid, you have some permanent-hardness water, of the sulphate kind, and that is harder to deal with. But even in that case, it will pay you to know what the trouble is, for sometimes you can conquer it, and at reasonable cost.

The idea that you want to carry with you is this: Temporary-hardness waters have to do mainly with carbonates of lime, while permanent-hardness waters have to do with sulphate of lime. Sulphate of lime is a compound of lime with sulphuric acid, the heavy oil of vitriol that you have seen about shops for cutting the scale off of forgings. There is one thing, too, that you want to remember about this sulphuric acid: It has a great liking for water; therefore, when you dilute the acid, always *pour the acid into the water* (never the water into the acid). The solution of sulphuric acid that came with your outfit is probably already diluted with water, that is part of the chemical story of water, which runs right along with the story of lime.

Screens for Pump Suctions

By Alonzo G. Collins.

In designing the arrangements for a supply of condensing water for the steam engines of an electric-light station some years ago, it was considered advisable to place the fine screen for intercepting the smaller trash in the water, near the station, where it would be more convenient for cleaning, and a coarse rack over the end of the suction pipe in the river to intercept the larger débris.

In addition to such things as logs, cordwood and branches of trees, this river water carried a large amount of semifibrous material, such as grass and small thread-like roots, for which a rather fine screen was required, and the screen must be arranged so as to be readily cleaned of the accumulation without interrupting the water supply.

This was accomplished by duplicating a short section of the suction pipe, just before it entered the building, with a cylindrical screen chamber in each branch and a gate valve each side of the screen chamber, the two branches being connected to the single pipe at each end, as shown in Fig. 1. Fig. 2 is a section through one screen chamber and an elevation of the other. The covers of the screen chambers were fastened by hinged bolts, which could swing through slots in the flanges, and with monkey-tailed nuts so as to avoid the use of wrenches.

The waste-water pipe from the condensers was laid in the same trench, but above the suction pipe, as shown in Fig. 2, and a 2-inch pipe led from the bottom of the waste pipe to each screen chamber, for filling the screen chambers after the screens had been cleaned and replaced.

In regular operation both valves were open in one branch and closed in the other. When the screen in use needed cleaning, which was about every six hours, the two valves on that side were closed and those on the other branch opened, thus diverting the water through a clean screen. The cover of the dirty screen was then removed, the screen frame, which set in grooves in the side of the chamber, was hoisted out, cleaned and replaced, the cover bolted on, the chamber filled with water through the 2-inch pipe from the waste pipe, an air cock in the cover allowing the air to escape.

This device worked so nicely that it

FIG. 1. PIPING CONNECTIONS OF SCREENS

was impossible to tell by observation of the pumps when the change of screens was being made. The vacuum gage would show it, as the clogged screen would cause an increase in the vacuum necessary to raise the water, which increase was not allowed to exceed 2 or 3 inches, and as soon as the engineer started the clean screen the vacuum would drop to its normal condition.

At the river end of the suction pipe, about 800 feet from the building, conditions were not so favorable. The river bank had been riprapped with heavy stone to prevent the bank being washed away, the slope being about 45 degrees and giving a good foundation to work on. Enough of the riprap was removed to make a trench that would cover the pipe, which was finally got into the water by

FIG. 2. STRAINERS IN POSITION

FIG. 3 [illegible]

making up a length of pipe on the bank, with a 45-degree elbow looking up stream on the lower end, and letting it slide part way down the bank with a tackle to prevent it getting away. It was anchored firmly by filling the trench around the pipe with concrete, the irregularities of the riprap making a most excellent anchorage. On the upper end of the pipe another 45-degree elbow brought it to line for the pipe to the building.

A number of old 30-foot railroad rails were procured and laid as a temporary falsework over the inclined pipe projecting out over the water, with the flanges up, and about 2 inches apart in the position shown by the dotted lines in Fig. 3. The reason for placing the flanges up was to ensure that the openings between the rails would be wider on the inside, so that anything that would enter the openings would pass on through and not be wedged fast.

Two pairs of heavy, flat cross bars were bolted across the bed of rails about 5 feet apart at the elbow end and one pair at the opposite end, with bolts between the rails to preserve the alinement. A substantial block of concrete was then built around about 5 feet of the shore end of the rails. When the concrete had hardened, a pair of shear legs was set straddling the nest of rails, with a tackle hitched to the outer end by a sling long enough so that the lower block of the tackle would be above water. Having taken the weight of the rails on the tackle, the falsework was removed and a wood fire built around the rails just where they projected from the concrete, first placing a layer of sand between the fire and the concrete to prevent injury.

As soon as the rails were red hot, the tackle was lowered and the rails bent to a neat curve, making as neat looking and as serviceable a rack as anyone could wish for.

The waste-water pipe was diverted from its position over the suction pipe before the rack was reached, and delivered the waste water downstream from the suction inlet, the velocity of the river giving ample assurance that there was no danger of the suction getting any of the warm waste water.

Burlap bags filled with concrete were then worked under the submerged portion of the suction pipe, and the triangular openings each side of the rails were closed up in the same way. The bags of concrete projected a little above the water line, and wooden forms were set up and filled with concrete to make a neatly finished job. Fig. 3 is a section of the rough screen in the river.

Catechism of Electricity

927. *Why is the word "abnormal" used in connection with the heating of direct-current motors?*

Because all motors in operation develop a certain amount of heat which cannot be prevented and which is not therefore considered a defect.

928. *Explain why a motor in perfect running order develops heat while in operation.*

Considering the motor electrically, heat is developed at the commutator and brushes and in the field and armature coils because it is impossible to force a current of electricity through a conductor without heating it.

Considering the motor mechanically, heat is developed in the bearings, commutator and brushes by reason of friction between moving parts.

Considering the motor magnetically, heat is developed in the iron portions, such as the frame and magnet cores, on account of the passage of magnetic lines of force through them.

929. *Is it an easy or difficult matter to locate the cause of abnormal heating in a direct-current motor?*

It is often difficult because both the defective and perfect parts become of practically the same temperature owing to the ease with which heat is conducted through and between them.

930. *How should such a case be treated?*

Stop the motor until it becomes perfectly cool. Then start it up and operate it under full load for about five minutes. Stop it again and carefully but quickly test each part for abnormal temperature by the sense of feeling.

931. *Give some rules to guide one in testing for temperatures by means of the hand.*

The ability to determine accurately in this manner the amount of heat developed can be acquired only by experience. If the hand can comfortably be held on the iron portion of a machine for several seconds, its temperature may be considered as being within the safe limits.

In connection with this test the condition of the hand must be taken into consideration as well as the conductivity for heat of the surface touched. Inasmuch as the back of the hand is far more sensitive than the palm, more reliable results will be obtained by testing with the back of the hand. If the surface of the iron is rough there will be more radiation than if it is smooth and, in consequence, its internal temperature may be higher than the sense of touch would lead one to suppose. Then, too, any paint on the surface of the iron also affects to a considerable extent the conductivity of the internal heat.

932. *How can more accurate results be secured than by the sense of feeling?*

By using thermometers.

933. *Give some rules for testing motor temperatures by means of thermometers.*

The bulb of the thermometer should be placed against the surface of the part whose temperature is desired and it should be protected from outside influences by a covering of cotton waste, the whole being held in position either by hand or tied by means of a string.

In connection with this test it is well to note the temperature of the surrounding air at the time the other reading or readings are taken, for the atmospheric temperature has, of course, a direct bearing upon the temperatures of the various parts of the machine.

934. *What temperatures of the different parts of a direct-current motor would be considered abnormal?*

For the field or armature, over 50 degrees Centigrade above the surrounding air temperature; for the commutator or brushes, over 55 degrees Centigrade above the surrounding air temperature; for bearings or other parts of the machine, over 40 degrees Centigrade above the surrounding air temperature.

935. *Is there any other method of obtaining temperatures of the parts of a motor?*

Yes, there is an electrical method particularly well adapted for securing the temperatures of the field and armature coils. The inaccessibility of these parts renders the hand and thermometer methods rather inadequate for the purpose. The electrical method is often used as a check on the temperatures obtained on the field and armature coils by means of thermometers.

936. *Explain how to obtain the temperatures of the field and armature coils by the electrical method.*

After the motor has been run under full-load conditions sufficiently long to insure the maximum temperatures being reached, the machine is shut down and a moderate direct-current voltage applied first between any two opposite commutator bars and then between the terminals of the field coils. In each case the amperes of current are carefully noted on an ammeter, and at the same time the drop or pressures between the points of application are also read on a voltmeter. Having, then, the current through the armature coils and through the field coils, and the respective pressures across them, their respective resistances hot may readily be calculated by dividing the latter values by the former ones.

In performing this test care must be observed that the testing voltage does not exceed the normal voltage for which the armature winding or the field winding is designed, in order that the testing current does not injure or unduly increase the temperatures of these parts; it is also necessary to note by aid of a thermometer the temperature of the surrounding air in degrees Centigrade at the time these measurements are being taken.

Having, then, at an atmospheric temperature of $T°$, the resistance in ohms which we will designate $R_{T°}$, the next step is to calculate what this resistance would be at zero degree Centigrade. Designating this unknown quantity by $R_{0°}$, the formula used is

$$R_{0°} = \frac{R_{T°}}{1 + 0.004\,T°}.$$

By substituting for the terms on the right-hand side of this equation their proper values, and dividing the numerator by the denominator, the value of $R_{0°}$ will be obtained. This value, together with that of $R_{T°}$, when substituted in the equation

$$T = \frac{R_T - R_{0°}}{R_{0°} \times 0.004}$$

will give the temperature in degrees Centigrade, at the time the measurements were taken, of the armature coils or of the field coils, depending upon whether $R_{T°}$ is the resistance hot of the one or the other.

Development of the Surface Condenser

Combination Condenser and Feed-water Heater; Condensers for Use with Steam Turbines; Countercurrent, Contraflo and Other Types

BY WARREN O. ROGERS

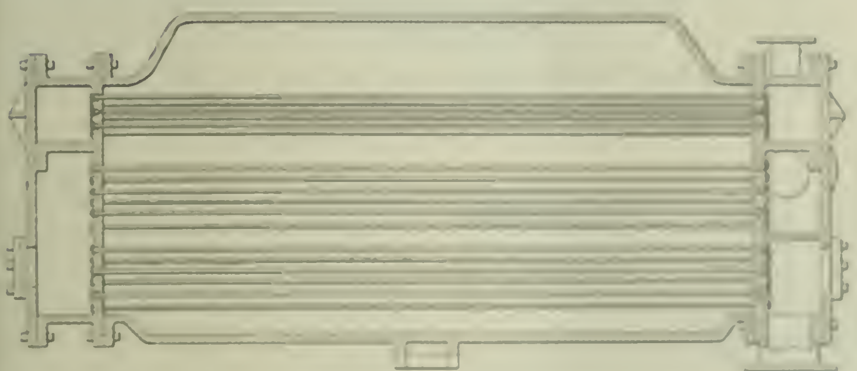

FIG. 15

As a condenser does not deliver the water of condensation to the hotwell at as high a temperature as the exhaust at the condenser, it must either be reheated in a heater or delivered to the boiler at a much lower temperature than is consistent with economy. A form of combined heater and surface condenser is obtained in the Volz surface condenser and feed-water heater, manufactured by the Wheeler Condensing and Engineering Company and illustrated in Fig. 15.

This combination condenser and feed-water heater saves considerable floor space and requires but little more head room than the ordinary type of condenser for a given size. The upper part of the shell contains a set of tubes through which the feed water passes to the boilers. The lower part of the shell contains the condensing tubes. The heater and condensing tubes are connected to their respective chambers, which are separated by a partition wall of iron, by the method adopted by the makers in their regular type of condenser. As the heater tubes are in the direct path of the incoming exhaust steam they are exposed to the hottest vapor.

A type of condenser used in connection with the steam turbine is shown in Fig. 16, and is manufactured by the Fred M. Prescott Steam Pump Company. It is made with a rectangular shell and an exhaust inlet which is especially designed to meet the requirements of the steam turbine. Fig. 17 shows a sectional view of the condenser, which contains the same features as the general run of this type of condenser. The tubes have supporting plates to prevent vibration. The air and uncondensed vapor are removed by a Prescott [illegible] vacuum pump, while the condensed water is removed by either a rotary or [illegible] pump.

In Fig. 18 is shown a type of condenser not often considered in connection with the condensation of steam. It is designed to be placed either on the roof of the building or in a tower where the air has access through the tubes. Water is then used as a condensing medium, flowing, as it does, over the tubes in a thin stream which, being caught at [illegible] the bottom in steel troughs and [illegible] small amount of fresh water [illegible] to replace the waste due to evaporation and other losses. The exhaust steam from the engine enters a header which is connected to several coils of [illegible]

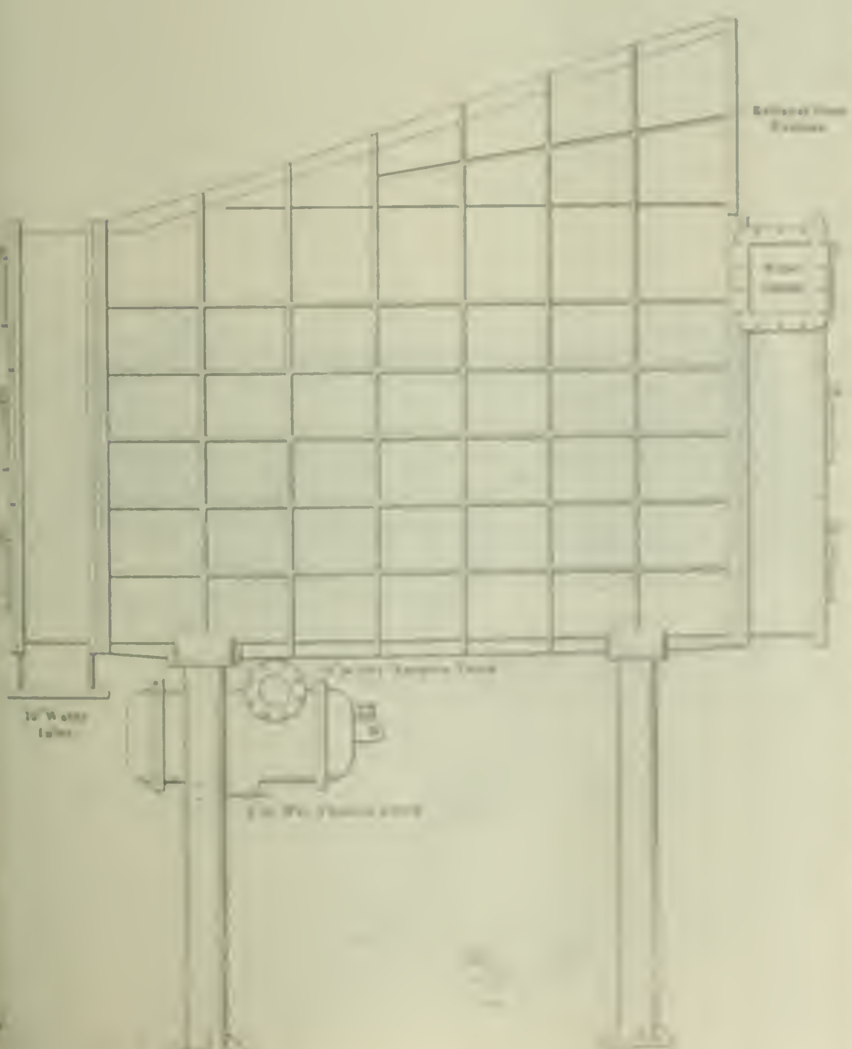

FIG. 16

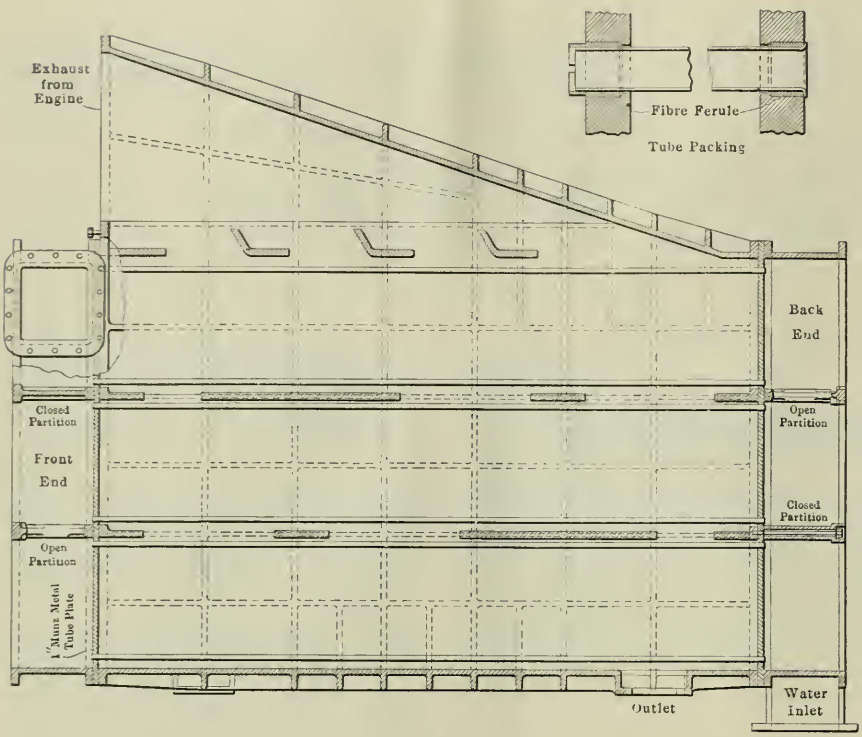

FIG. 17

densing tubes and is circulated through them from the top to the bottom. The top row of tubes in each set of coils contains steam; the next, partly condensed steam, the amount of steam decreasing, and the amount of water increasing as the lower lines of tubes are reached. The water of condensation and air are drawn from the tubes by an air pump located in the pump room, the suction being attached to a return header to which the lower tube of each coil is connected. The circulating water is delivered to a header located over the center of the condenser, with branch distributing pipes for each condensing coil. This type of condenser is manufactured by the Minneapolis Steel and Machinery Company.

In Fig. 19 is shown a countercurrent type of condenser, in which the vapor flows between the tubes, the steam line being parallel with the flow of the condensing water. The baffle plates cause the entering steam to flow in a direction parallel with the upper condensing tubes; when striking the end of the condenser body, the direction of flow is reversed; this operation being repeated as often as there are baffle plates.

Another type of countercurrent surface condenser is illustrated in Fig. 20. In this condenser, which is manufactured by the Alberger Condenser Company, the exhaust steam enters the shell of the condenser at the bottom, while the circulating water enters a water pipe at the top at one end and, after passing back and forth several times through the nest of tubes, becomes heated by the steam and leaves the condenser at the other end, at the bottom. As the exhaust steam enters the body of the chamber it rises and meets the tubes containing the hottest water first, and becomes partially condensed. It then passes up through, and around, the remaining tubes, which are cooler, and the steam is completely condensed. The air and the vapor which has not condensed collect at the top of the condenser shell, where they are dried and cooled by the cold water flowing through the upper nest of tubes before being removed by the air pump.

The water of condensation falls to the bottom of the shell and toward the entering steam. If its temperature is lower than the entering steam it acquires heat from it and, as a consequence, the water of condensation leaves the bottom of the condenser at a temperature equal to that of the entering steam. It will be seen that the distinctive features of this condenser are that the water not only circulates in a complete countercurrent, but the condensed steam and the incoming exhaust steam flow counter to each other. Owing to this arrangement of counter water and steam flow it is possible to reduce the amount of tube surface and circulating water, because the water of condensation carries off heat that under ordinary condenser conditions would have to be transmitted through the tubes to the condensing water. The air is removed from the condenser body from a point farthest from the water of condensation.

In contraflo condensers the steam flows at right angles to the condensing tubes. The latest design of this type of condenser is shown in Fig. 21 and following illustrations. It is manufactured by the Contraflo Condenser Company, Limited, London, and is represented in the United States and Canada by the Elwold Company, North American building, Philadelphia, Penn. The advantages claimed for this type of condenser are minimum cooling surface and circulating water, a high vacuum and high thermal efficiency.

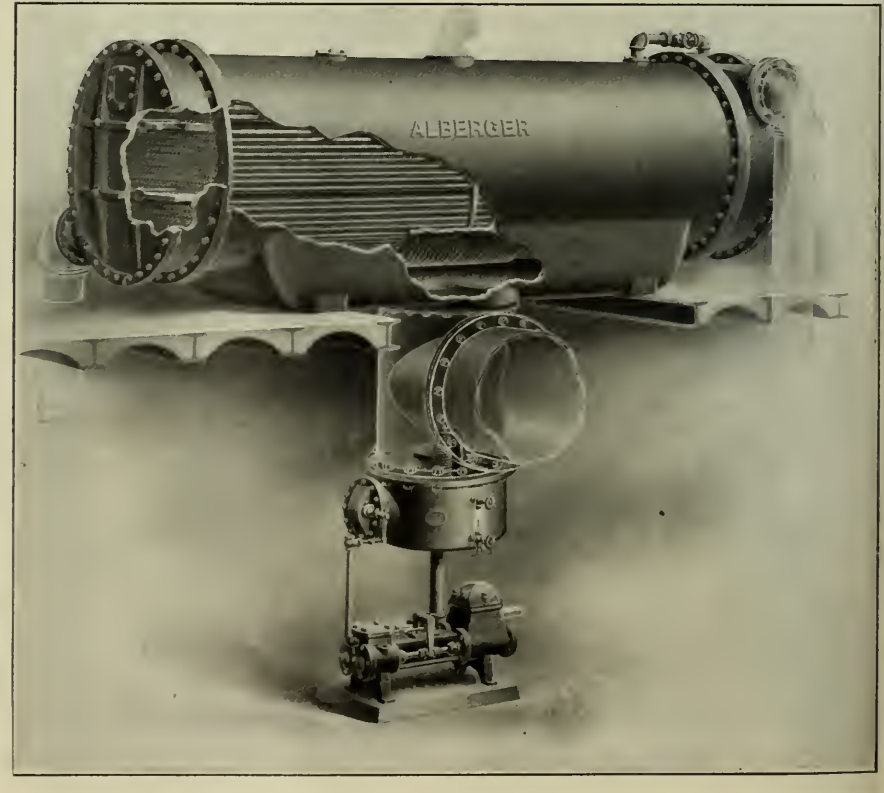

FIG. 20

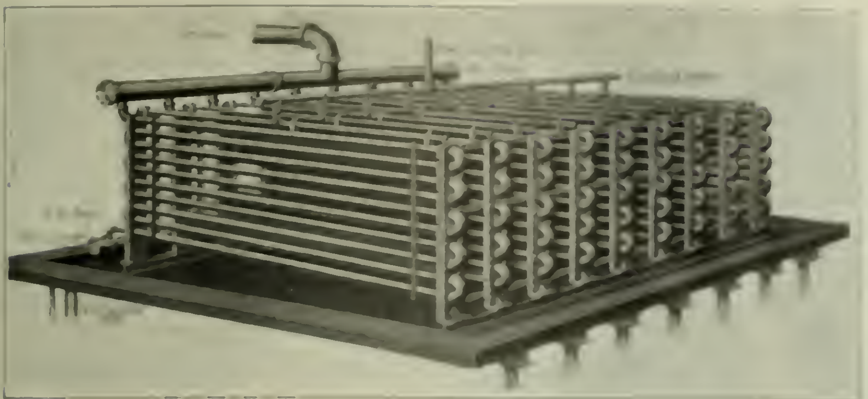

FIG. 18

ferred to, each tube is made to do a proportionate amount of work. The efficiency of the tubes is also increased because the steam in zigzagging down over the several nests of tubes increases its rate of travel, which increases the efficiency of the condensing surface.

The cooling water enters the lower nest of tubes as shown at A, Figs. 22 and 23, and, passing through the horizontal cooling tubes, reverses its direction of flow at the other end and returns through the nest B, reversing again and passing through the nest C to the same end of the condenser, where it is again reversed and returned through the nest D. The cooling water is then discharged through the

In Fig. 22 is shown an end elevation of a contraflo condenser connected to a triple-expansion engine. The condensing tubes are arranged in compartments, as shown. The steam coming from the engine cylinder follows the path indicated by the arrows through the upper nest of tubes in an even flow over the entire length of each tube, and at right angles to them. As the steam reaches the upper tubeless chamber it reverses its direction of flow, because of the upper baffle plate, and passes over the second bank of tubes, reversing again in the next lower tubeless chamber and passing over the third and lowest nest of condensing tubes. As the tubeless chambers have ample area, the change in the direction of the flow of steam is not sudden. From the lowest nest of tubes the water of condensation passes to the air pump, changing its direction of flow for the last time in the tubeless space in the bottom of the condenser base. By this successive passing of the steam over all the tubes in one compartment, and again being uniformly distributed in the tubeless chambers already re-

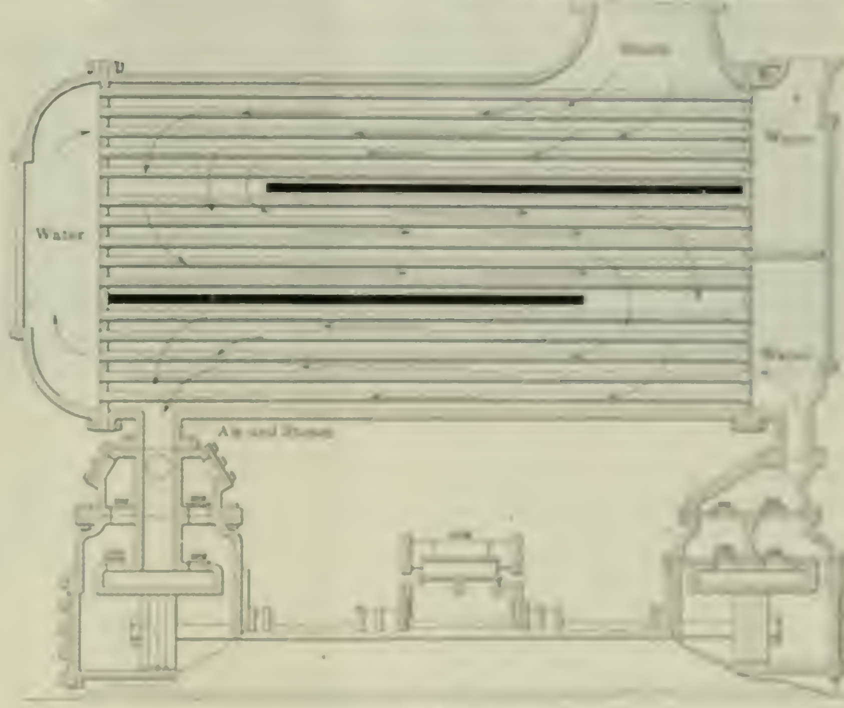

FIG. 23

outlet E, Fig. 23. From this it will be noted that the hottest water and steam are brought in contact with the cooling tubes at the top, while the coldest water and coldest steam and vapor are brought in contact with the cooling tubes at the bottom of the condenser body.

One of the reasons why the cooling tubes are very effective is because as the exhaust steam is condensed it falls on the baffle plate under the nest of tubes over which the steam is passing. As these baffle plates have [illegible] slope at the [illegible] tubes overhanging the condenser tubes, the water of condensation [illegible] to the bottom of the condenser body without coming in contact with the nest of other tubes. This same process of removing the water of condensation is carried out with each nest of cooling tubes, thus preventing them from becoming flooded by falling streams of water.

In order that the air pump may remove the greatest quantity of air from the condenser, it is necessary to [illegible]

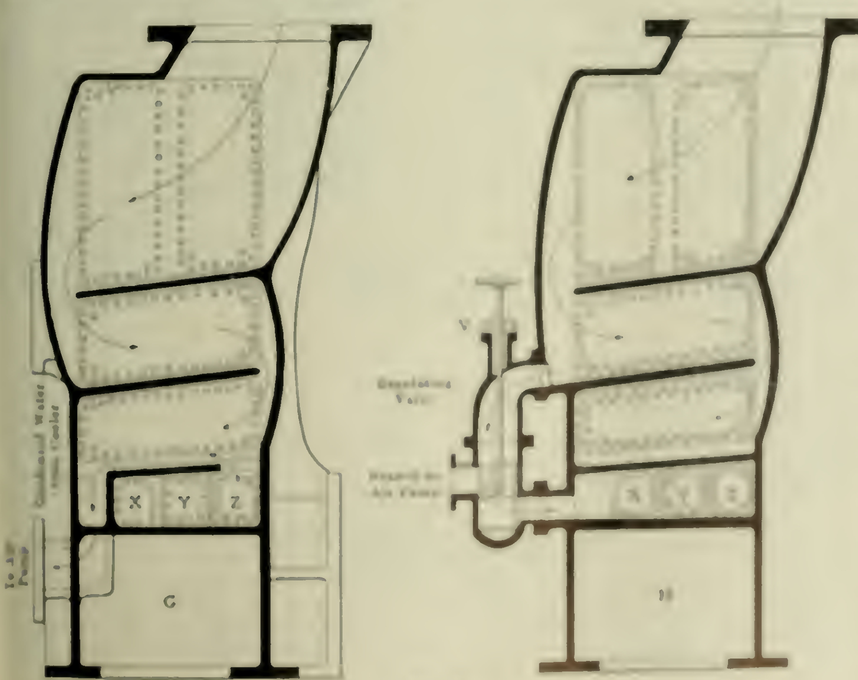

FIG. 22

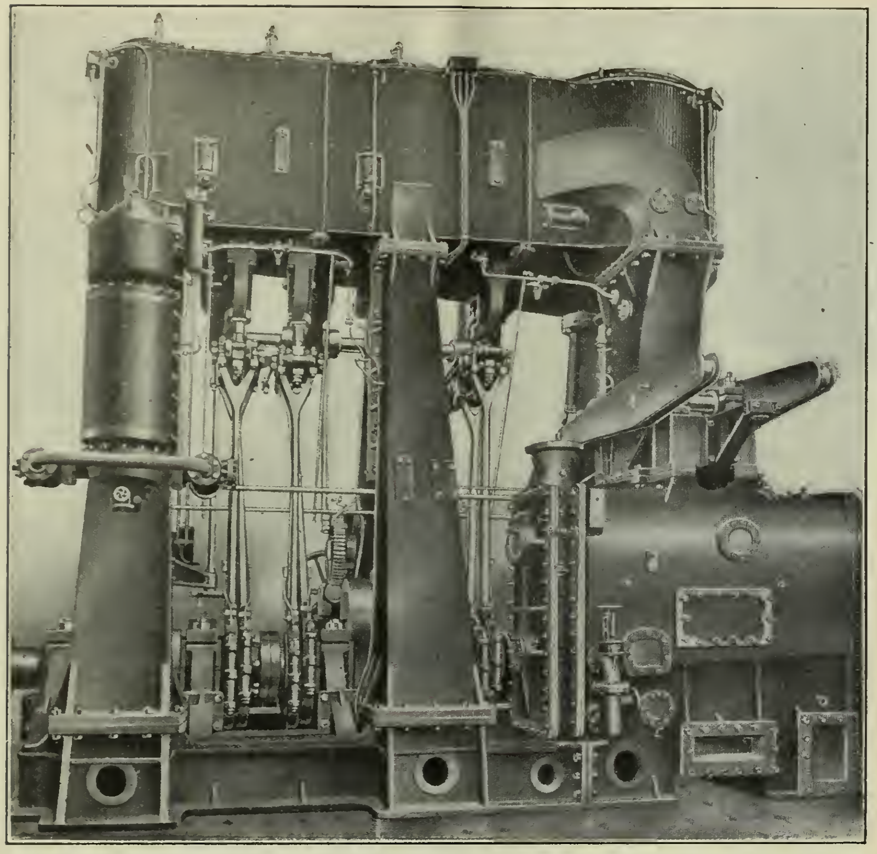

FIG. 21

passes through division Y, and finally returns through Z to the outlet. By this arrangement of regulating the water of condensation and cooling water, the highest temperature of feed water under any given condition, and the ability to maintain the most economical vacuum at all seasons of the year, may be attained; at the same time, the power efficiency of the engine may also be raised to a maximum when desired, by raising the degree of vacuum considerably above the normal.

Dinner of Alumni of Stevens Institute

The Alumni of the Stevens Institute of Technology will give their annual dinner on Friday, February 19, at the Hotel Astor, New York. A large attendance is expected, and among the speakers will be Alex. C. Humphreys, president of Stevens Institute; Alfred Noble, past president of the American Society of Civil Engineers and a former member of the Panama Canal Commission, whose topic will be the Panama Canal; Col. H. G. Prout, vice-president of the Union Switch and Signal Company; Dr. John A. Bensel, commissioner of the Board of Water Supply of New York City, and Col. George Harvey, editor of *Harper's Weekly*.

vapor with which the air is mixed. In this instance a cooling chamber has been incorporated in the design of the condenser, which is placed in the bottom, as shown at F, Figs. 22 and 23. The sealing water, after passing through the air pump, is returned to the cooler, so that the same water is used over and over again. In case it is desired to obtain the highest vacuum, the entire feed water can be cooled down before passing into the air pump. On the other hand, when it is desired to maintain a fairly high thermal efficiency, the amount of water admitted to the cooler can be regulated so as to reduce the amount of water admitted to the cooler and lower the temperature of the air-pump discharge sufficiently to obtain just the vacuum desired. The cooler is, therefore, a ready means of increasing the effective capacity of the air pump. In Fig. 24 is shown a sectional view of the condenser and cooling chamber. In G is shown a sectional view of the condenser through F. In Fig. 23 is shown the outlet to the air pump for the condensed water after passing through the cooler. The sectional view H, Fig. 24, shows a section on CD, Fig. 23, and the arrangement for passing the condensed water direct to the air pump or through the cooler. This is made possible by the regulating valve V, Fig. 24. In H, the cooler is in three divisions; the condensing water first passes through the division X, entering the end on which is located the regulating valve; it then

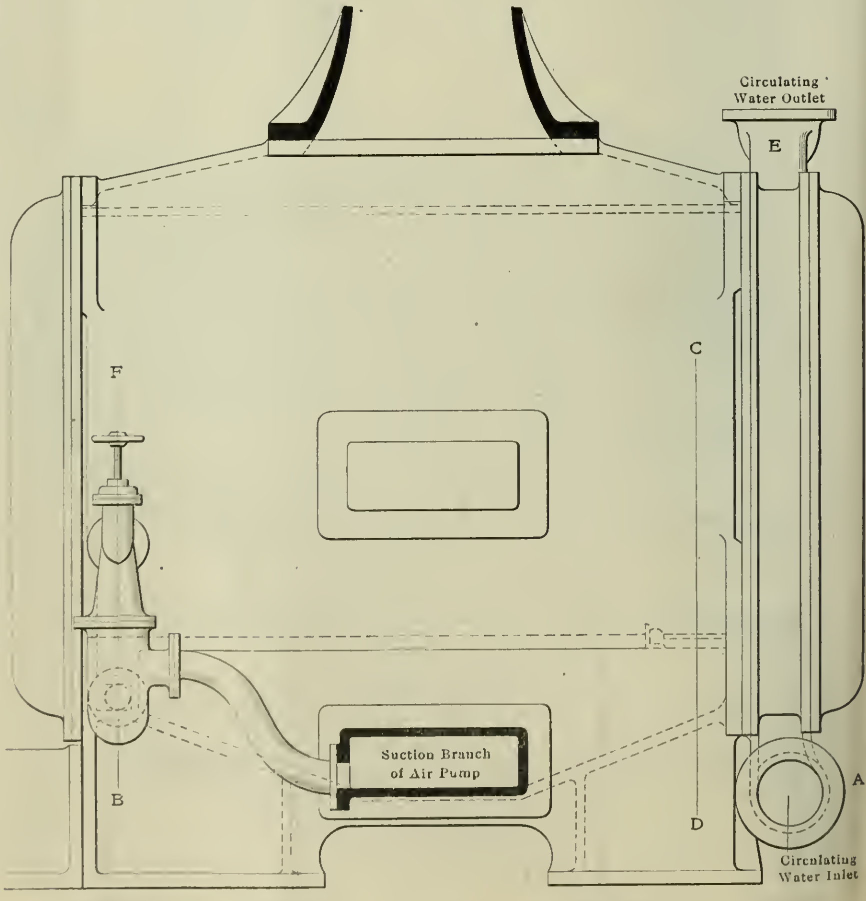

FIG. 23

Monthly Meeting A. S. M. E.

The next monthly meeting of the American Society of Mechanical Engineers will be held on February 23, the fourth Tuesday of the month, instead of the second Tuesday, as usual. The subject of the evening's discussion will be "Safety Valves," introduced by a brief paper by Frederic M. Whyte, general mechanical engineer of the New York Central lines.

Mr. Whyte will discuss the principles of the application of safety valves to steam boilers with special reference to locomotive practice, including questions of design and construction, and the requirements and limitations of valves. His paper will be followed by a general discussion covering marine and stationary practice and conditions existing in connection with low-pressure heating boilers.

Wisconsin Society of Engineers

It is proposed by forty or more engineers of the State of Wisconsin, representing cities, public utilities, manufacturing plants and colleges, to organize a State society along the same lines as those which are now in existence in Illinois, Indiana and other States.

The purposes of this society are to get the engineers of the State better acquainted with each other and to get a better understanding of problems that are of mutual interest to all, and to discuss some of the leading municipal and other problems of the day.

It is proposed to hold the first meeting in Madison, Wis., in the engineering building at the University on February 25 and 26. Prof. F. E. Turneaure, dean of the College of Engineering, is chairman of the program committee and [illegible] Kirchoffer is secretary of the committee, to whom all correspondence should be addressed.

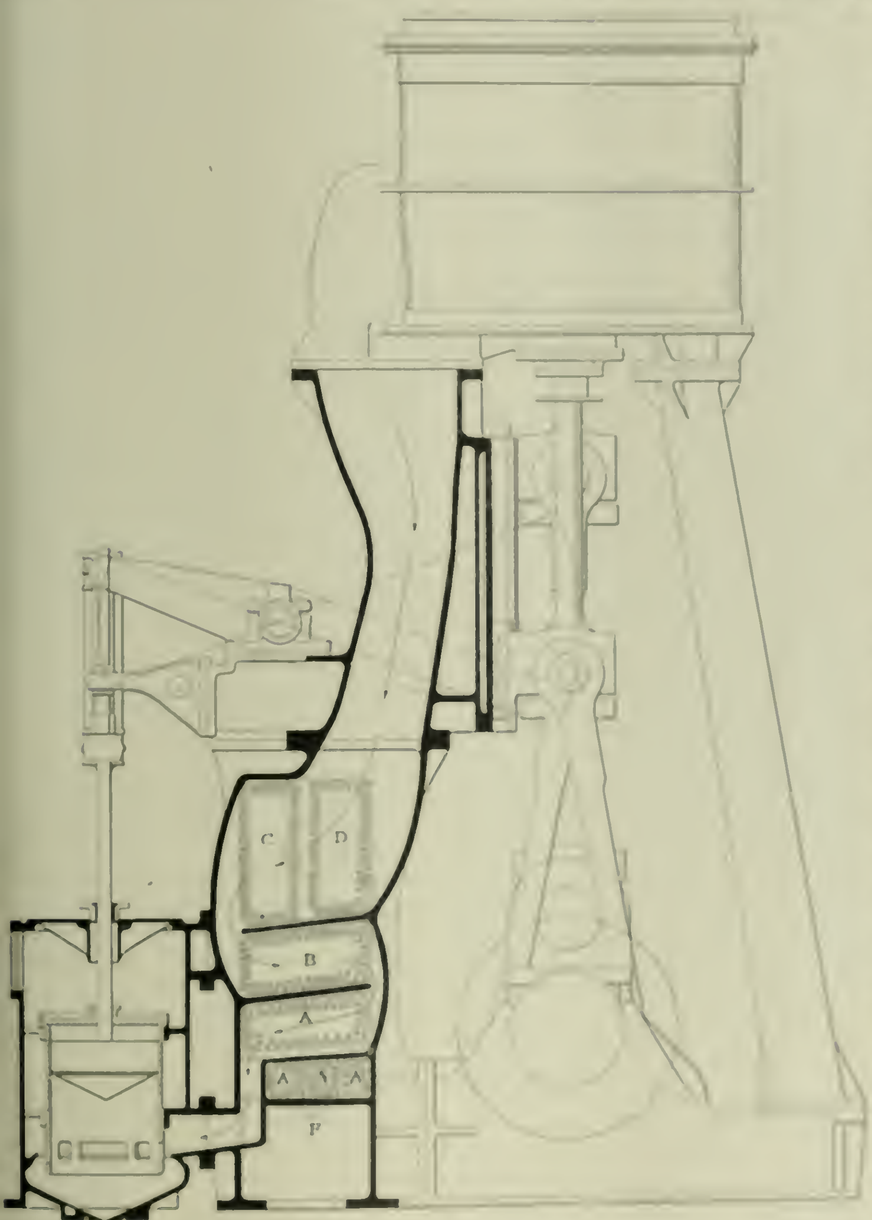

FIG. 22

Phoenix Association Banquet

Phoenix Association No. 24, N. A. S. E., of New York, held its annual dinner on Wednesday evening, February 3, at the Broadway Central hotel. More than four hundred members and friends were seated at the tables. Although some were inconvenienced by the crowded condition of the large dining room, the committee succeeded in keeping everybody in good humor and a most enjoyable evening was the result. When the service reached the coffee and cigars, W. J. Farr, the toastmaster, introduced W. T. [illegible], national vice-president; Joseph F. Carey and Herbert Stone, past national presidents; Thomas Cole, national president; James [illegible], S. J. Schaff and Arthur Vincent. The entertainers were "Joe" McKenna, "Billy" Murray, "Bob" Welsh, Frank Corbett and "Jack" Arnold. [illegible]'s orchestra furnished the music. It is the social affairs of this kind that are drawing the engineers closer together for mutual benefit.

Personal

George A. Orrok, secretary of the Gas Power Section of the A. S. M. E., lectured on Wednesday evening, February 3, on the subject of the gas engine, before the Blue Room Engineering Society, in the society rooms of the United Engineering Societies building, 29 West Thirty-ninth street, New York.

George F. Swain, professor of civil engineering at the Massachusetts Institute of Technology, and H. E. Clifford, professor of electrical engineering at the Institute, have been elected professors at Harvard University in the School of Applied Science, established under the McKay bequest.

Samuel S. Spalding recently resigned as superintendent of motive power of the Brooklyn Rapid Transit Company to go with the Pennsylvania Railroad Company. His associates in the electrical-engineering department of the Brooklyn company gave a dinner in his honor, and later the power-house and substation employees presented him a diamond ring, at the same time honoring Mrs. Spalding by presenting her a cut-glass centerpiece for the table.

According to Consul-General [illegible] at Gothenburg, windmills are principally used in Holland for the purpose of pumping water out of flush ditches, which must be done regularly in order to keep the fields and meadows dry, the ground itself of the Netherlands lying below the level of the sea. [illegible]

"Available" Heat

In considering any engineering problem involving the transfer of heat one needs to keep constantly in mind the distinction between the heat units contained by a liquid or a vapor or a gas and the heat units in that liquid, vapor or gas that are available for the purpose under consideration. For example, exhaust steam at atmospheric pressure contains 1146 heat units, reckoning from the freezing point of water, but it does not necessarily follow that 1146 B.t.u. are available for heating purposes. If the substance being heated escapes at 148 degrees, then 1030 of the 1146 heat units can be utilized, theoretically. But if the substance being heated escapes at a temperature of 198 degrees, only 980 heat units can be extracted by it from each pound of the steam and condensate. (With "counterflow" heating the range would be increased.) With gases and liquids the case is even worse because there is no latent heat of evaporation as with steam. Gases at one thousand degrees thermometer temperature are 1460 degrees above absolute zero, and if they are applied to a substance which must be raised to 270 degrees (730 degrees absolute) then only one-half of the heat contained by the gases will be available, because when that one-half has been extracted, the temperature will have fallen to 730 degrees absolute and a condition of heat equilibrium between the gases and the receiving substance will be established. It is this phenomenon, coupled with the high latent heat in steam, which militates against utilizing exhaust gases from an engine for raising steam for power purposes, and it was the ignoring of these facts which led Mr. A. T. Kasley into error when he undertook to correct our figures on the quantity of steam that can be made with gas-engine exhaust heat. On page 61, in the January 5 number, he assumes that because the exhaust gases of an engine contain about 4000 B.t.u. per brake horsepower of engine output, this entire quantity is available for making steam, subject to the efficiency of the boiler. The facts in the case are that the absolute temperature of steam at 150 pounds gage pressure is 810 degrees, so that if the temperature of the gases were 1620 degrees absolute, only one-half of the heat, or 2000 B.t.u., would be available; and that if all of the heat could be extracted from the gases, as Mr. Kasley's computation makes it necessary to assume, then their pressure and temperature, and consequently their volume, would be reduced to absolute zero!

Without intending the least discourtesy toward our correspondent, we are moved by the incident to caution students and beginners in work involving heat phenomena to keep constantly in mind the significance of absolute temperature and the fact that heat, like water, cannot flow from a lower to a higher level (temperature). The proportion of the total heat that is "available" is determined by the difference between the temperature of the source and that of the receiving substance.

Replacing Old Equipment

It is the disposition of most steam engineers and managers to retain old equipment as long as it will do the work, regardless of its efficiency. It is a great mistake, however, to keep in operation a machine that can be replaced by one that will do more work at the same cost or equal work at a lower cost. That this assertion is true can be proved by a visit to any large, progressive steel mill, where in the "scrap yard" will be found thousands of dollars worth of machines with which nothing is the matter except that they are out of date—they have been discarded because there are newer types of machines that will do the work better, faster and cheaper. The same principle applies to the steam plant.

Much of the objection raised is due to the expense of replacing old units. It makes the man of money wince to see good hard cash put out for a machine to replace one that has been doing the work for years and is still able to do it. What the cost has been through lost time for repairs, low production in the factory due to unsteady speed, and waste of steam and fuel because of obsolete design, is not taken into serious consideration, mainly because the loss is not known, and "anyway it occurred a little at a time, so what is the odds?" The little losses do not hit so hard a blow, apparently, as the sum invested to prevent them; therefore they are allowed to continue. Some day the manager will wake up to the real significance of operating second-rate machinery, or a new manager will take matters in hand who knows that inefficient apparatus will not permit him to compete with the up-to-date establishment, and will bring about changes. The weeding-out process, although it costs money, pays.

Every steam plant contains drones that produce nothing. They should be removed and the space devoted to something that will produce results. In one instance an electric-light plant was operated day and night. The day load was small; so was the night load after midnight. The units consisted of one large engine belted to a line shaft from which were belt-driven three generators. Owing to the friction load of the shafting, belts, etc., it was necessary to fire two boilers during the light-load periods, although the use of a small engine and generator capable of handling the light load during the day and the greater part of the night would have allowed one boiler to be cut out, the wear and tear on the large engine and belting to be eliminated, and a considerable saving in steam and coal consumption to be effected. Such a unit was finally installed and the saving has shown that its purchase was justifiable.

There are many steam plants in which may be found an old wornout engine carefully held for a reserve unit. Its days of continuous service have long since passed and the chances that it will ever be used again are most remote, but it will run if required, and its efficiency during the short and infrequent periods of its probable use is a matter of small moment. In this case the advantage of a standby or reserve unit is obtained at the expense of the interest upon what the old unit would be sold for practically as junk. In the same plant, perhaps, the feed-water pump "limps along on one leg."

Every engineer and manager can look about his steam plant and see where changes can be instituted that will be a means of increasing the economy of operation. "Improvements" can very easily be carried to excess, however, and a decision must be tempered with common-sense. An old slide-valve engine is just as adaptable for a sawmill as a Corliss engine, provided it will give steady speed, a factor which is usually lacking because of overloads. It is just as adaptable because in most cases the fuel not only is of no value, as it consists of sawdust, but must be got rid of, and burning it in the boiler furnace is the easiest way to dispose of it.

Homemade Appliances

From time to time correspondence describing various "homemade" devices is received, and we usually give it a place because engineers who might never appreciate the possibilities of such devices, or who might never be able to induce their employers to purchase them, may be induced to make them and be led into their use. As a general thing, however, appliances of such advantage as to be in general demand are to be had from the dealers in so much more efficient and presentable forms and at such reasonable prices that it hardly pays the user, especially if his time is worth anything, to build them on his own account. It stands to reason that a manufacturer, making things by special machinery and in quantities, devoting special study to their manufacture and profiting by the wide experience of the users of his wares, can turn out a more satisfactory article than the man who with pipe fittings and soft solder works out a single one. Nevertheless, the man who makes an automatically feeding oil cup, or a filter, or any of the many devices proposed, will find out some things about it which he might not otherwise have learned, and be in better position to take care of the regular "store" article which he will doubtless eventually acquire.

The Surface Condenser

The steadily increasing use of the steam turbine has caused the condenser and its accessories to assume an importance entirely disproportionate to that accorded to it but a few years ago by builders and users of reciprocating engines. As has been many times pointed out, the turbine can use a high vacuum, and the reciprocating engine cannot. Theory shows that an increase of vacuum from 24 inches to 28 inches should increase the power developed from 1 pound of steam by some 18 per cent., and with some types of turbine it is claimed that the actual gain is very nearly equal to that theoretically due. More commonly, however, the actual saving is slightly less than the theoretical, a rise of vacuum from 24 inches to 28 inches reducing the steam consumption by nearly 17 per cent. Though this saving is less than that theoretically due, it is, nevertheless, sufficiently substantial, and fully accounts for the importance attached to a high vacuum by all those engaged in the manufacture or supply of turbine-driven machinery. Any attempt to realize with a reciprocating engine any like proportion of the work due to a similar increase in vacuum would necessitate the employment of low-pressure cylinders rivaling in dimensions those 14 feet in diameter, adopted by Captain Ericsson in his famous hot-air engine. In actual practice the saving effected by increasing the vacuum of a reciprocating engine from 24 inches to 28 inches is only about 2 per cent., so that the lightheartedness with which the average marine engineer regards a bad vacuum is readily intelligible, and we have known even transatlantic liners worked regularly with a vacuum in the condensers of but 24 inches or so. Specifications even for tramp steamers often demand a 28-inch vacuum, and this may be obtained on trial, but in actual service anything above 25 inches to 26 inches may be reckoned exceptionally good in ordinary marine service. Higher vacua, though frequently recorded, are not often actually realized, and, when achieved, are very difficult to maintain, [illegible] vigilance being absolutely essential to success. Moreover, many records of such are undoubtedly due to the use of defective gages. As Mr. Morison pointed out at a discussion on this subject before the Institution of Marine Engineers, the ordinary Bourdon vacuum gage is most unreliable, forming a [illegible] in this regard, to the famous [illegible] of [illegible] in which the [illegible] stood. We have known a vacuum of over 30 inches recorded on both gages of a [illegible] fresh from the builder's hands, [illegible] the barometer stood at 30 [illegible] and the condensers were [illegible] as a vacuum [illegible]. Mr. Morison [illegible]

[illegible] in a power station in which three gages on the same service all recorded widely different vacua. On remarking to the engineer-in-charge that the gages seemed a bit wrong, the functionary agreed, with the added remark that "it was only Wednesday as this." In explanation of this it may be stated that these gages were corrected every week-end, but had, nevertheless, agreed to differ in the [illegible] by midweek.

Great ignorance in regard to the principles governing condenser practice is to be found even in quarters where better might be expected. It is but three or four years since a prominent Rand engineer refused to adopt steam turbines because, owing to the height above the sea, it is not possible in the *Johannesburg* district to obtain a vacuum of more than 28 inches, and better guarantees were obtained from reciprocating-engine builders than from turbine makers for plants to work with low vacua. As a matter of fact, the normal low barometer renders easier the maintenance of a low absolute pressure in the condenser, as part of the work of the air pump is already done by nature. The confusion doubtless originated in the English practice of reckoning vacua negatively—that is to say, an absolute pressure equal to 1 inch of mercury is reckoned as a vacuum of 29 inches. It is, of course, on a low absolute pressure that the economy of the steam turbine rests, and not on inches of vacuum recorded by an ordinary gage, which may mean almost anything, varying with each change in the atmospheric pressure.

The discussion at the Institute of Marine Engineers turned, to a large extent, on the claims for the "contraflo" condenser. In the "[illegible]," engined by [illegible] & Co., the tube surface in the contraflo condenser is only 1 square foot per indicated horsepower in place of the usual 1½ square feet, yet, with sea water at 60 degrees Fahrenheit, there has been, it was stated, no difficulty in maintaining a vacuum of 28 inches, making use of a [illegible] [illegible] of the condenser to lower the temperature of the air entering the air pump. It is reported, moreover, that the economical results, in the matter of fuel actually obtained by Messrs. [illegible] with the "[illegible]," which is, it will be remembered, fitted with reciprocating engines combined with a turbine, were at least partially due to the excellent vacuum, averaging about 28½ inches, maintained in the contraflo condenser. Other builders claim that equally good results can be obtained with other forms of condenser, and [illegible] Messrs. [illegible] and Wrightson for a clear exposition of the principles involved in [illegible] condenser design.—*Engineering*.

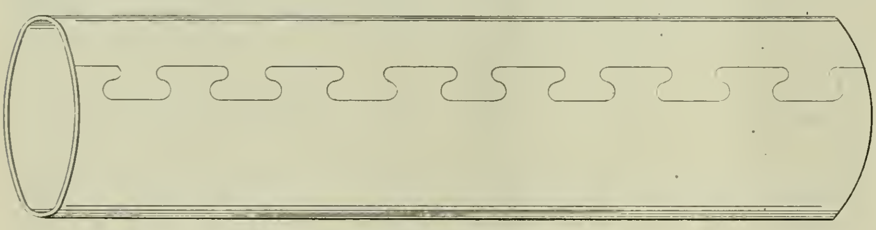
MUST BE NEW OR INTERESTING

Copper and Brass Pump Lining

The copper and brass lining shown herewith is manufactured by the Hamilton Copper and Brass Works, Hamilton, Ohio. These linings are used to line cylinders of large diameter, where seamless tubing above a certain diameter, say about 8 inches, becomes too expensive, when a lining made of composition sheet brass and sheet copper is substituted.



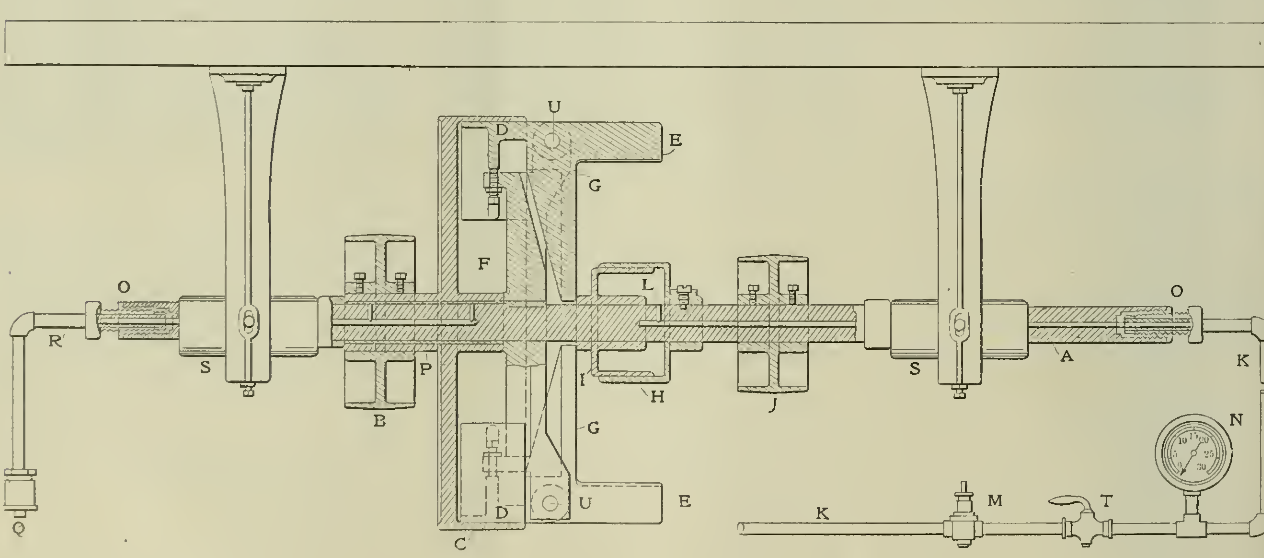
NEW PUMP LINING

The cylinders are bored out the size of the outside diameter of the lining and left in a somewhat rough cut. The linings are then pushed into the rough-bored cylinder. After this is done a burnisher or round-faced tool is placed in the boring bar and rubbed or burnished slowly, with a uniform pressure, against the lining from one end to the other. This brings the lining tight against the cylinder and also makes a smooth and polished surface. Plenty of oil is used when the lining is being rubbed against the cylinder. When this is done the ends of the lining, which should extend out about ¼ inch from the ends of the cylinder, are turned over the ends of the cylinder, making a water-tight fit.

A Variable Speed Clutch

The principles involved in this clutch and the method of speed control may be readily understood by reference to the diagram, where *A* represents a shaft supported by hangers *S S*, *B* a pulley driven by a belt from the line shaft, and rigidly mounted on the long hub *P* of the drum *C*. The pulley, hub and drum revolve together loosely on shaft *A*. At *D D* are clutch shoes, fulcrumed on the pivot bolts *U U* in the ends of the spider *F*. Integral with these shoes are the weights *E E* and the inwardly extending arms *G G*. The spider *F* is rigidly keyed to the shaft *A*. At *J* is a pulley fastened to the shaft. From this pulley, a belt passes to the machine to be driven. The cylinder *H* is secured to the shaft *A*, and rotates with it. One end of this cylinder is open and from this end projects the sliding piston *I* engaging the arms *G G*. An opening through the shaft communicates with the interior of the cylinder. When air or any fluid under pressure is admitted through the opening into the cylinder, the piston is forced against the clutch arms *G G*, thus forcing the weights *E E* inward and the clutch shoes *D D* outward toward and against the inner face of the drum *C*, causing the drum to impart its motion to the shoes. Acting against this tendency to impart motion, is the centrifugal force of the weights *E E*, which tends to separate the shoes from the drum and overcome the tendency of the drum to impart motion. It is the balance between these two forces that determines the speed transmitted.

In practice, the pressure on the piston, acting on the shoes and against the centrifugal force of the weights, imparts to the shoes a series of minute impulses that are apparently uniform, conveying steady rotary motion from the driving member to the driven member, the speed under no circumstances exceeding that which the regulating valve is set for. When pressure is released from the piston *I*, causing the clutch shoes to break contact with the drum, the drum acts as a loose pulley on the shaft. The controlling force is admitted to the cylinder from the supply pipe *K* through the stuffing box *O* and inlet *L*, regulation being effected by the



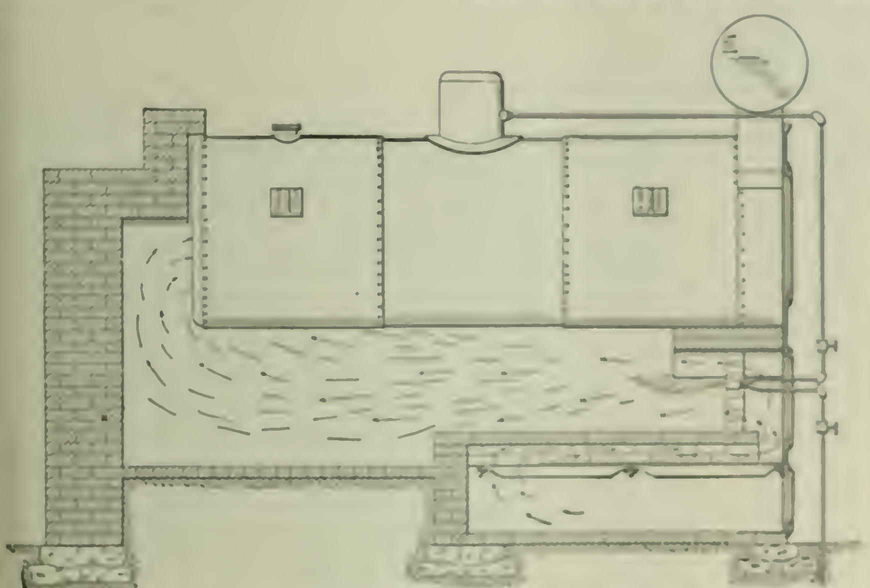
SECTIONAL VIEW OF VARIABLE SPEED CLUTCH

pressure-regulating valve M, the pressure being indicated by a gage N, the valve M being readily set to give any desired pressure. The cock T is used to turn on or off the supply of air, to start or stop rotation. At Q is a grease cup from which lubricant is fed through the pipe R and the central hole in the shaft and a small radial hole to the bearing surfaces of the sleeve P.

This clutch is manufactured by the Variable Speed Clutch Company, Milwaukee, Wis.

Mason Furnace

The accompanying illustration shows one style of preheated-air oil furnace constructed by the Mason Smokeless Combustion Company, 201 Kerckhoff building, Los Angeles, Cal. The method used in burning oil is the introduction of highly preheated air at the point of combustion.



MASON PREHEATED-AIR OIL FURNACE

As will be seen, the furnace is equipped with a brick arch over the grate, so constructed that the air in passing up through the grate is heated before entering the furnace proper, due to its contact with the brick arch.

It is claimed that by this method the air used at the burner is greatly expanded, heated by the heat produced in the combustion chamber, resulting in an instantaneous and complete gasifying of the oil.

The combustion is said to take place in the form of a short flame, the clear and transparent flux showing complete combustion of the gases and a very high intensity of heat which is rapidly imparted to the boiler body.

Greatly increased furnace temperature together with an even distribution of the heat is said to be the result, and all the available units of heat are therefore enabled to do their proper work of increasing the evaporation of water.

A New Line of Belt Driven Alternators

A new line of polyphase belt-driven alternators has been brought out by the General Electric Company for use in small generating plants and in isolated lighting and power plants where rapidly increasing inductive loads and consequently low-power factors are encountered. The machines are designed for 80 per cent. power-factor service, but will of course operate satisfactorily on higher power factors.

Fig. 1 is a general view of one of these generators. Although designed for belt drive, they are readily adapted for direct connection to prime movers of suitable speed by omitting the driving pulley and subbase and adding a coupling. Each generator has on the collector-ring end of the shaft an extension to receive the exciter driving pulley.

The armature frame is of cast iron with cored ventilating openings which allow free circulation of air around the ends of the windings and through ducts in the laminated core, as illustrated in Fig. 2. The armature coils are form-wound and individually insulated, so that any coil may be readily replaced if necessary.

The field structure, which is the revolving member, consists of laminated rotary cores dovetailed into a laminated spider. The punchings are carefully punched and riveted together, forming a [illegible] well adapted to withstand high speeds. Two methods of building the field-magnet coils are used. For the [illegible] and [illegible] kilowatt sizes the wire is wound on spools through which are slipped the magnet poles, the spools being held in place by the enlarged pole tips. In the larger sizes, the coils consist of a single strip of flat copper wound on edge so that one surface of every turn is exposed to the air. The collector rings are mounted on insulating sleeves on the shaft and are exposed to the air on all three sides. Two or more carbon brushes are provided for each ring.

At [illegible] factors these generators have

FIG. 1. A NEW BELT-DRIVEN ALTERNATOR

been especially designed for use in isolated plants where mixed lighting and motor loads are the rule rather than the exception. It is practically impossible in such cases to obtain good voltage regulation by hand control and some form of automatic voltage regulator must be

FIG. 2. ARMATURE FRAME OF BELT-DRIVEN ALTERNATOR

used. For this service the well known T A regulator manufactured by the General Electric Company is recommended and, when used in connection with the exciters for the [illegible] alternators, automatically maintains practically constant voltage at the bus-bars or at the center of the system, according to adjustment. The exciters have a normal voltage of 125 volts, but are capable of delivering 150 volts continuously. This margin of power enables them easily to overcome the demagnetizing effect of the armature current on circuits.

When intended for operation as synchronous motors, these generators are equipped with squirrel-cage windings set in the field-magnet pole faces. These windings are said to give ample starting torque with a moderate starting current and they do not in the least affect the operation of the machines as generators. The generators are at present available with either two- or three-phase windings and for 240, 480, 600, 1150 or 2300 volts.

Atlantic City A. O. S. E. Dinner

The twelfth annual dinner of Atlantic City Council No. 4, of the American Order of Steam Engineers, was held at the Hotel Jackson, Atlantic City, N. J., on Saturday evening, February 6. An excellent collation was served to over 150 members, friends and guests, among them being several prominent citizens of the city, and also many familiar faces of the engineering fraternity. Short addresses were made by Mayor F. B. Stoy, Harry Wooten, Fred Marcoe, supreme president of the A. O. S. E., and Commodore Louis Klunnel. An enjoyable entertainment was given by Charles E. Carpenter and "Jack" Armour. T. D. Just was the affable toastmaster. The committee in charge of the successful occasion were W. S. Price, A. H. Francks, J. W. Frampton, C. F. Noble, E. N. Meloney.

Business Items

J. Everton & Son, of Deer River, Minn., has placed an order with the Minneapolis Steel and Machinery Company for an 80-horsepower Muenzel producer gas engine and gas producer plant, and a 53-kilowatt double-cylinder generator, which will be direct-connected to the engine. This machinery will be installed in the electric light plant at Deer River.

The Southern Engineering and Supply Company has opened offices at 220 Avenue D, Henry Terrell building, San Antonio, Tex. They propose to make a specialty of pumping and irrigating machinery, also isolated and small light and refrigerating plants. Manufacturers interested in southwestern territory not having representatives are invited to send catalogs and descriptive literature.

The Burnite Machinery Company, with Thomas B. Burnite as manager, has succeeded the Burnite-Leonard Engineering Company, of Denver, Colo. The company has moved into a commodious office and storeroom at Seventeenth and Glenarm streets and represents the Hardsocg Wonder Drill Company, the Erie City Iron Works, the Bury Compressor Company, the Krogh Centrifugal Pump Company, and various other lines, making equipment for mine, mill or power plants of all descriptions.

The Fountain-Shaw Engineering Company, which began business the first of this year as civil, sanitary, electrical and mechanical engineers, with offices in the Binz building, Houston, Tex., is composed of Thomas L. Fountain and Joseph D. Shaw, with P. S. Tilson as collaborator. Until recently Mr. Fountain was assistant to Alexander Potter, civil and sanitary engineer, of New York City, and Mr. Shaw was assistant to the chief engineer of the Pittsburg Railways Company and the Allegheny Company.

The Crocker-Wheeler Company, of Ampere, N. J., has just closed a contract to equip with motor drive the new woodworking factory of the John Hofman Company, Rochester, N. Y. The order includes 40 induction motors ranging from 1 to 30 horsepower, with a total capacity of about 200 horsepower. These motors will be used for individual drive, each machine being equipped with its own motor. The motors, with the exception of one, are of the squirrel-cage type. The generator for this plant and three lighting transformers are also included in the order placed with the Crocker-Wheeler Company.

The Buckeye Boiler Skimmer Company, South End, Toledo, O., has received a letter dated January 28, 1909, from Gilmore Brothers, contractors, Toledo, in which they say: "We have used your skimmer on our two dredges the past three years and find that they do all that you claim for them. We have worked alongside of other dredges, equipped with the same style of boiler, and whereas the others have had to clean their boilers every two weeks, we ran eight weeks before cleaning and then found no mud or scale. We open up our boilers every eight weeks, more to inspect them than in the expectation of finding mud or scale. We figure we save double the price of the skimmer each season, in fuel and time."

The Nelson Valve Company, Philadelphia, Penn., which was originally incorporated in the State of New Jersey, has surrendered its charter and has been incorporated in the State of Pennsylvania. This company began in 1893 to manufacture valves of all kinds under the Nelson patents and made such a success of the business that it now employs from 200 to 250 men. It is now proposed largely to increase the facilities so as to meet the growing demand for the company's product. The new charter will empower the company to manufacture and sell pipe, valves, machinery, fittings and steam specialties, and will have an authorized capital of one million dollars. The president of the new company, who was also president of the old one, is Samuel F. Houston, who is vice-president of the Real Estate Trust Company, and vice-president of the Winifrede Coal Company and of the Winifrede Railroad Company. Carlisle Mason is the vice-president and, as heretofore, general manager, and Russell Bonnell, the secretary-treasurer. Henry H. Bonnell is also one of the incorporators.

New Equipment

City of Elgin, Texas, has voted $30,000 bonds for construction of water works.

The Deer Lodge (Mont.) Electric Company contemplates installing engine, alternator, etc.

The Gilmer (Tex.) Ice, Light and Power Company has been incorporated with $40,000 capital by T. E. Barnwell, Lewis Monroe and J. E. Barwell.

The city council, Hartshorne, Okla., is said to have decided to construct water-works at a cost of $80,000.

The citizens of Ashburn, Ga., voted to issue $55,000 bonds for construction of electric-light plant, water works, etc.

It is reported the Le Roy (Ill.) Electric Light, Power and Heating Company contemplates the installation of a new heating and ice plant.

New Catalogs

Lehigh Stoker Company, Fullerton, Penn. Catalog. Mechanical stoker. Illustrated, 12 pages, 6x9½ inches.

Weber Steel-Concrete Chimney Company, Chicago, Ill. Catalog. Chimneys. Illustrated, 48 pages, 4x9 inches.

The Corbett Supply Company, Trenton, N. J. Catalog. General mill supplies. Illustrated, 520 pages, 6x9 inches.

Joseph Dixon Crucible Company, Jersey City, N. J. Pamphlet. Lubricating the Motor. Illustrated, 24 pages, 5½x8½ inches.

Dean Bros. Steam Pump Works, Indianapolis, Ind. Catalog No. 74. Condensing machinery. Illustrated, 56 pages, 6x7½ inches.

The Caskey Valve Company, 422 Arcade building, Philadelphia, Penn. Catalog. Valves. Illustrated, 19 pages, 3½x6½ inches.

The Jeffrey Manufacturing Company, Columbus, Ohio. Catalog 67D. Rubber-belt conveyers. Illustrated, 48 pages, 6x9 inches.

The Climax Smoke Preventer Company, Equitable building, Boston, Mass. Catalog. Climax smoke preventer. Illustrated, 16 pages, 6x9 inches.

Bush Terminal Company, 100 Broad street, New York. Catalog. Model loft buildings for shipper and manufacturer. Illustrated, 12 pages, 9½x12 inches.

Recent Refinements in Boiler Testing

Descriptions of Apparatus and Methods Employed in Conducting Tests Along Uptodate Lines; Special Devices Used by the Author

BY ALBERT A. CARY

During many years of boiler-testing experience the writer has constantly endeavored to improve his testing equipment, so as to reduce the possibility of error to a minimum, to diminish the number of expert assistants required during a test and to make it possible *personally* to take all of the required observations with sufficient frequency to obtain ample data showing every important varying condition occurring during the test.

Probably one of the most troublesome matters connected with the equipment for boiler testing where the engineer is called to conduct a special test, is the feed-water apparatus. I have used tanks, one of which is fitted upon a special scale platform and each charge of water is actually weighed before it is dumped into the lower tank which, acting as a pump, holding a reserve supply to be delivered directly to the feed pump. This arrangement requires the construction of a heavy platform of sufficient hight to allow the lower tank to be placed beneath it and it must be strong enough to carry both the scale and the upper weighing tank with (usually) two men who weigh the water and check each other's results.

If it is desired to keep track of the amount of water actually evaporated over each small interval of time during the [illegible]

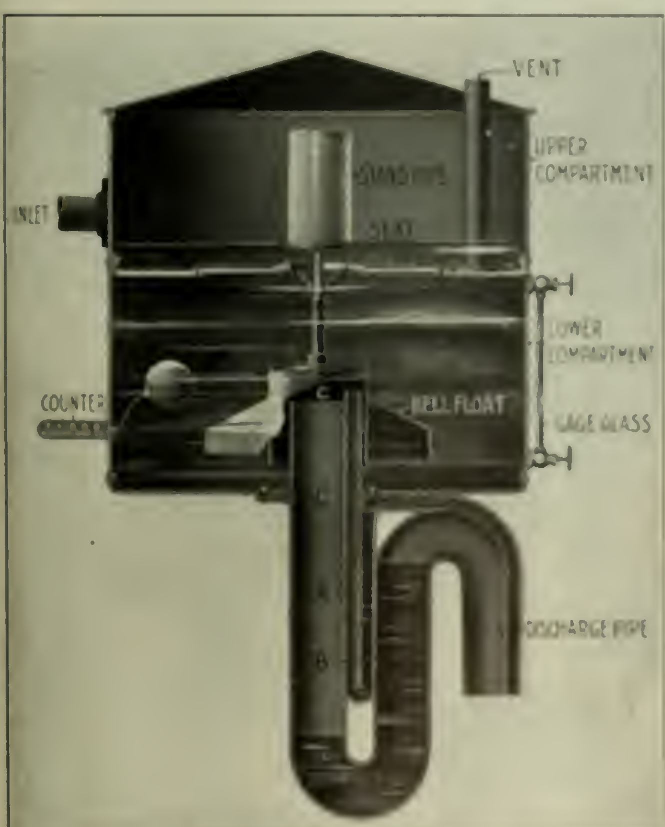

FIG. 1

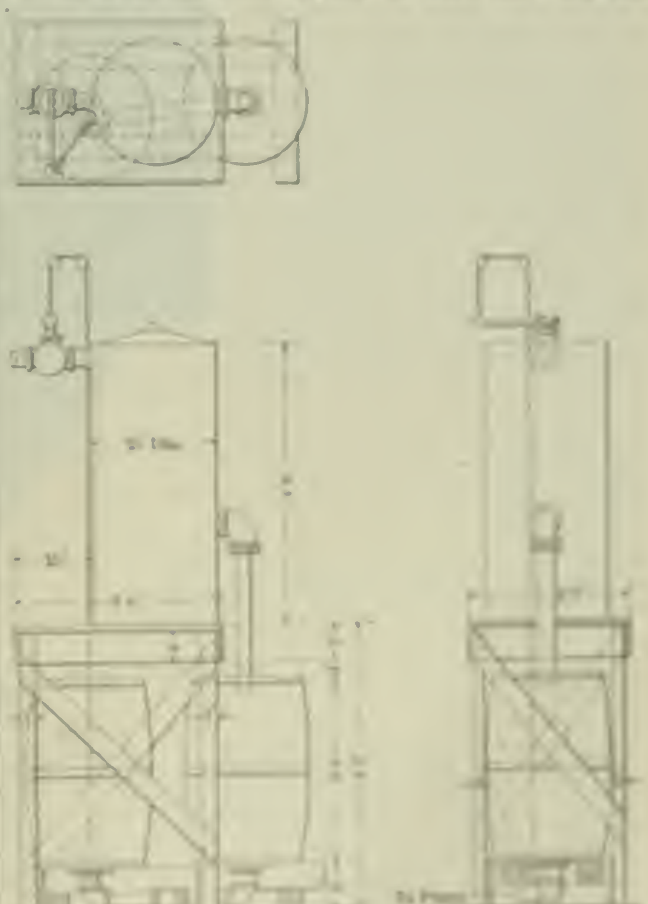

FIG. 2

as disarranged during shipment, and to the expense usually incurred upon the owner of the plant for a properly built platform.

Water measuring is quite generally used in place of weighing apparatus, which admits of the use of a somewhat simpler equipment but with some sacrifice of accuracy. I have several designs for mounting such apparatus in place, one of which is sent to the steam-plant owner with instructions for erection. This equipment requires the lower sump tank and [illegible] heads having been removed) a hole is bored through each bottom head and a 2- or 2½-inch pipe flange is bolted to this bottom with a rubber gasket between the wood and the flange.

In the bottom flange of each of the upper (or measuring) tanks is screwed a nipple with a valve holding another lower nipple from which the water is discharged into the lower sump tanks placed below the level of the elevated platform. A hole is bored into the side of each of the upper, or measuring barrels, near the top of one of the staves, and into this is screwed a short length of pipe projecting into and outside of the barrel. Error is introduced in this form of apparatus in filling the barrel (from the lower closed valve to a level where the overflow pipe ceases to deliver water), due to the speed of manipulation sometimes found necessary, and to carelessness (often due to fatigue) on the part of those in charge.

Many special arrangements have been introduced by users of such apparatus to diminish this error. The opening and closing of the supply valves delivering water to these measuring tanks and the proper opening and closing of the discharge valves under these barrels involve considerable activity on the part of the man or men manipulating the apparatus, especially when it is worked anywhere near its capacity, to which work is generally added the clerical duty of keeping the water log, on which should be noted the exact time of each dump. Errors are sometimes introduced by opening the discharge valve before the overflow pipe has ceased to drip, by imperfectly closing the lower valves and occasionally owing to forgetfulness or to a rush when a sudden demand for more water occurs, due to failure in closing the discharge valve before the water-supply valve is opened to fill the barrel.

Where intention to deceive exists, this form of apparatus lends itself to easy manipulation despite the careful watching of the man conducting the test.

The lower barrels are connected by bottom piping so as to form practically one sump tank, from which lower connection water is piped to the feed pump.

In carefully conducted tests the common level of the water in the lower tanks should be noted in the log at the time of each dump from the measuring tanks, together with the level of the water in boiler-gage glass. With such information it is possible to determine whether a number of rapidly dumped barrels has been necessitated by a momentary large evaporation in the boiler, or by neglect in keeping the water in the boiler up to the level selected for the trial; or neglect in keeping the sump tanks full of water.

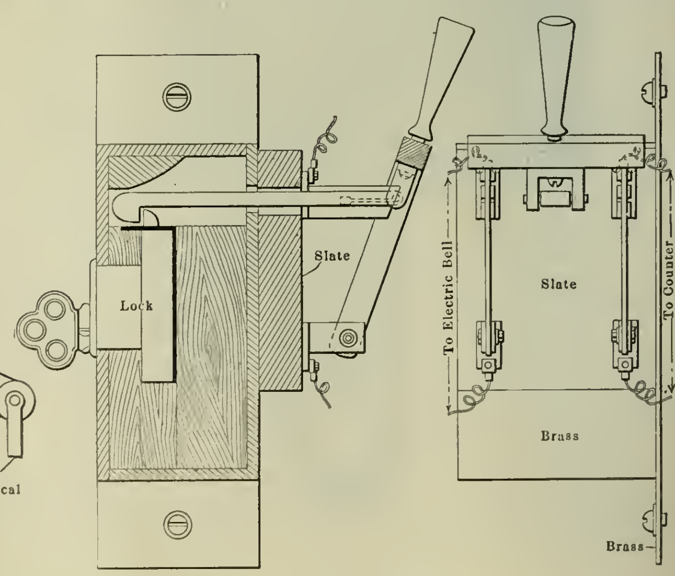

FIG. 5

Automatic Liquid Weigher

There have been many more or less automatic weighing or measuring tanks presented, to reduce the labor required in keeping account of the feed water used during a boiler trial, but nearly all of these have proved undesirable as portable apparatus, due to their considerable bulk or weight, or due to their delicate or complicated parts, to say nothing of their considerable cost in some cases; but finally, after investigating a number of these devices, the writer found what he has been looking for in a comparatively recent apparatus known as the Wilcox automatic liquid weigher. This weigher was described in a paper presented before the American Society of Mechanical Engineers at the May, 1906, meeting and it was also described in Power in the issue of June, 1906.

It is piped directly to the water system supplying the boiler, and after receiving a charge of water in its upper compartment, which charge is carefully weighed by balancing it against a column of water of a predetermined hight, the water supply is cut off within the tank automatically and the weighed charge is dumped; and then follows one weighed charge after the other, each successively dumped into the sump from which the water is delivered to the boiler-feed pump. A section of the apparatus is shown in Fig. 1.

If the supply of water to the weigher was not restricted, the continuous working of the apparatus would be apt to overflow the sump tank, but by placing a float in the sump tank and by connecting it to a balanced valve placed in the inlet piping to the tank (the tank being mounted upon an elevated platform) this valve automatically cuts off the supply of entering water when the level of the water in the sump tank rises above a predetermined level.

Each time this weighing apparatus tilts and dumps, the rising and falling water level lifts and lowers a ball float within the lower compartment. This causes a small shaft, passing through the side of the apparatus, to make a partial revolution, first in one direction and then in the opposite direction, being actuated by the float to which the shaft is attached by a lever.

By referring to Figs. 3 and 4, it will be seen that the outer end of this shaft carries a lever, projecting upward, and having a slot at its upper extremity. This slot engages a pin placed at the bottom of the lever of a counter mechanism and as the top of the float lever moves backward and forward the counter is made to add one to the figure previously registered. Thus each dump is automatically registered on the counter.

The foregoing description presents the automatic weigher as it reached the writer, but after testing it carefully, and finding that it could be relied upon to deliver water with an error in weight of not over one-quarter of one per cent., and after subsequently using it in a boiler test it was found that the mere counter, showing the number of dumps, did not give sufficient information to follow the irregularities in evaporation occurring during the course of the boiler trial, unless very frequent readings were taken. The labor required in climbing up to the counter, located some 10 feet above the floor to obtain a reading every few minutes during the test (when numerous other readings had to be taken) was found to be quite fatiguing before the test was completed, so means were devised by the writer to overcome this objectionable feature.

To illustrate, roughly, what is meant by the necessity for frequent readings, let us suppose that the boiler evaporated 6000 pounds of water in one hour and 12,000 pounds of water during the second hour, and the counter reading was taken at the end of the second hour. It would be found that 18,000 pounds had been evaporated since the last reading. One would, by averaging, say that there was an evaporation of 9000 pounds per hour, which conclusion would give a very erroneous idea of what had actually occurred during [illegible] part of the test.

When carrying the regular steam load of one plant tested, I found that [illegible] dumping [illegible] during [illegible] interval [illegible] seconds, while later in the test the dumps occurred about [illegible] apart. In another test, where the [illegible] [illegible] [illegible] the [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] I found that the average load for the day was only [illegible] boiler horsepower, but during one-half hour in the afternoon the steam requirements ran up to [illegible] boiler horsepower.

In order to obtain the full required data from the apparatus, I devised the attachments shown in Fig. 3 and shown with greater clearness in Fig. 4. To attach these to the sheet-metal weighing tank, a strip or band of brass, 2 inches wide, was firmly secured around the tank, running past the counter mechanism between the ball-float shaft and the bracket holding the counter. To this brass band a bracket was secured, carrying a lever with right-angled arms, similar to the so-called "bell-crank lever" used by bell hangers. It will be seen that the vertical arm of this crank is attached by a link to the vertical lever of the counter mechanism, which lever is oscillated by the rising and falling ball float in the tank. To the horizontal lever arm of this crank a second link is secured, dropping to the actuating lever of a Bristol float recorder, which instrument accurately revolves the recording paper chart by clockwork.

By this arrangement, when the ball float in the tank rises with the inflowing water, the stylus of the recorder is moved away from the center of the chart (placed on the face of the recorder) toward its outer circumference. There it remains until the dump occurs, when the falling water level causes the stylus to move back toward the center of the chart.

These two approximately radial lines are traced on the paper chart with ink, when the stylus holds ink, but I have found a paper chart having its face coated with smoke much more satisfactory, as with very frequent dumps, causing these "radial" lines to occur quite close together, the closely adjoining fresh ink lines are apt to run into each other, thus causing an obliteration of the lines into a continuous blot. With the smoked charts (furnished by the Bristol company) lines lying quite closely together can be distinctly distinguished, and the very accurately smoked lines, with its contained record, is easily "fixed" after the test, so as to preserve the writing or soot from rubbing off.

Fig. 6 shows one of these charts with a record obtained during a test. The clock mechanism used in this case revolves the chart one complete revolution in twelve hours. The paper chart shown is made for use with a twenty-four-hour clock and, therefore, two of the hour divisions must be counted for one hour to maintain the record correctly. It will be understood that with double the number of small divisions [illegible] based on the twenty-four-hour chart the number of dumps in a given time interval [illegible] [illegible] [illegible] [illegible].

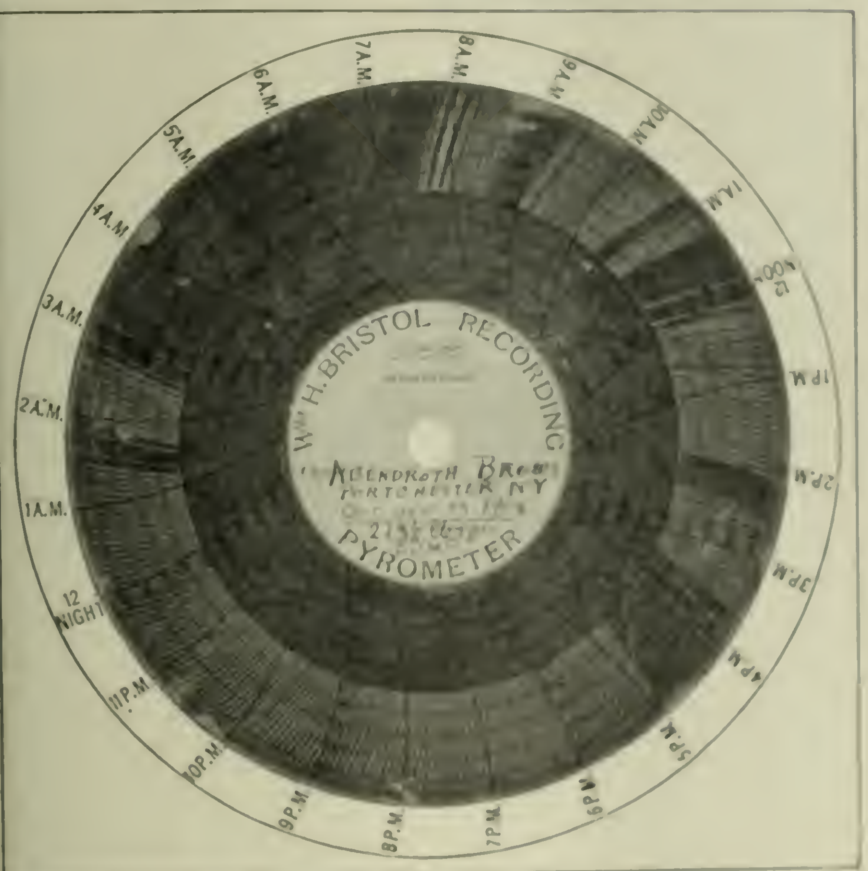

FIG. 6

[illegible] [illegible] [illegible]

[illegible] [illegible] to the [illegible] shown in Figs. 3 and 4 [illegible] [illegible] will be [illegible] [illegible] [illegible] [illegible] [illegible] of the bell crank toward the float shaft. Weights are suspended from this rod to counterbalance the weight which has been imposed upon the lever operating the counter by adding the attachments to the clock mechanism. Having this convenient projecting rod, the writer was tempted to add another refinement to this weighing-tank mechanism which has proved a great convenience. I refer to an electric counter.

The inconvenience of using the regular mechanically actuated counter provided with the machine, and located some 10 feet above the floor, has already been referred to. To actuate the Mandi electric counter a circuit from a battery (of three dry cells) must be closed and then opened. The closed circuit from the battery must not be maintained long, otherwise the battery will soon be exhausted. In order to accomplish this result, I borrowed (by permission) part of the patented mechanism used in the Desper elevated-travel recorder. This is plainly shown in Fig. 4, where will be seen the outer end of the counterbalance rod projecting from the hub of the bell crank, placed directly over an angle-shaped brass wiper. This wiper is secured to the blocking holding the bell crank by an easy-fitting pin passing through the hub of the wiper near the apex of the angle.

To hold the wiper in the position shown with the least interference to its movement around its supporting pin, a short rod is secured in its hub, projecting at right angles to the pivotal pin and standing midway between the two arms of the angular wiper. To the outer end of this rod one end of a spring is attached, the other end being fastened to an electric binding post secured to the supporting blocking, and with this extension spring in tension the angular wiper must be held with its upper face horizontal but a very slight pressure applied near the end of this horizontal face will cause it to deflect and turn around the pivotal pin, and it will recover its normal position the instant this pressure is removed.

The upper or horizontal face of this wiper is covered with an insulating material which projects over its outer edge, but the under horizontal face presents a bare metal surface.

Electrical connections are made with the batteries and the Mandi electrical counter by connecting one wire to a binding post secured to the counterweight rod near the hub of the bell crank, while the other wire is connected to the binding post at the outer end of the wiper spring, the current being conducted through the spring and rod to the angle piece, as shown.

With this equipment, it will be seen that as the tank fills with water, the outer end of the counterbalance rod is made to descend and, striking the top insulated surface of the wiper, no current will pass through the system. As the water continues to fill the tank, the end of the counterbalance rod continues to descend and finally it slips over the edge of the insulated face, when the wiper springs back to its normal position, leaving the end of the counterbalance rod beneath the horizontal face, and out of contact with it.

The discharging operation of the automatic weigher requires a very short space of time, and as the water level falls the end of the counterbalance rod rises, striking the lower horizontal metal face of the angle and wiping over it as it rises thus closes the circuit and causes the electric current to flow through the magnets which operate the counter. As the end of the counterbalance rod continues its upward motion, it soon slips over the edge of the wiper, thus breaking the circuit, and this rod soon reassumes the position shown in Fig. 4.

With this device, it is possible to place the electric counter in any convenient position about the boiler room, where the readings can be taken with the least effort. With an autographic record, showing not only the number of dumps but also the exact time of each dump, the use of this electric counter may be questioned. I have found it most useful during the course of the test, showing as it does, almost immediately, the general evaporative result accomplished up to the time of the reading. With the many lines found on the recording chart, it is difficult to find time, during the test, to count them. By pasting a piece of paper on the front of the electric recorder just below the line of moving figures on its face, and by writing thereon the figure recorded immediately before the start of the test, it is a very simple matter to subtract this written figure from the recorded figure above, and then one has, almost at a glance, the number of dumps which have occurred during the test, up to the time of taking the reading.

Just below the initial figure on the pasted slip I write the exact number of pounds of water discharged at each dump, as determined by a previous calibration of the automatic weigher. With all of this information in plain view, anyone interested in the test may, by multiplying the number of dumps by the weight of each dump, which I do very rapidly on a slide rule, obtain the number of pounds of water fed to the boiler up to that time.

The average temperature of the feed water and the steam pressure are soon found, and we can then easily determine the number of pounds of water evaporated under these conditions; required to show a heat absorption of 33,305 B.t.u., which constitutes a boiler horsepower. This is found to be 30 pounds with feed water at 100 degrees Fahrenheit and with a steam pressure of 70 pounds, and 34.488 pounds with feed water at 212 degrees Fahrenheit and with steam at standard atmospheric pressure.

We have merely to multiply this "horsepower conversion figure" by the time elapsed since the test began (in hours) and divide this product into the pounds of water fed to the boiler, to obtain with close approximation the average boiler horsepower that has been developed. This is done quickly on the slide rule, and with equal rapidity, by the use of another apparatus described hereinafter, there can be known at any instant the average evaporation of water per pound of coal stoked to the boiler. Such information is not ordinarily obtainable until after the conclusion of the test, and then it is often too late to straighten out mistakes or irregularities that may have occurred.

Advantages Gained by the Use of This Apparatus

The advantages gained by use of an automatic water apparatus of this kind must be quite apparent. In the first place, the stand required to mount this weigher, as shown in Fig. 2, costs but about $5, and by using two whiskey barrels for a sump there is added but $2.50 to this amount. No extra observers are required to note the quantity of water delivered to the boiler and check each other's results.

With the float operating in one of the sump barrels, the one which does not receive the discharge from the weigher, and with this float connected by a small "jack chain" to the lever of the balanced valve which regulates the flow of supply water to the automatic weigher, the necessity of constantly noting the hight of the water level in the sump tanks is done away with, as I have found the level of the water in the sump constantly falling and rising between two fixed levels which do not vary ⅛ inch. We therefore have only to note the level of the water in the boiler's gage glass to make corrections for periodic water readings, and as long as the water level in the boiler is kept at a constant hight the necessity for all such water-level readings is done away with.

The regularity with which the water is supplied to the boiler may thus be noted by a mere glance at the lines shown on the chart of the autographic recorder. If the demand for steam from the tested boiler is constant, these lines should be very regular in their spacing; otherwise, the trouble may be traced to a careless water tender, who may allow the water to drop or rise to an inexcusable distance below or above the string tied around the water-gage glass. The best results in a boiler test are generally obtained by keeping the water at a constant level, rather than allowing this level to fall far below the selected hight and then periodically rapidly forcing in large quantities of cold water.

If the fluctuating load of a plant is carried by the boiler tested, and the water level in the boiler is kept constant, the recording chart will show the exact fluctuation of the load by the unequal spacing of its lines. This fact proved very useful in a plant I tested where an electrical equipment was to be substituted for the steam-operated plant. The whole characteristics of the load were thus exhibited, showing the variations in load to be cared for by the electric generator.

In testing steam engines or turbines for their steam consumption, when they are operated under a varying load, the indicator card or brake load at any instant is easily compared with the chart of the automatic weigher by noting the amount of water evaporated at that same time. In competitive boiler or furnace trials, the regularity with which each boiler is operated is easily compared by reference to the autographic chart, and there are numerous other advantages to be gained by use of this water-recording apparatus, which I will not attempt to recite.

Coal Recording

Having thus developed the water-accounting apparatus, I turned my attention to coal recording, which is hardly capable of equal refinement without considerable complication.

Where a good iron wheelbarrow is found, as is the case in most boiler rooms, a runway from the floor is usually constructed upon which the wheelbarrow can be wheeled on and off a platform scale. The tare weight of the empty wheelbarrow is then noted and a 200- or 300-pound weight is added to this tare weight on the scale beam (according to the size of the wheelbarrow) and the wheelbarrow is filled with coal to balance this weight.

I usually have about half a shovel of coal in addition in each barrow load, which is thrown into a convenient dry iron ash can, to obtain an average sample of coal used during the test. This sample is carefully crushed and quartered down at the end of the test, and the last quarter is filled into a Mason fruit jar of two quarts capacity and hermetically sealed.

In order to keep track of the quantity of coal used over definite intervals of time during the test, I have the floor in front of the tested boiler carefully cleaned, so that there will be considerable distance preserved between the coal used for the test and any other coal in the boiler room. I then have dumped a single barrow load of coal at a time in this cleared space. If the smaller wheelbarrow is used it is known that each dump represents exactly 200 pounds of coal, and no more coal is delivered to the fireman until this last barrow load has been entirely stoked to the furnace.

In order to obtain a useful record of this coal, and have my attention positively called to each delivery of coal to the fireman, I invented a simple apparatus which is operated by the fireman, combining a two-pole electric switch with a Yale lock from which is operated an electric bell which can be heard throughout the boiler room, and an electric counter the same as is used with the automatic water weigher.

When the last weighed charge of coal is completely stoked to the furnace, the fireman throws in the switch, which rings the bell and registers one more on the electric counter. To avoid the possibility of mistake by the fireman, or meddling by someone else, this switch is constructed so as to be securely locked (by the Yale lock) the instant the electric contact is made. Thus it is impossible to pull the knife of the switch out of the clip contact until I open the lock with my key.

The moment the bell rings I note the time on my log and, going to the scale, I see that the proper weight of coal is in the wheelbarrow. I also assure myself that the last of the previous charge of coal is in the furnace, and then I see the next charge of coal dumped. In the meantime I insert my key in the lock and thus release the switch which stops the ringing of the bell and throws the switch handle back in position to be operated again by the fireman.

The electric coal recorder thus adds up the number of fixed charges of coal stoked to the boiler and, by subtracting the number noted on the pasted paper slip on the face of the recorder, which is the number found on the counter immediately before the commencement of the test, from the last number automatically recorded, anyone interested may quickly see the number of wheelbarrow loads used since the test was started. By multiplying this result by the weight of each barrow load (also noted on the pasted slip) he may quickly determine the weight of coal used up to that time.

As I place both the electric coal and water recorders next to each other, in some convenient location, it is easy to determine approximately the number of pounds of water evaporated per pound of coal up to the time of the observation and any change in the result thus obtained during the course of the test can be immediately accounted for. Events are thus noted which are apt to be lost sight of or unaccounted for satisfactorily in cases where the results of test are not known until after the test has been concluded.

Some discretion must, of course, be used in interpreting these results during the course of a test. Early in the test a considerable excess of coal consumption will generally be shown, due to building up the fires and heating the boiler walls and surroundings; while the reverse condition may be shown near the conclusion of the test when the fire bed is being burned down. Thickness or cleaning the fire bed during the test, as well as the time of cleaning, must be taken into consideration, and also the amount of unburned fuel in the ashes; but one experienced in furnace work should have no difficulty in making such allowances and the noting of such conditions will be [illegible] of value when the results of a test are found to be in any way out of the ordinary.

The duration of a test should be continued until a sufficient number of even and regular results are obtained to show the normal characteristics of the furnace or boiler under trial, and the system described for recording results during the course of the test will enable the testing engineer-in-charge to know before he finishes whether he has secured the desired information. It is a very simple matter to obtain an autographic record of the coal consumption during the test by using a second mechanical recorder operated by an electric solenoid. The writer has worked out the details of such an apparatus and may adopt it in future test work.

Yale-locking Switch

As the details of the locking switch used may be of interest, the following description is given. By referring to Fig. 5 it will be seen that the Yale cylinder lock used is inclosed within a brass case. A regular two-pole electric knife switch is secured to one side of this brass case and between the two knives of the switch, and in line with the central handle, a fork bracket is secured. Between the two prongs of this bracket a brass tongue or latch is hinged by an easy-fitting pivot. This latch, projected within the lock case, has a hook-shaped end which engages the spring bolt or latch of the lock. When the key is turned, the bolt is drawn into the body of the lock and the switch latch is then free, so that when the handle of the switch is moved out its knives may be withdrawn from its clips or contact pieces.

In my latest design this operation of opening the switch is performed by the action of a tension spring, the switch knives being set automatically [illegible] as soon as the key in the lock is turned. The switch, thus opened, is then ready for the fireman, who closes it when his last charge of coal is entirely stoked into the furnace. As one pair of poles of this switch are connected to the electric bell, and as the second pair of poles are connected to the electric counter, the closing operation operates both of these apparatus and the moment this double operation takes place the switch is locked so that it cannot be opened without the key. I locate this locking switch in a convenient position for the fireman, usually upon a vertical plank secured to the boiler front between two adjoining boilers.

Competitive Tests

With the coal and water records thus carried out, so as to secure the greatest accuracy with the least amount of labor, there will be found another [illegible] in boiler testing which [illegible] and [illegible] on the observer before the end of the test. [illegible] readings of the [illegible] the throttling steam calorimeter. In most cases I place the perforated collecting nipple of the calorimeter in the vertical run of pipe leaving the steam outlet from the boiler. With the calorimeter placed at this position, an observation means a climb to the top of the boiler, a walk across the hot and dirty roof of the boiler setting, frequently with several steam pipes to climb over or dodge, and then the troublesome thermometer reading in an atmosphere of steam (which steam is necessarily emitted from the calorimeter), and this trouble is greatly aggravated if one wears glasses, which become clouded with vapor. To overcome this trouble, I use the telescope borrowed from my surveyor's level.

Frequently, the telescope can be placed in a convenient position on the boiler-room floor, and as it magnifies the thermometer scale and mercury the readings are taken with the greatest ease, a gas or electric light being placed in front of the thermometers to illuminate the scales. When the calorimeter is placed in a position where the thermometers cannot be seen from the boiler-room floor, I am sometimes able to place my telescope near the top of a ladder, on the outside wall of a battery of boilers, which merely necessitates a climb to the top of the ladder, without the hot objectionable trip over the top of the boilers, when a reading is to be taken.

I have also used another means for obtaining the readings from these inaccessible thermometers by placing concave mirrors (similar to those used as shaving mirrors) back of the calorimeter and after thus magnifying the thermometer scale I obtain a reflection of these images from the concave mirrors upon a plane mirror, placed in a position where it can be seen from the boiler-room floor. I then take my reading from below the plane mirror through the telescope.

To prevent these mirrors from clouding with the steam I rub their faces with pure castile soap, cleaning them afterward with a soft rag until they are bright. The same method can be employed in coating the lenses of eye glasses, to prevent their clouding in an atmosphere filled with escaping steam.

The foregoing means for making observations during a boiler trial reduce the amount of fatiguing work necessary in conducting such tests very materially, and with the least amount of energy expended the engineer-in-charge will find himself in better condition to follow all the details of the test very closely from start to finish.

There are other minor details used by me which also contribute to this end. For example, in reading the steam gage, draft gages, the nitrogen-filled thermometer for temperature of escaping gases, the feed-water thermometer, etc., I frequently use opera glasses to excellent advantage. Sometimes, for taking temperatures through the boiler setting, between the furnace and the chimney, I use thermoelectric couples, protected in quartz tubes which are connected to a multipole switch. By throwing the switch to its several pairs of poles, the readings are taken one after the other in rapid succession on a single millivoltmeter. I have under consideration, with Mr. Bristol, the construction of a pair of sensitive thermoelectric couples for use with the throttling steam calorimeter, which will be quite unique in principle of operation.

The testing engineer finds it very necessary to keep close track of the time during the course of the test and in order to do this with the least effort I use a leather wrist bracelet which holds a watch. When holding the board carrying the log sheets, the face of this watch is in plain view, and the exact time of the observation is thus easily read and entered on the log sheet.

With this equipment I have been able to take, *personally*, with comparative ease, every reading of instruments used during a commercial boiler test, with intervals between all readings of not over 15 minutes, and have a good check on the coal and water observations in the recording and autographic apparatus.

In such tests I have also been able to find time to make numerous gas analyses, by the use of a special gas-collecting and analyzing apparatus which allows me to obtain the percentage of CO_2, O, CO and N (by difference) contained in the furnace gases in five minutes' time.

The only assistance I have needed in these tests is a fireman and a man to load, wheel and dump the coal. Further, the use of these means has enabled me to remain the greater part of the time in front of the boiler, where I can personally observe all that occurs there during the time of the test.

The Tuileries hydroelectric works, the largest of the kind in France, now nearing completion, is 10 miles from Bergerac (Dordogne). It is designed to develop 23,000 horsepower. It is built on the Dordogne river, which has been dammed. The water drives nine 2700-horsepower turbines. The hydraulic works is supplemented by a steam works with Curtis turbines and 6000 kilowatts of Thomson-Houston alternators. The current is supplied at 55,000 volts, and conveyed 62 miles to Bordeaux, 28 miles to Periguex and 74 miles to Aledin Angouleme.

A movement has been set on foot by the English Ceramic Society for a conference of representatives of the various technical institutes and societies, to consider ways and means of arranging for the "grading" and standardizing, as far as possible, of the refractory materials, such as fireclay, magnesite, etc., used in the construction of furnaces, kilns and ovens.

Wave Motors and Windmills

By F. L. Johnson

One of the office boys asked me if I was too busy to see Mr. Sawyer this morning. Of course I am never too busy to listen to anything my young friend has to offer and he was admitted. Seating himself on the edge of the chair as a sort of an intimation that his visit was to be a short one, and refusing for the first time within my memory the cigar I offered, he said:

"I did not intend to come in at all this trip, as my time is limited, but I saw something on Broadway, near Thirtieth street, that carried me back to my childhood days. In a brilliantly lighted window I saw what was called a new wave motor; in general appearance it looked like one rather tall turbine wheel set inside another. The outer wheel was composed of carved slats intended to deflect the current of water which passed between them at a proper angle against the slats or blades of the inner wheel which revolved on an axis, as the old school books used to say.

"The sight carried me farther back to childhood memories than could even Wrigley's spearmint gum. It was a breath from the Illinois prairies where I was born. I went inside and talked with the man at the desk, who explained the construction and operation of the motor. He went into a whole lot of demonstration of the power that could be developed from a thirty-mile-per-hour wave or current, just as though the Coney Island surf rolled in all the time at an average rate of thirty miles an hour or more. And then he told me that the power of the wave varied as the cube of the speed, and said that with a sixty-mile wave eight times as much power could be developed as with a thirty-mile wave.

"He showed me photographs of a four-thousand-horsepower installation now under construction, with a windmill appendix intended to operate the machinery at a slightly reduced capacity in case there should come a few hours when there were no waves but plenty of wind. I intended to ask him whether storage batteries had been provided to keep up production in the event of a dead calm on both land and sea, but forgot it. I had not much time, so did not stay long, but came away with a pocketful of literature and blank applications for blocks of stock.

"While the man was telling me the usual promoters' stories of the wonderful progress of the last few years I almost had to ask him how he knew that forty years ago there were no looms or sewing machines; no typewriter and no Pullman cars. For I had seen a sewing machine that was built in 1840, a typewriting machine that was used in 1863, and the body of the martyred Lincoln was transported to the West in a Pullman car.

"He showed me a copy of a letter from a man who said that President Roosevelt and Speaker Cannon were delighted with it and pronounced it, if successful, the greatest fuel-saver of the age. I remembered of reading somewhere about a machinist who made a machine to do a certain kind of work, and when the machine was done he showed it to all of the lawyers, doctors, preachers and school teachers that he could get to look at it, and they all pronounced it the work of a mechanical genius. But he never showed it to a mechanic because he knew what mechanics would think and say. I wondered a little if the same reason actuated the selection of politicians for trumpeters of the new motive power.

"But I am forgetting about my boyhood days. These were passed near a town in Illinois named Urbana, and the prairie around the village was dotted with windmills built, as nearly as I can remember, just like this new wave motor. From a distance one of these mills looked like a turret from the deck of one of Ericsson's monitors set up in the air on posts. The mill or rotor proper, as I recall it, was about 20 feet in diameter and 6 feet high, and as it revolved it operated a pump which supplied water for stock.

"One of my boyhood tasks was to take the place of the mill and operate the pump when the wind was not brisk enough for the work, and a part of my mischief was the cutting of short sticks from the osage or the willow hedges, which I used as a sort of 'trig' to place in a neighbor's mill to keep it from starting when the wind came. A little stick no bigger than my finger and a foot or so long, braced between a stationary and a moving vane, would hold the rotor from turning in a good stiff breeze, and my fun came from watching the irate farm hand hunt for the cause of the stoppage of the motive power.

"The starting power of the mill was so small that I do not think it would take anything much stronger than a cotton thread to hold it from turning in a good stiff breeze. But these Western mills, although they looked, as I remember them, just like the new wave and wind motor, may be different. After I came East I saw a great many tide mills along the Atlantic coast, but one after another they have dropped out of sight and out of the field of economical power producers. One mill, I remember distinctly, had a pond of about 250 acres area and ground corn for the horses that drew the cars from one town to another. The cars are not drawn by horses now and the little cornmeal that comes to town is ground by steam where the corn is raised, and the old tide mill has gone to join the stagecoach in the collection of things our daddies used.

"I guess I won't stop to moralize. I would be glad to see heat, light and power made and transmitted by better methods than are now used, but I hardly think the shortest road to this end leads through obsolete windmill designs.

"I have some stray ideas on the future of power production, but time is too short today even to outline them, so I will leave them for a chat the next time I am in town."

Testing of a Three Phase Induction Motor

By E. H. Stacey

Nowadays, when the induction motor is used for such a wide range of service conditions it most frequently happens that the operation of such a motor becomes unsatisfactory for some reason or other. There are many causes for trouble which take some little investigation to reveal, but the chief trouble is excessive heating and consequent danger of charring the insulation, followed by the inability of the motor to carry its normal load. The question must then be determined whether the motor is capable of carrying its rated load. If not, and it is a new machine, of course it is up to the maker to fulfil his guarantee, but if it is overloaded, either the load must be reduced, or a larger motor put in; otherwise the smaller one may be permanently ruined by the continuous overload.

To decide this question of overload the rotor should first be examined to see whether the bars are all tightly screwed to the short-circuiting rings, and also whether the insulation separating the bars from the iron is in good condition. This insulation may have been burned by a temporary overload and only require renewing for the motor to run all right. While the bars are practically short-circuited to the iron the local currents generated in the rotor will be excessive and the power which should be used to drive the machinery will be largely wasted in heating the rotor, so that the motor will be able to transmit only part of its rated power to the shaft.

Supposing, however, the bars to be tight and the insulation in good condition, the only course open is a test to ascertain the actual work the motor is doing, by measuring the input in watts and the output in horsepower. For this are required a voltmeter, an ammeter and a wattmeter, and, depending on the voltage and current used, a potential transformer or series transformer, or both, may be needed. For controlling the circuits, two single-pole single-throw switches and a double-pole double-throw switch capable of carrying the full-load current of the motor are needed, also a small double-pole double-throw baby knife switch. With these appliances the motor [illegible]

[illegible] which may be used for any motor up to [illegible] horsepower. As the majority of motors up to this capacity are operated on 220 volts, this is assumed to be the voltage in the present case, though by changing the transformer ratios and exercising more care with the insulation, motors of higher voltages may be tested in exactly the same manner. Arrange the switches on a board, as shown in the accompanying sketch, and wire up the motors as indicated.

Suppose, for example, that the motor to be tested is rated at 50 horsepower. The meters must be able to carry [illegible] amperes, or if they are of smaller capacity, a current transformer must be inserted in the line and the meters connected to the transformer secondary circuit. A convenient rule for finding the approximate current that a three-phase motor should require at 220 volts is to take the horsepower rating and assume that as the amperes per leg.

Or it may be worked out thus:

$$\frac{\text{Watts output}}{\text{Power factor} \times \text{volts} \times \text{efficiency} \times \sqrt{3}} = \text{amperes per leg.}$$

Example

A 50-horsepower motor with a power factor of [illegible] and an efficiency of [illegible]

$$\frac{50 \times 746}{220 \times 1.732 \times 0.9 \times 0.85} = [illegible]$$

amperes per leg. The voltmeter and the potential lines to the wattmeter should be connected as shown in the sketch, with transformers of [illegible] ratio, the voltmeters and wattmeters being connected for 110 volts. Multipliers, if supplied with the instruments, may be used instead of transformers.

When the board is wired up, close the single-pole switches and open the double-throw switch until the motor comes up to speed, in order to avoid having the large starting current pass through the meters. When the motor has attained normal speed, put the load on and throw the double-pole switch to one side; open the single-throw switch on that side and close the small switch in some direction to get the voltage between the third wire and the one in which current is being measured.

Read the volts, amperes and watts and record the readings. Now throw the switches over to the other side and take readings again, being careful to get the voltage between the line connected to the meters and the third line, as before. Possibly one wattmeter will read in the wrong direction, and all that is necessary to correct this is to transpose the connections of either the current or the potential circuit, but not both.

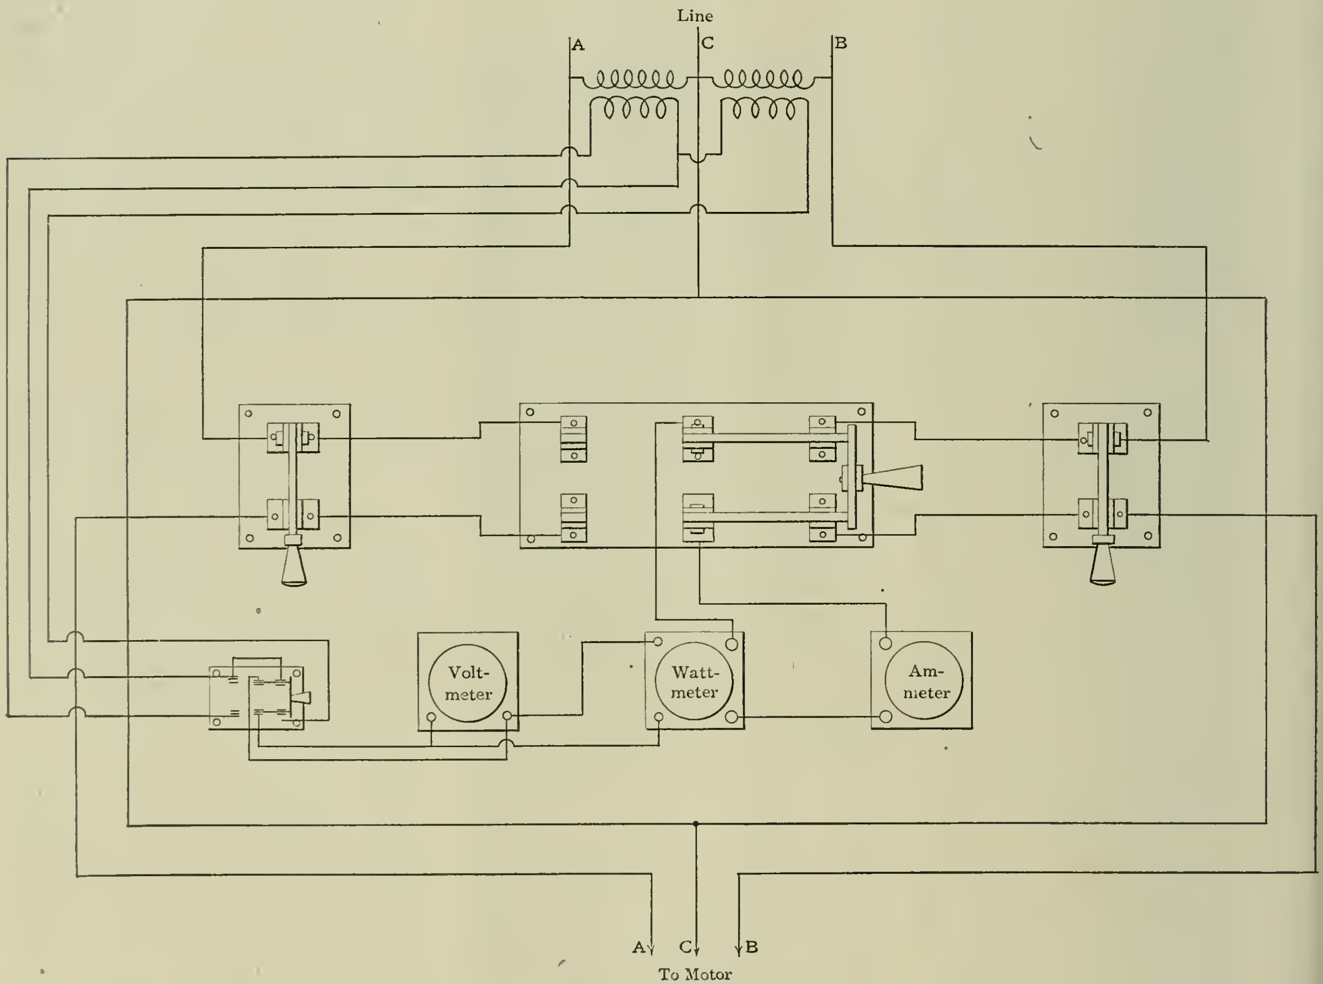
Having taken the readings in the two legs, add the watts and divide by [illegible]. This will give the horsepower of input, and multiplying this input by [illegible] [illegible] sumed efficiency, will give very nearly the power that the motor is delivering. An efficiency of 85 per cent. is assumed because this is a fair average for motors of this size, and the process of ascertaining the actual efficiency is hardly practicable outside a testing room or laboratory.

The next step is to multiply the average amperes by the average volts; multiply again by the transformer ratios, if any, and by $\sqrt{3}$; divide the watts by the final result and the power factor is obtained. If this is 0.85 or greater and the motor is fully loaded, it may be considered fairly satisfactory in this respect, though many motors of this size show as high as 92 or 93 per cent. power factor at full load.

The temperature of the iron of the stator should be taken by placing a thermometer in contact with the laminated core and covering the bulb with putty or a small wad of waste to screen it from the cooler air.

Take also the temperature of the air about 2 feet from the motor. The difference is the temperature rise, usually guaranteed by makers not to exceed 45 degrees Centigrade at full load. If the air temperature is 20 degrees Centigrade this would allow the motor temperature to reach 65 degrees and yet be within the guarantee. This is quite hot, too hot for the hand to be held long on the iron, but many motors run well up to 70 degrees Centigrade without injury to the insulation; inferior insulating material, however, would doubtless be injured in time by this degree of heat. If the temperature exceeds this and the motor is not overloaded the trouble may be caused by the machine being located where there is no circulation of air which, if remedied by ventilation, may remove the heating difficulty. To sum up, then, if the rotor insulation is good and the bars tight, and the temperature of the stator higher than 65 or 70 degrees Centigrade, the machine is either below standard in construction or is overloaded.

If the test shows the input to be more than 1.2 times the rating of motor, the machine must be of poor design, in bad condition, or else overloaded; if the latter, it should be replaced by a larger motor as soon as possible, or the load reduced to suit the motor.



WIRING OF SWITCHES AND METERS FOR TESTING THREE-PHASE INDUCTION MOTORS

In these days of high-speed machinery there may be a difference of as much as 5 per cent. in the efficiency of an engine by using an inferior grade of oil.

Blowing Soot Out of the Boilers

C. J. Larson, chief engineer of the Union Electric Company, of Dubuque, Ia., has rigged up a simple device to blow soot out of the combustion chambers of the boilers without cooling the boilers down. A 1½-inch pipe leads from the main steam riser between the boiler and the main steam header, down the side of the boiler and enters the combustion chamber. The boilers are Babcock & Wilcox type and the soot rapidly collects back of the furnace, the trouble probably being augmented because of the fine grade of coal burned at this station. The end of the pipe within the combustion chamber is fitted with a spray nozzle. By opening a check valve, the steam enters the pipe at about 190 pounds pressure and 125 degrees of superheat, entering the chamber in a strong blast which effectively loosens the soot from the floor and side walls and blows it up the stack. By using the steam blast for five minutes every week or two, the combustion chamber is kept entirely free from soot. Without the blast it would be necessary to shut the boilers down at frequent intervals for cleaning.

High Pressure Steam Piping Systems

Some Notes on Recent Design, Including a Discussion of Expansion, Vibration, Pipe and Pipe Fittings, Joints, Separators and Valves

BY WILLIAM F. FISCHER

In laying out a piping system the designer should aim to do away with all unnecessary piping, and carry his lines as direct as possible, making proper allowance for expansion and contraction. The piping should be dripped wherever necessary, and all water of condensation returned to the boilers. Where the piping is carried through a wall or floor, what is known as pipe sleeves or thimbles should be built in around it. The inside diameter of these thimbles should be greater than the outside diameter of the pipe flanges to allow for the removal of the pipe when necessary. A steam pipe should never under any circumstances be built rigidly into the walls of a building, as the expansion strains or vibration in the line are almost sure to loosen the wall in time. A piece of pipe of the proper diameter and length with a plain-faced, undrilled flange at each end is a good substitute for a cast pipe thimble, although if a number of the same size are to be used, the casting will be found to be the cheaper of the two.

No definite rule can be given for the arrangement of steam lines, for the conditions met with in different stations vary greatly. As a general rule, however, in most of the modern power houses of today, no main steam header is being used larger than 14 inches inside diameter, or, as they are designated, 15 inches outside diameter. The station is subdivided into complete and independent units, the piping being so arranged that the boilers feed the main steam header uniformly, or nearly so, throughout its length, and provision is made to feed the engines or turbines in a similar manner. In this way each unit is taken care of by a certain number of boilers, the header being divided up into sections by the use of gate valves so placed that any section of the header may be cut out of service for repairs if necessary without interfering in any way with the successful operation of the station, or, in other words, by closing valves in the main steam header each unit is made entirely independent of the others. In some cases a valve is placed in the main steam header between each connection to or from the header. Steam to the auxiliaries is taken direct from the main steam header, or from a separate auxiliary header. Where it is desired to use superheated steam for the main engines and saturated steam for the auxiliaries, a separate header and separate boiler connections are required for each case.

The elaborate system of duplicating steam mains and connections is not necessary to a good design, although on rare occasions the designer may find it an advantage. Some few years ago, in order to overcome deficiencies in valves, fittings and workmanship, and also to insure greater reliability, the duplicate system was introduced and became a fad for awhile, but seeing the steam gages in the larger stations stand at from 200 to 250 pounds, and still indicating a tendency to creep higher, the manufacturers did a little figuring, and as a result they are today, and have been for the past few years, meeting the demand with all necessary materials for a first-class single piping system. As a consequence, the duplicate system is rapidly becoming a thing of the past. Reliability is better insured by the careful design of all valves and fittings, combined with the use of higher grade materials and superior workmanship. The judicious placing of cutout and bypass valves, properly providing for expansion and contraction, locating separators and drip pockets where necessary and trapping all water of condensation back to the boilers as fast as it forms, will result in a system far superior to the elaborate and expensive duplication of the past.

Valves

Two valves should be placed in a line connecting a battery of boilers with the header. One of these valves should preferably be an automatic stop and check valve placed at the outlet of the boiler, and the other a gate valve placed next to the main steam header. There should also be a valve in each connection from the header.

As globe valves introduce considerable friction and form water pockets in the line, they are seldom, if ever, used on a good job, except as throttle valves placed next to the engine or pump cylinders.

Gate valves over 6 inches in size should be provided with bypass connections, to enable them to be easily opened by equalizing the pressure on both sides of the gate, also permitting steam to be admitted slowly into the cold end of the line, warming it up gradually. This prevents water hammer, and also distributes the expansion strains more uniformly throughout the piping system.

All gate valves 8 inches and larger are, as a rule, specified outside screw and yoke, with [illegible] handwheel and rising stem. With this type the rising stem shows at a glance the approximate position of the gate or disk. These valves are furnished with indicators graduated to show the exact opening at all times, if so specified when ordering. The threaded stem being outside the stuffing box, does not come in contact with the hot steam, and is therefore easily lubricated. If desired to operate the valve from the floor line or other accessible position, the stationary handwheel may be replaced by a system of gearing with a [illegible] extension stem and handwheel carried to the desired position.

Expansion

The average main steam header, unless firmly anchored, has a tendency to creep or move out of position parallel to the length of the line. This is due to the expansion and contraction strains set up in other branches of the system and also to vibration. The header should be firmly anchored to prevent as far as possible this shifting of position, as it brings the strain on the connections to and from the header, and also to steady the piping against vibration. In piping of any length proper provision should always be made to take up or relieve the expansion strains in that section, to prevent the straining of the joints, which is almost sure to cause leakage or perhaps rupture at the weakest point. When a pipe line is anchored or fixed at two points an expansion bend should be installed in the line somewhere between the points, as the ordinary elbow or [illegible] will [illegible] the [illegible] of [illegible], even if they did the [illegible] would fall on the [illegible].

Steel pipe bends of long radius are used in preference to cast elbows of short radius, as they reduce the number of joints in the system and secure greater flexibility throughout. Where possible all bends should be curved to a radius of not less than five pipe diameters, a greater radius being preferred in all cases where the expansion strains are [illegible].

Bends can now be made from pipe of [illegible] in lengths [illegible]. This is accomplished by welding two or more pieces of pipe together, either before or after bending. Expansion bends made from pipe greater than [illegible] inches in diameter are necessarily [illegible] radius [illegible] bends made up from the smaller sizes.

and as any distortion of a bend beyond a certain stage leads to high strains on the joints, this stiffness should be taken into account when designing. A thorough knowledge of the effects of expansion on the piping system is essential to every engineer, and the writer feels he can do no better than to refer the reader to the June 2 and October 20, 1908, numbers of Power and The Engineer, where the subject is covered to some length.

Vibration

Steam flowing at a velocity of from 5000 to 6000 feet per minute in the supply pipe of a modern high-speed engine, is alternately stopped and raised again to this velocity several hundred times a minute, due to the quick opening and closing of the steam valves. This intermittent motion of the steam in many cases causes vibration and hammering in the supply pipe, which in turn is transmitted to other branches of the piping system. Vibration is also caused by suddenly changing the direction of the steam flow through short-turn elbows or tees, and also to an unequal velocity of the steam flowing through different branches of the system. Where possible to do so, the pipes should be so proportioned that the velocity will be as near uniform as possible in all branches to and from the main header.

In one case of the writer's knowledge, a vibrating pipe line was anchored at a certain point. This decreased the vibration to a large extent, but no provision was made to take up the expansion in that section of the piping between the anchor and the boiler nozzles. The plant was shut down each night, and started up again early each morning. In about a week's time the joints in the piping farthest away from the anchor were found to leak badly. They were repacked with new gaskets and made up steam-tight, but about a week later were leaking almost as badly as before. The engineer-in-charge, being a practical mechanic, at once decided that the anchor was causing the trouble, as these leaks had not occurred before the anchor was placed in position, so in place of wasting more time and material in repacking the flanges, he decided to investigate, and soon found the cause of the trouble. It appears that the anchor, which was very rigid, was installed while the line was hot and the piping clamped firmly in position. The expansion in this line was found to be nearly 1⅞ inches; consequently at night when the plant was shut down, the line shortened, throwing a heavy strain on the pipe and bolts at each joint and causing the leakage.

The engineer removed a section of the piping and installed an expansion loop of long radius. He decided it would be better to throw part of the strain on, the piping while cold, so the bend was sprung into position. The next morning steam was turned on as usual, and there was no more trouble from leakage or vibration.

Separators

A large "slug" of water is not a very healthful "dose" for a steam-engine cylinder, especially in high-speed engines where the clearance space between the cylinder head and piston is reduced to a minimum. In all modern work each engine supply pipe is usually equipped with a separator of large volume, placed as near the engine throttle as possible, and all main steam headers are equipped with drip pockets.

Besides intercepting the moisture in the steam the separator performs another function of great value, in that it provides a reservoir where the steam is stored after the steam valves close at each stroke of the engine piston. This insures a more uniform pressure in the engine cylinder up to the point of cutoff and also provides a cushion of steam near the engine cylinder to take the reaction caused by the quick cutoff in the steam chest, thus preventing vibration from being transmitted to the piping system.

Separators also tend toward a continuous and steady flow of steam in the direction of the engine instead of the otherwise necessary stopping and starting of the flow with every movement of the engine valve, in this way preventing to a large extent the usual drop in pressure between the boilers and the steam chest, also reducing the tendency of the boilers to prime during a momentary excessive demand.

Separators having a capacity of from three to four times that of the high-pressure cylinder are making it possible in many cases to reduce the size of the engine supply pipe, up to the inlet side of the separator, from 5 to 15 per cent. over that called for by the engine builders, the piping between the separator and the engine remaining the same size as called for.

This last rule does not seem to apply to separators where used in connection with steam turbines, as the velocity is much higher and more uniform throughout. The piping should therefore be of full size throughout its length, from the main steam header to the throttle inlet. Separators of the receiver type are preferred.

Mechanics are sometimes careless in erecting new work, leaving bolts, nuts, wrenches, cold chisels, oil cans, etc., inside the piping. The operating engineer comes across this junk some few week later in a place where only an engineer would ever expect to find such things. Small junk, unless stopped by a separator, eventually locates in the engine cylinders, scoring and cutting them so badly that in many cases they have to be rebored. A small bolt or nut going over with the flow of steam would rip the blades from a steam-turbine rotor, owing to the small clearances between the blades and casing. For this reason the turbine supply pipe is nearly always equipped with a net or strainer to stop such junk before it reaches the turbine inlet. These strainers are furnished with the turbines.

Loose junk remaining in the piping system after erection also has a tendency to come to rest directly under the seats of stop valves, making it impossible to close them. A good separator will remove nearly, if not all of this small junk before it could reach the engine cylinder, and prevent injury to the interior parts, or even engine wrecks.

Pipe

Wrought-steel pipe, especially in the larger sizes, is preferable to wrought-iron pipe for general use. As ordinary commercial pipe may vary in thickness from the standard, as listed in catalogs, "full-weight pipe" should be specified. As a rule full-weight pipe will be found to run full card weight, but should never vary more than 5 per cent. either way.

Full-weight pipe of steel or wrought iron is suitable for working pressures up to 250 pounds per square inch, if not reduced in thickness by threading outside the hub of the flanges. For bending purposes lap-welded steel pipe is better than butt-welded, as the seam is less liable to open up under the stress of bending to a short radius. For threaded joints, if sharp dies are used, steel pipe has been found to cut and thread as readily as wrought-iron pipe, but blunt dies have a tendency to tear or break the threads.

Where used in connection with Van Stone joints or joints where the pipe is turned over the face of the flange, wrought-iron pipe has been found to split badly, both at the weld and all around the outer circumference when rolling or flanging over. Steel pipe is better in all cases, and open-hearth steel pipe is preferred to bessemer steel, both for Van Stoning and welding purposes, as the quality of the metal is more uniform and low in carbon.

The following tests, taken from a Crane catalog, will serve to demonstrate the strength of steel pipe as compared with wrought-iron pipe. The pipe was picked from stock at random:

Ten-inch standard wrought-iron pipe burst at 1900 pounds; 10-inch extra-strong wrought-iron pipe burst at 2700 pounds; 10-inch standard wrought-steel pipe burst at 3000 pounds.

None of this pipe burst at the weld, but some distance from it, showing the weld to be in this case at least as strong as the pipe itself. Extra-strong and double extra-strong pipe is used more in hydraulic work, for turbine step-bearing oiling systems or boiler-feed lines, than for steam.

Pipe Joints

Many of the earlier stations are using screwed or threaded joints in their steam mains successfully where the pressure is 150 pounds or even greater. In man cases, extra-heavy pipe is used in connection with the screwed and peened joint, where the end of the pipe is peened or rolled into a recess at the face of the flange to prevent leakage through the threads, and to prevent the loosening of the flange at the threads. This is a good joint if properly made and is still used quite extensively in new work. For pressures above 150 pounds and for superheated-steam work the general tendency is to specify either the Van Stone or welded type of joint in sizes 5 inches in diameter and larger, the screwed or screwed and peened joints being used only in the smaller sizes.

There seems to be one objection to the old type of Van Stone joint, in that the turned over or flanged portion of the pipe is thinned down considerably in rolling and finishing the face of the joint, making this the weakest point, as shown in Figs. 1 and 2. In the first illustration the dotted lines *C* show the position of the pipe before rolling. Line *A A*, slightly exaggerated for clearness, shows the bevel of the face of the joint after rolling, due to the gradual thinning down of the metal at the edge *B*, which is due to the stretching of the metal on the outer circumference of the flanged portion. Fig. 2 shows the same joint after the face has been finished off true in the lathe. Note the thinning down of the metal at *D* as compared with *T*, the original thickness of the pipe.

To overcome this defect joints known as the "Cranelap" and "improved Van Stone" were put on the market some years ago, and are now used in preference to the old type. The method of constructing the Cranelap joint is shown in Fig. 3. At *E* the face of the flange is shown beveled inward to compensate for the difference in the thickness of the pipe between the inside and outside portions of the lap. This brings the face of the joint almost true after rolling, a light cut being all that is necessary in facing.

The improved Van Stone joint is made by securely welding a tapering band of steel to the end of the pipe around the outer circumference as shown in Fig. 4. Fig. 5 shows the same joint after rolling and facing. The flange is bored out to a slight taper, as shown at *G*. The thickness of the pipe *F* at the face of the joint is greater after finishing than the original thickness *T*.

Both of these joints are being used extensively for superheated-steam work. The flanges on all joints of the Van Stone type are loose and swivel on the pipe, a fact appreciated by erecting engineers, as it is sometimes necessary to change the position of bolt holes in the field.

Another joint coming into use for high pressures is the welded joint, made by welding a wrought-steel flange direct to the end of the pipe. Fig. 6 shows what is known as the screwed-and-peened joint. The pipe is screwed into the flange steam-tight, leaving a short length projecting beyond the face of the flange. This end is then heated and either rolled or peened over, filling the recess *H* at the face of the flange. The flange is then faced off true in the lathe and drilled. This is a good joint if properly made, and is much superior to the ordinary screwed joint, which is too well known to require any description.

FLANGES

Cast-iron and cast-steel flanges are sometimes used in connection with the Van Stone and similar joints, but in all cases a good rolled-steel flange is to be preferred. The cast-steel flange in many cases costs nearly as much as the flange of rolled steel and is far inferior, as the metal may not run uniform throughout. The writer has seen cases where cast-steel flanges in the rough looked sound and perfect in all respects, but upon facing and drilling were found to be honeycombed with blowholes beneath the surface, and as a consequence were rejected. Blowholes can be entirely prevented in steel castings by the addition of manganese and silicon in sufficient quantities, but both of these elements cause brittleness and should be added with caution on this account.

GASKETS

The gasket might be called the connecting link of the piping system, and is of more importance than would appear at first thought. Much trouble has been experienced in an otherwise perfect system of piping, due to bad gaskets. The cost of renewing gaskets is so far greater than [illegible] and should not be overlooked. First it is necessary to shut off pressure on that part of the line, open the joint, scrape and clean the face of the flanges, insert the new gasket and make up the joint again steam-tight. From two-thirds to three-fourths of the actual expense of renewing a gasket under favorable conditions is for labor alone, and shutting off pressure from any one section will probably cause shutting down one or more units, boilers or engines as the case may be.

There are many different ways, too numerous to mention here, of forming the face of flanges to prevent the gasket from blowing out. With flanges of the tongue and groove, or male and female type, it is necessary to spring the pipe apart at the joints to remove the old gasket and replace the new one, and at times this cannot be done without taking down a section of the piping. The straight-face joint, if properly put together with a good gasket suitable to the work, will stand a test of [illegible] pounds without blowing out.
